ABSTRACT

J1044+0353 is considered a local analog of the young galaxies that ionized the intergalactic medium at high-redshift due to its low mass, low metallicity, high specific star formation rate, and strong highionization emission lines. We use integral field spectroscopy to trace the propagation of the starburst across this small galaxy using Balmer emission- and absorption-line equivalent widths and find a poststarburst population ($\sim 15 - 20$ Myr) roughly one kpc east of the much younger, compact starburst $(\sim 3-4 \text{ Myr})$. Using the direct electron temperature method to map the O/H abundance ratio, we find similar metallicity (1 to 3 sigma) between the starburst and post-starburst regions but with a significant dispersion of about 0.3 dex within the latter. We also map the Doppler shift and width of the strong emission lines. Over scales several times the size of the galaxy, we discover a velocity gradient parallel to the galaxy's minor axis. The steepest gradients ($\sim 30 \text{ km s}^{-1} \text{ kpc}^{-1}$) appear to emanate from the oldest stellar association. We identify the velocity gradient as an outflow viewed edge-on based on the increased line width and skew in a biconical region. We discuss how this outflow and the gas inflow necessary to trigger the starburst affect the chemical evolution of J1044+0353. We conclude that the stellar associations driving the galactic outflow are spatially offset from the youngest association, and a chemical evolution model with a metal-enriched wind requires a more realistic inflow rate than a homogeneous chemical evolution model.

1. INTRODUCTION

Gas-phase metallicity is a product of the intricate interplay among inflows, outflows, and star formation (e.g., Davé et al. 2011). Infalling primordial gas can dilute metallicity and trigger more intense star formation. In contrast, galactic-scale outflows of gas (or galactic winds) can carry supernovae ejecta and redistribute metals to large galactic radii. The recent balance between inflows and outflows regulates the amount of gas that can be converted into stars, hence the metallicity. The intertwined processes between inflows, outflows, and star formation activities impede our ability to identify the dominant physical mechanism that affects the metal content in star-forming galaxies.

Corresponding author: Zixuan Peng (彭子轩) zixuanpeng@ucsb.edu The spatial distribution of metals has been utilized to decipher the chemical evolution of galaxies. For example, negative metallicity gradients are commonly observed in spiral and disk galaxies, where the inside-out growth (Boissier & Prantzos 2000; Mollá & Díaz 2005; Pilkington et al. 2012) produces the observed gradients. In contrast, the majority of dwarf irregular galaxies appear to be chemically well-mixed based on observational data (e.g., Kobulnicky & Skillman 1997; Haurberg et al. 2013).

Gas outflows and inflows can impact the spatial distribution of metals within a dwarf galaxy. Several studies argue that metal-enriched galactic winds redistribute metals more effectively the shallower the gravitational potential well (Ma et al. 2017; Tissera et al. 2019). The metallicity scatter seen within high-redshift galaxies may reflect the chaotic accretion processes during formation (Maiolino & Mannucci 2019). The accretion of cold and metal-poor gas can produce positive metallicity gradients in star-forming galaxies (e.g., Cresci et al. 2010). Interactions between galaxies are another mechanism that drives cold gas inward via gravitational torques (Barnes & Hernquist 1991, 1996), diluting central metallicities (e.g., Hwang et al. 2019; Luo et al. 2021).

Chemical inhomogeneities in local dwarf galaxies remain a subject of ongoing debate but may identify rapidly growing low-mass galaxies (Bresolin 2019; James et al. 2020). Consequently, a further investigation of spatial metal distributions throughout star-forming dwarf galaxies can contribute to our understanding of the interplay among star formation, inflows, and outflows.

This paper aims to measure the distribution of metals and the gas kinematics in a local analog of a reionizationera galaxy to discern between supernova-driven outflows and inflows induced by interactions or mergers. Only a small fraction of local galaxies possess nebulae with physical conditions akin to those in young galaxies observed with JWST; however, ultraviolet and optical spectroscopy effectively identify them by their emissionline strengths and ratios (Berg et al. 2022). In this work, we present our analysis of the metallicity and gas kinematics of J1044+0353 based on a Keck Cosmic Web Imager (KCWI) observation (Martin et al., in prep). Similar to most local analogs, J1044+0353 has an exceptionally high [O III] $\lambda 5007$ equivalent width (~ 1400Å) and a compact, UV-bright starburst. Its high specific star formation rate $(\log(sSFR/year^{-1}) = -7.73^{+0.081}_{-0.41})$ and significant high-ionization emission lines (e.g., He II λ 1640 and CIV $\lambda\lambda$ 1548, 1550) identify it as a young, rapidly growing galaxy (Olivier et al. 2022).

The structure of this paper is summarized as follows: We present the KCWI data, outline the discovery of three post-starburst stellar associations, and detail the line-fitting measurements in Section 2. In Section 3, we estimate the ages of the stellar populations within these stellar associations. We then measure the "direct" oxygen abundance for each post-starburst association and the starburst region. To visualize the kinematics and metallicity distribution of this galaxy, we apply an adaptive binning algorithm to generate a peculiar velocity map and a metallicity map. The implications of these findings are discussed in Section 4. We summarize our key results in Section 5. Throughout this paper, we use $Z_{\odot} = 0.0134$ for solar metallicity, corresponding to $12 + \log(O/H) = 8.69$ (Asplund et al. 2021).

2. DATA PROCESSING AND LINE FITTING MODEL

2.1. Target

The corrected luminosity distance of J1044+0353 is 59 Mpc from the peculiar velocity model of Willick et al. (1997), but another model gives a distance of 55 Mpc (Masters 2005). We carry this systematic uncertainty forward throughout our analysis. Masses and SFRs adopted from the published literature are converted to the adopted distance $(57 \pm 2 \text{ Mpc})$ in Table 1. Both this study and Berg et al. (2022) use the Chabrier (2003) IMF, but the MPA-JHU catalog adopt the Kroupa (2001) IMF. We neglect the ~ 0.03 dex systematic difference between these two IMFs, but we propagate this difference to the uncertainty of each quantity (Moustakas et al. 2013). The stellar mass of J1044+0353, $10^{6.83^{+0.41}_{-0.26}} M_{\odot}$, identifies it as a dwarf galaxy. Berg et al. (2016) and Berg et al. (2022) (hereafter B16 and B22) measure a very low metallicity of 12 $+ \log(O/H) = 7.45 \pm 0.02$ and 7.44 ± 0.01 respectively.

Figure 1 shows a color image constructed from the g, r, and z band DECalS images (Blum et al. 2016; Dey et al. 2019).² The spatial resolution, 0".262 pixel⁻¹, is limited by atmospheric seeing and is not sufficient to resolve individual star clusters. However, several local intensity maxima are detected east of the compact starburst. In Section 3.3.3, we will argue that the starburst is offset from the centroid of the stellar mass. In contrast to most dwarf galaxies, there is no obvious low surface brightness component.

$2.2. \ Data \ Cube$

KCWI is a sensitive optical (350 - 560 nm) integral field spectrograph on the Keck II telescope (Morrissey et al. 2018). The KCWI observations of J1044+0353 (R.A.=10:44:57.80, Decl.=+03:53:13.2) were obtained on 2018 January 14 with an average seeing of 0"9. We reduced raw frames and built data cubes using the KCWI Data Extraction and Reduction Pipeline v.1.1.0 (Morrissey et al. 2018, KDERP). We employed the CWITools Python package³ O'Sullivan & Chen (2020) to coadd the individual data cubes, creating a mosaic cube with $0.146 \times 0.146 \times 0.5$ Å voxels. We refer the reader to our companion paper (Martin et al., in prep) for details about the observations and data reduction. Here we summarize the properties of the data cube central to the metallicity and kinematic measurements presented in this paper.

The data cube is a mosaic of three pointings of the 8" by 20" field of view of the small slicer. The observations were made with the BL grating, which provides contiguous wavelength coverage from the atmospheric limit to the dichroic cutoff at 5600 Å. In this configuration, the slits of the image slicer are 0".34 wide, and the average resolution over the bandpass is $R \approx 3600$. Three 1200 s

Figure 1. Left: Color composite image of J1044+0353 constructed from the DECalS g,r,z-images. The stretch is an inverse hyperbolic sine function. The yellow circle (SB) is the Sloan-like circular aperture with a radius of 1."5 covering this galaxy's starburst region. The three red circles (FEN, MEN, and NEN) identify lower surface brightness stellar associations. The furthest is 4."9 (1.4 kpc) east of the starburst. The blue circle represents the background galaxy identified by Martin et al. (in prep). *Right:* The extracted spectrum of each stellar association.

Table 1. Physical Properties of J1044+0353 Collected from the Literature

Source	Aper. $\log(M_*)$ (M_{\odot})	Tot. $\log(M_*)$ (M_{\odot})	Aper. log(SFR) $(M_{\odot} \text{ yr}^{-1})$	Tot. log(SFR) $(M_{\odot} \text{ yr}^{-1})$
MPA-JHU	$6.71_{-0.06}^{+0.47}$	$6.83\substack{+0.45\\-0.05}$	$-0.79\substack{+0.05 \\ -0.05}$	$-0.82^{+0.06}_{-0.06}$
B22	$6.16\substack{+0.23\\-0.09}$	$6.83^{+0.41}_{-0.26}$	$-0.87^{+0.08}_{-0.11}$	$-0.56^{+0.11}_{-0.14}$

NOTE—Stellar mass and SFR (aperture and total) of J1044+0353 extracted from the MPA-JHU Catalog (Row 1) and Table 6 of B22 (Row 2) are converted to the Chabrier (2003) IMF and the adopted distance $(57 \pm 2 \text{ Mpc})$ in this work. Columns 2 and 3 list the aperture and total stellar masses. Columns 4 and 5 list the aperture and total SFR. For row 1, the value for each column is extracted from the median estimate of the (log) stellar mass or SFR PDF. The 1- σ error of each value is calculated from the 16th and 84th percentiles of the (log) stellar mass or SFR PDF. For row 2, the stellar masses or SFRs are derived using BEAGLE SED fitting for both the light within the COS aperture and the entire galaxy, respectively.

and three 300 s integrations were combined to form the full mosaic. In the 1200 s frames, the cores of the [O III] $\lambda\lambda$ 4959,5007 and H β emission lines saturate in a few spaxels centered on the compact starburst. We measure the [O III] λ 4959 and H β line fluxes directly from a mosaic of the 300 s frames in these regions. The spectral resolution $R \approx 3600$ produces an instrumental line width of about 83 km/s FWHM. The atmospheric seeing was estimated to be 0."90, and a relative flux calibration was performed using the standard star Feige 34.

2.3. Stellar Associations

We utilized Photutils (Bradley et al. 2022) to carry out an automatic identification of objects on the raw rband DECalS image of J1044+0353, where each object is a group of unresolved stellar clusters that we called a stellar association hereafter. To better trace the boundary of each stellar association, we generated a 2D background model using an instance of MedianBackground (i.e, the sigma-clipped median) in Photutils. Before the deblending process, the constructed 2D background model was subtracted from the r-band image. To deblend the local intensity maxima detected east of the starburst, we established the threshold for identifying sources at 10σ , with a minimum of one pixel above this threshold required for analysis. We found that only this minimum threshold value can deblend the local maxima into three stellar associations found by eye in Figure 1. We also employed 1024 deblending levels and a deblending contrast of 1%. Combining with the starburst, we refer to four stellar associations as the far-east nucleus (FEN), north-east nucleus (NEN), middle-east nucleus (MEN), and compact starburst (SB) (shown in Figure 1). We will show that these eastern associations are significantly older than SB (Section 3.1), so we refer to their collection as the post-starburst region (PSB).

Following the deblending map, we utilized Petrofit (Geda et al. 2022) to calculate the Petrosian radius and flux (Petrosian 1976) for each stellar association. We used the half-light radius, r_{50} , to define the size of each stellar association. An accurate determination of r_{50} is related to the radius that encloses the total flux, r_{total} . To attain r_{total} , we must multiply the Petrosian radius with a constant ϵ . ϵ is set to 2 by default in Petrofit, which is appropriate for a Sérsic light profile with the Sérsic index n = 1 (i.e., an exponential light profile; Yasuda et al. 2001). To find the best-fitting ϵ of each detected stellar association, we constructed a grid of ideal Sérsic profiles, convolved with the DECalS coadded PSF (point spread function) of $J1044+0353^4$, with different half-light radii and Sérsic indices to implement the Petrosian correction⁵. After obtaining the corrected r_{50} for each object, we adopted a common practice in the literature (e.g., Law et al. 2012), to convert r_{50} , calculated along the semimajor axis, to a circularized effective radius $r_c = r_{50} \sqrt{b/a}$ (b and a are the minor and major axis, respectively), where the area enclosed by these two radii are the same (see Table 2).

2.4. Extraction of Spectra

Using **pyregion**⁶, we extracted optical spectra of the stellar associations circled in the left panel of Figure 1 to estimate their stellar population ages, stellar mass, and gas-phase oxygen abundance. The right-hand panel of Figure 1 shows the emission lines of the starburst region are two orders of magnitude stronger than those of the three eastern associations.

We scaled the error spectra because the variance produced by the KCWI Data Reduction Pipeline underestimates the noise (O'Sullivan et al. 2020). To determine the variance rescaling factor, we compare the median variance with the square of the root-mean-square noise of the continuum near strong emission lines. The typical scaling factor is ~ 2.0 for all extracted spectra.

For purposes of mapping the spatial variations in peculiar velocity and metallicity, we can measure these physical properties at smaller scales. The data cube comprises 15,456 spaxels; however, the signal-to-noise ratio (SNR) of numerous emission lines extracted from individual spaxels is insufficient for providing robust constraints on physical properties.

Facing this issue, we applied an adaptive binning algorithm⁷ based on the Centroidal Voronoi Tessellation (CVT) method described in Cappellari & Copin (2003) that improves the SNR of the emission lines by aggregating spaxels, giving us a stronger constraint on the local physical properties. Since the size of each spaxel is $(0.146)^2$, we have to make sure the minimum bin has $\pi(3 \text{ spaxels})^2 \approx 28$ spaxels in total, the resolution limit. We require this minimum bin size during the initial formation of the bins.

Our adaptive binning code runs on emission-line images. The local continuum has been fitted and subtracted at each spaxel. Random noise fluctuations cause half the spaxels with no (or low) emission-line intensity to have negative fluxes. The original CVT method cannot accommodate negative spaxels, so we devised a modification that initially masks the negative spaxels during bin formation before applying the binning to the original data.

This modified CVT method has difficulty maintaining minimum bin size. Thus, the version we use (method "VT" in the code) lacks the centroidal feedback that equalizes SNR between bins by crowding them in high SNR regions. This "VT" method prioritizes the size of the bins over the scatter of bin SNRs around the target SNR.

2.5. Line-Fitting Model

We used the fitting algorithm based on the Levenberg-Marquardt method from the package LMFIT (Newville et al. 2021). Each iteration of this algorithm attempts to improve the fit by varying the parameters along the gradient of improvement in the multi-dimensional parameter space.

Each extracted spectrum is continuum-subtracted before fitting any line profile. To estimate the local continuum level around each line, we first extract two wavelength regions on both sides of this line and fit them with a polynomial of the first order. We mask out other strong emission or absorption lines around the line profile and use a sigma-clipping algorithm (Sánchez-Monge et al. 2018) to ensure an accurate local continuum determination. Then, we extrapolate this first-order polynomial to estimate the continuum level within the line profile.

A single-Gaussian model suffices for fitting symmetric emission line profiles without a second velocity component. We find two exceptions: (1) the Balmer lines with underlying, stellar absorption troughs and (2) emissions lines (e.g., [O III] λ 4959) with two velocity components, sometimes making the combined profile asymmetric. We

conduct an F-test on each exception at a 3-sigma significance level to determine whether a two-component model (see Section 2.5.1 and Section 2.5.2) performs statistically better than the single-Gaussian model (Xu et al. 2022).

We constrain the gas kinematics by assuming the velocity center and width of each component (stellar or nebular) in the intended emission lines (including [O II] $\lambda\lambda$ 3726, 29, [O III] λ 4363, [O III] λ 4959, H δ , H γ , and H β) are the same. Here we summarize the details of each two-component fitting strategy.

2.5.1. Two-component Fitting: Emission + Absorption

For Balmer lines with significant stellar absorptions, we must be aware of their impacts on the observed line ratios. We prefer a "Gaussian plus Lorentzian" model (GL model) to fit both the emission and absorption components simultaneously (Figure 2). The Gaussian (or Lorentzian) function of the GL model is used to fit the emission (or absorption) component. All three eastern stellar associations have obvious stellar absorption troughs that require a GL model to fit their Balmer lines well.

2.5.2. Two-component Fitting: Narrow+Broad Emissions

Apart from significant stellar absorptions, we observe that $H\beta$, [O III] λ 4363, and [O III] λ 4959 lines in the starburst region (shown in Figure 2) or the [O III] λ 5007 lines around the post-starburst region (shown in Figure 6) exhibit another component that is poorly fitted by single-Gaussian models. To improve the fit, we introduce an additional Gaussian function with a positive amplitude and increased width. Nonetheless, substantial residuals persist in the broad wings of double-Gaussian fits (e.g., the starburst's [O III] λ 4959 line in Figure 2), implying the presence of a "very-broad" velocity component (FWHM ~ 700 km s⁻¹; Martin et al., in prep) or the non-Gaussian nature of these broad wings (e.g., follows a velocity field of power law in Carr et al. 2022). However, these residuals constitute $\leq 1\%$ of the total flux, indi-

cating a negligible effect on electron temperature and oxygen abundance measurements.

Utilizing the best-fitting parameter values, we compute the flux of each component in every line profile. For lines that require a double-Gaussian fit, we report in Table 5 the flux of the narrow and broad components, respectively. In this study, we interpret the narrow component as gas tracing virial motions within the examined region and the broad component as turbulent outflowing gas. Therefore, we rely solely on the narrow component's flux to determine the nebular physical properties of each region (except intrinsic A_V measurement in SB; see Section 2.6.2).

The flux uncertainty is obtained from the LMFIT covariance matrix. To determine the statistical errors for line ratios, we follow a Monte Carlo approach to perturb each line profile according to its error spectrum, recalculate the corresponding line ratio, and repeat the previous steps 1,000 times to build up a distribution of perturbed line ratios. Then, the 68 percentile width of the distribution accounts for the statistical error of this line ratio.

2.6. Extinction

In this work, we use the Galactic extinction curve interpolated from Table 3 of Fitzpatrick (1999) to correct for the influences from the Milky Way dust. We adopt the mean E(B - V) value (0.03670) from the NASA/IPAC Infrared Science Archive⁸ (Schlafly & Finkbeiner 2011). For intrinsic extinction, we use the SMC extinction curve interpolated from Table 4 (SMC Bar) of Gordon et al. (2003).

The intrinsic extinction A_V is determined from the Balmer decrement. Reddening attenuates the bluer line more than the redder line, so the observed Balmer ratio should always be larger than the intrinsic ratio. However, in regions of J1044+0353 with low dust content,

⁸ https://irsa.ipac.caltech.edu/applications/DUST/

Figure 2. Fittings of Balmer lines $H\beta$, $H\gamma$, and $H\delta$ for each stellar association labeled in Figure 1. For each stellar association, the best-fitting model (red dashed line) is plotted with the observed line profile (black solid line) in the first row. For double-Gaussian or Gaussian-Lorentzian fittings, the broad and narrow components are shown as the blue dashed line and the cyan dashed line, respectively. The grey areas represent the 1- σ uncertainties of raw data. The residual (i.e., (data - model)/error) plot is included in the second row. The two red dashed lines in the residual plot represent residual = ±1.

minimal extinction corrections can occasionally result in unphysical extinction values.

Here we summarize our method (Section 2.6.1) to determine the intrinsic A_V of each stellar association (Section 2.6.2 and 2.6.3) and our approach to dealing with unphysical extinction values (Section 2.6.4) when we create the metallicity map.

2.6.1. Intrinsic Balmer Ratio

We need to know the intrinsic Balmer line ratios well to obtain physical reddening values. In this study, we extract the intrinsic ratios from Storey & Hummer (1995). Compared to n_e, the intrinsic ratios depend more on T_e and the assumption of the H II region being optically thin or thick (Case A or Case B). Case A and B's intrinsic ratio is higher for the H II region with a higher T_e. At fixed T_e and n_e, the intrinsic ratios of Case A regions are smaller than the ones of Case B regions. The stellar-mass-weighted average T_e and n_e for these four stellar associations are 19727^{+347}_{-311} K and 99^{+57}_{-37} cm⁻³, respectively. Hence, we apply the Balmer line intrinsic ratios at T_e = 20,000 K and n_e = 100 cm⁻³ (for Case B (or Case A), we have H β /H γ = 2.10 (or 2.07) and H γ /H δ = 1.80 (or 1.78)) to determine A_V .

The A_V values derived from Balmer line ratios $H\beta/H\gamma$ and $H\gamma/H\delta$ typically differ. We adopt the A_V determined from the line ratio of $H\beta$ and $H\gamma$ lines, less sensitive to stellar absorption, as a more accurate estimate of the true value.

2.6.2. Extinction of the Starburst Region

Due to the broad emission wings of H β line, we use a double-Gaussian model to fit the broad and narrow components simultaneously (Section 2.5.2). The contribution of the broad component to the total H β flux is ~ 6%. In contrast, the low SNR of the broad components in H γ and H δ lines prevents using a double-Gaussian model, which did not significantly improve the fitting as it could not pass the F-test. Moreover, the contribution of the broad component in H γ and H δ lines are negligible (less than ~ 3%), so a single-Gaussian model is used instead. Due to the unresolved broad component in H γ , we utilize the total line flux ratio of H β and H γ lines to determine the starburst's A_V .

Our derived A_V $(0.20^{+0.10}_{-0.10})$ of the starburst region is similar to the one reported by Berg et al. (2021) (hereafter B21; $A_V = 0.24^{+0.03}_{-0.02}$) but smaller than that determined by B16 ($A_V = 0.37^{+0.03}_{-0.03}$), where they do not correct for Milky Way extinction. Both studies use the relative intensities of the four strongest Balmer lines ($\text{H}\alpha/\text{H}\beta$, $\text{H}\gamma/\text{H}\beta$, $\text{H}\delta/\text{H}\beta$) to determine the intrinsic dust reddening value. This value is then used to reddening-correct other optical emission lines using the Cardelli et al. (1989) extinction law. Our observed Balmer line ratio $\text{H}\beta/\text{H}\gamma = 2.21\pm0.07$ is consistent with B21 (2.19 \pm 0.02). These systematic differences cause minor variations of A_V in the starburst region between our study and B21.

2.6.3. Extinction of the Post-Starburst Region

FEN $(A_V = 0.20^{+0.04}_{-0.04})$ and NEN $(A_V = 0.21^{+0.13}_{-0.12})$ have similar intrinsic reddening values as the SB. On the contrary, we find the correction factors for intrinsic extinction are large in MEN $(A_V = 0.56^{+0.09}_{-0.09})$. This result is unexpected in a low-metallicity environment because the color excess, E(B-V), typically increases with metallicity (e.g., Zahid et al. 2014). If confirmed with $H\alpha/H\beta$ measurements, the implied dust lane would run roughly north-south between the SB and FEN. Similar dust lanes have been seen after galaxy mergers (Whitmore et al. 2010).

2.6.4. Regions Where Case B Fails

Some bins show negative intrinsic A_V when we create the metallicity map (the binning criteria detailed in Section 3.3.3). To deal with this issue, we propagate the error spectrum of each Balmer line 1000 times to get the distribution of the observed Balmer line ratio. If the intrinsic Balmer ratio falls within the 95% percentile width of the distribution, we attribute zero extinction to those bins (i.e., $A_V = 0$), given that the noise within the observed Balmer line ratios can occasionally result in an observed line ratio that is smaller than the intrinsic ratio.

A few bins show unphysical reddening values, such that the intrinsic ratio for Case B resides outside the 95% percentile width of their observed Balmer ratio distribution. Figure 3 shows that many of these bins are immediately north of SB. Since the galaxy might be optically thin in this direction, we calculated A_V using the intrinsic Case A ratio and obtained physical values for most of the bins, depicted by the non-overlapping red contours in Figure 3. We suggest that these optically thin bins, corresponding to holes in the H I distribution, likely provide an escape channel for ionizing photons.

3. RESULTS FROM INTEGRAL FIELD SPECTROSCOPY

In this section, we estimate the stellar population age of each stellar association (Section 3.1). We also map the gas kinematics across the ionized nebula (Section 3.2). We use the direct method to measure gas-phase oxygen abundance and examine how metallicity varies across these stellar associations (Section 3.3.1 & 3.3.2) and with distance from the stellar-mass-weighted center. (Section 3.3.3).

3.1. Star Formation History

Previous studies focus on analyzing physical properties determined from the starburst region of J1044+0353 (e.g., B16; B22). The Balmer lines in the starburst spectrum show minimal stellar absorption, consistent

Figure 3. The observed $H\beta/H\gamma$ line ratio map. Some regions surrounding the northern part of SB exhibit unphysical extinction values when their observed ratios are compared to the intrinsic ratio for Case B (red contours) or Case A (white contours). These optically thin regions, corresponding to holes in the H I distribution, might reveal the escape channels for ionizing photons.

with a very young stellar population. However, an inspection of the KCWI data cube east of the compact starburst revealed significant absorption troughs under Balmer lines, indicating they have older stellar populations (see Figure 2). To understand the propagation of the starburst, we measured the strength of Balmer lines in spectra of the stellar associations defined in Figure 1.

To assign stellar population ages, we use a stellar population synthesis model, BEAGLE (Chevallard & Charlot 2016), to build mock galaxy spectra at different ages and measure equivalent widths (EWs) for both emission (EW(EM)) and absorption (EW(AB)) portions of the Balmer line profiles. We take the absolute values of EW(EM) and EW(AB) to compare the relative strength of emission and absorption portions of each line profile (see Table 5). Each EW grid has ages ranging from 10^6 to $10^{8.5}$ years. Although the Balmer profiles are fitted simultaneously (Section 2.5), the absorption trough in the $H\beta$ line of each eastern stellar association is too weak for precise fitting, yielding roughly one dex lower measured EW(AB) than the corresponding mock spectrum. As a result, we rely on the $H\gamma$ and $H\delta$ lines to construct the EW grids shown in Figure 4.

In our simulation, we assume the initial mass function of Chabrier (2003) and the two-component dust attenuation model of Charlot & Fall (2000). To determine an appropriate SFH that is consistent with our EW measurements in Table 5, we first generate mock galaxy spectra for a constant-SFH model adopted in B22 and a pure SSP (simple stellar population) model. The constant-SFH model overestimates the absorption EWs of the older stellar associations at their emission EWs. Instead, the pure SSP model has zero emission EWs at age $\gtrsim 10^7$ years because all O stars die off. Hence, we propose a composite SFH that includes a recent burst with $\log(\text{SFR}_c/M_{\odot} \text{ yr}^{-1}) = -0.85$ and a timescale $\Delta t_{\text{SFR}_c} = 10^6$ year (see Table 3), in addition to the first burst occurring at the ignition of the star formation. If we set the SFR_c as the total SFR from B22 (Table 1), the offsets in our age estimations are within the uncertainties for all regions.

BEAGLE simulates the spectrum from both stars and photoionized gas. The value of each stellar or nebular fixed parameter is listed in Table 3. We assume *in situ* star formation of these stellar associations so we can input the same fixed parameters in BEAGLE for each stellar association.

We estimate the age of each stellar association (see Table 4) by finding the nearest model points in the EW space (Figure 4). Our age estimation for SB (3.02 ± 0.03) Myr) is consistent with the finding of Olivier et al. (2022) (4.01 ± 1.13 Myr), who modeled the FUV spectrum, encompassing photospheric and stellar wind lines that are sensitive to the presence of the most massive stars. The uncertainties of NEN and MEN are overlapped with each other in both $H\gamma$ and $H\delta$ EW spaces, which suggests they have similar stellar population ages $(10^{7.2\pm0.1}$ years). Even though the stronger emission EWs of these two Balmer lines might imply that FEN's stellar population is relatively younger, the estimated age is relatively older $(10^{7.3\pm0.05} \text{ years})$. These age estimations are based on the argument that the stellar and the gas-phase metallicities are similar, as found in a sample of low-redshift star-forming galaxies (Chisholm et al. 2019). Instead, if we assume the stellar metallicity is 0.2 dex lower than the gas-phase metallicity (De Rossi et al. 2017), the estimated ages of SB and FEN would stay the same. However, the measured age of MEN or NEN would increase by a factor of ~ 1.3 to $10^{7.33\pm0.06}$ years.

The stellar mass of each stellar association can be estimated by the scaling needed to match the model continuum (at $10^{6.8} M_{\odot}$) to the observed continuum. To avoid the regions with strong emission lines, we only use the continuum level with wavelengths ranging from 5100 to 5500 Å. This method shows MEN (or FEN) has the largest (or smallest) stellar mass (Table 4). One main caveat of this approach is that we do not explore other complicated SFH models in determining the stellar mass. Even though the estimated starburst's stellar mass from B22 (assume constant SFH) lies within the uncertainty of our result, the MPA-JHU value lies 2σ away from ours. Therefore, the assumption that J1044+0353 follows the composite SFH model might introduce significant systematic uncertainties and lead to deviations from previous studies. Besides this issue, since the mass-to-light ratios in the BEAGLE mock galaxies are extremely sensitive to age, an accurate age estimation is needed to constrain the stellar mass (e.g., the determined stellar mass is differed by a factor of 15 with age ranging from $10^{6.45}$ to $10^{6.50}$ years).

3.2. Global Gas Kinematics

We used the strong emission lines ([O II] $\lambda\lambda 3726, 29$, H β , H γ , H δ , and [O III] $\lambda\lambda 4959, 5007$) to measure the spatially extended velocity field. In saturated regions (Section 2.2), all lines except [O III] $\lambda 5007$ were fitted, while only [O III] $\lambda 5007$ was fitted in unsaturated regions. We first generated a 2D narrow-band image around the strongest emission line, [O III] $\lambda 5007$, with a target SNR of 10, and then adaptively binned the image in order to define apertures for spectral extraction. Bins failing to meet our threshold SNR of 3 for peculiar velocity were masked.

To measure the peculiar velocity, v_p , for each bin, we need to measure the peculiar redshift, z_p , because $v_p = cz_p$ in the non-relativistic regime. If we define the parameters z_{single} , z_{all} as the redshifts derived from a single bin and from all the bins respectively, the peculiar velocity of each bin can be determined by the ratio of these two redshifts $v_p = c \left[\frac{1+z_{\text{single}}}{1+z_{\text{all}}} - 1 \right]$. Following the procedure described above, we obtain the peculiar velocity map shown in the left panel of Figure 5. It is clear that most bins along the photometric major axis have v_p ranging from -5 km s^{-1} to 5 km s^{-1} (i.e., black color). We discover a strong velocity gradient parallel to the galaxy's minor axis, with the steepest gradients $(\sim 30 \text{ km s}^{-1} \text{ kpc}^{-1}; -40 \text{ to } 50 \text{ km s}^{-1} \text{ over } \pm 1.5 \text{ kpc})$ appearing to emanate from the oldest stellar association of the post-starburst population (i.e., FEN).

If rotation produces this velocity gradient, then the galaxy is roughly a prolate spheroid rotation about the major axis. The possibility of a prolate rotator galaxy is relatively small. As pointed out in Tsatsi et al. (2017), the prolate rotators are more commonly found among the most massive early-type galaxies (ETGs) $(M_* \gtrsim 2 \times 10^{11} M_{\odot})$. They claim two progenitors with different disk orientations are responsible for the prolate rotation in the ETGs, a scenario that is unlikely to happen for our low-mass galaxy.

In contrast, the minor-axis gradient can indicate the existence of galactic outflows (e.g., Ho et al. 2014). Based on our age estimations in Section 3.1, the post-starburst stellar associations are old enough (i.e., ≥ 6 Myr; Leitherer et al. 1999) to explode supernovae and provide a specific amount of mechanical energy to power galactic outflows (Martin et al., in prep). In Figure 5, regions with high absolute peculiar velocities also have large FWHM values because these broadest lines have asymmetric line profiles (see E1 and E3 regions in Figure 6). Higher-resolution spectroscopy would resolve these into two components. The front and back sides of the outflow would each produce a component with different velocity centroids if it follows a biconical morphology (Heckman et al. 1990; Lehnert & Heckman 1996). Hence

the most significant widths represent two distinct components along the sightline rather than the local velocity dispersion.

Besides the existence of galactic outflows, the positive velocity gradient (i.e., the magnitude of v_p increases from the inner regions to the outskirts) tells us it is an accelerating wind instead of a decelerating one. Estimating the escape velocity using the relation $v_{\rm esc} \approx 3v_{\rm circ}$ (Veilleux et al. 2020), and considering $v_{\rm circ} = 15.6^{+3.0}_{-3.7}$ km s⁻¹ (Xu et al. 2022), we find that the deprojected velocity $v \approx v_p/\cos(i) \gtrsim 80$ km s⁻¹ $(i \approx 60^\circ$; see the caption in Figure 5) of the largestvelocity bin in either the northern or southern cone exceeds $v_{\rm esc}$. Therefore, the outflow may escape from the gravitational potential rather than slowing down and falling back onto J1044+0353.

It is interesting to note the asymmetric velocity field around the starburst region. The top left panel of Figure 5 shows most of the bins in the north direction of the starburst region have $|v_p|$ less than 5 km s⁻¹. The bins in the south direction, however, have $|v_p|$ ranging from 5 km s⁻¹ to 20 km s⁻¹. These southern bins have relatively symmetric and narrow [O III] λ 5007 line profiles, so a single-component fitting is reasonably good. This finding indicates the offset in systematic velocities between these southern bins and the whole galaxy. This offset may reveal the presence of induced inflows that fuel the starburst region during mergers or interactions (Section 4.2.1), a hypothesis requiring validation through future H I mapping.

3.3. Gas-Phase Metallicity

The temperature-sensitive auroral line $[O \text{ III}] \lambda 4363$ is observable in both the starburst and the post-starburst regions, so we can use the "direct" method to determine their gas phase oxygen abundances (Pérez-Montero 2017; Kewley et al. 2019).

Due to the wavelength coverage in KCWI, we can use the line ratio of [O II] $\lambda\lambda 3726, 29$ doublet to determine electron density. The lower-density limit is set to be 10 cm⁻³. For temperature diagnostics, we utilize the line ratio between [O III] $\lambda 4363$ line and [O III] $\lambda\lambda 4959, 5007$ doublet to derive the temperature T_e[O III]. Due to saturation of the [O III] $\lambda 5007$ line in both long and short exposure cubes of the starburst region (Section 2.2), we estimate this line flux for all regions in J1044+0353 using the intrinsic ratio of the [O III] $\lambda\lambda 4959, 5007$ doublet (I_{$\lambda 5007$}/I_{$\lambda 4959$} = 2.98; Storey & Zeippen 2000). This method ensures consistency and a physical T_e[O III] across all regions.

 $T_e[O III]$ is employed to determine the high-ionization zone temperature when measuring the O^{2+}/H^+ abundance. Adopting a two-ionization-zone model, we also need to know the ionic abundance of O^+/H^+ (i.e., O/H= $(O^+ + O^{2+})/H^+$). This assumption is valid because B21 apply a four-ionization-zone model to determine the

PENG ET AL.

Parameter	Value	Description
$\log{({ m Z}_*/{ m Z}_{\odot})}$	-1.24	Stellar Metallicity of the composite SFH model
$\log{({ m Z}/{ m Z}_{\odot})}$	-1.24	Gas-Phase Metallicity of the composite SFH model
$\log{({ m M}_*/{ m M}_\odot)}$	6.80	Total Stellar Mass of the composite SFH model
$\log({\rm SFR_c/M_\odot~yr^{-1}})$	-0.85	SFR of the recent burst in the composite SFH model
$\Delta t_{ m SFR_c}/ m yr$	10^{6}	Timescale of the recent burst in the composite SFH model
$\log\left(\mathbf{U}\right)$ (nebular)	-1.75	Effective Galaxy-Wide Ionization Parameter
$\xi_{ m d}$	0.1	Effective Galaxy-Wide Dust-to-Metal Mass Ratio
μ	0.3	Fraction of Attenuation Optical Depth Arising From the Diffuse ISM

Table 3. Fixed parameters of the composite SFH model adopted in BEAGLE to generate the mock galaxy spectra.

NOTE—Column 1 lists the fixed parameters of BEAGLE in our composite SFH model. Column 2 lists the fixed value of each parameter. The stellar metallicity (row 1) is assumed to be the same as the gas-phase metallicity (row 2) in the ISM. Their values are based on the measured starburst metallicity in this paper. For reference, BEAGLE adopts a solar metallicity $Z_{\odot} = 0.0152$. The values of stellar mass (row 3) and SFR (row 4) are extracted from the MPA-JHU database. The value of ionization parameter (row 6) is taken from Table 5 in Olivier et al. (2022). The value of ξ_d is set to be 0.1, the typical value derived in Chevallard et al. (2018) when fitting the combination of HST/COS photometry and Balmer emission lines. The value of μ is the default value from BEAGLE. Column 3 shows the description of each parameter.

 Table 4. Stellar population age and stellar mass of each stellar association.

	STARBURST	MEN	NEN	FEN
$\log(Age)$ (year)	6.480 ± 0.005	7.2 ± 0.1	7.2 ± 0.1	7.30 ± 0.05
$\log(M_*) \ (M_{\odot})$	$5.82^{+0.39}_{-0.12}$	$6.26\substack{+0.05\\-0.18}$	$6.08\substack{+0.05\\-0.18}$	$5.57^{+0.10}_{-0.04}$

NOTE—Row 1 lists the estimated stellar population age for each stellar association on the logarithmic scale. Row 2 lists the estimated stellar mass of each stellar association on the logarithmic scale.

metallicity of J1044+0353 and find the fraction of oxygen in the neutral and very-high ionization states is insignificant (i.e., $(O^0 + O^{3+})/O \sim 4\%$). Therefore, it is reasonable for us to use the simplified two-zone model here. Because most temperature-sensitive [O II] emission lines lie in the UV region or in the red-end of the optical region (e.g., [O II] $\lambda\lambda7320,7330$), a scaling relation between T_e[O III] and T_e[O II] is needed to determine the ionic abundance of O⁺/H⁺.

We apply temperature relations proposed in Arellano-Córdova & Rodríguez (2020) (hereafter AR20) to determine metallicity for each stellar association or each bin (in Section 3.3.3). We choose not to use the relation of Garnett (1992) (see also Campbell et al. (1986)) adopted in B16 because this relation tends to overestimate the temperature of the low-ionization zone for galaxies with low metallicities ($12 + \log(O/H) \leq 7.6$; Figure 3 in AR20). Owing to this fact, Garnett (1992) might underestimate the ionic abundance of O⁺ in the low-metallicity environment like J1044+0353 that it does not depend on the $P={\rm I}_{\rm [O\,III]\lambda\lambda4959,5007}$ / $({\rm I}_{\rm [O\,III]\lambda\lambda4959,5007}$ + ${\rm I}_{\rm [O\,III]\lambda3726})$ parameter defined in AR20.

Given the temperatures of these two ionization zones, we can derive the ionic abundance of O⁺/H⁺ or O²⁺/H⁺ using its calibration with the relative intensity of [O II] $\lambda\lambda$ 3726, 3729 or [O III] $\lambda\lambda$ 4959, 5007 doublet to H β . Following a similar approach as Pérez-Montero (2017), these calibrations are obtained from fittings to PyNeb v1.1.14 using the default collision strengths of O⁺ and O²⁺ (Kisielius et al. 2009; Storey et al. 2014). These two relations are given in Equations 1 and 2 with $t_l =$ $10^{-4} T_e[O II]$ and $t_h = 10^{-4} T_e[O III]$. These two new calibrations have precisions better than 0.01 dex in the temperature range $T_e[O III] = 7,000 \text{ K} - 25,000 \text{ K}$ and in the density range $n_e = 10 \text{ cm}^{-3} - 1000 \text{ cm}^{-3}$.

$$12 + \log\left(\frac{O^{+}}{H^{+}}\right) = \log\left(\frac{I_{[O II] \ \lambda 3726} + I_{[O II] \ \lambda 3729}}{I_{H\beta}}\right) + 5.90 + \frac{1.65}{t_{l}} - 0.54 \cdot \log\left(t_{l}\right) + 7.99 \times 10^{-5} \cdot n_{e}$$
(1)

$$12 + \log\left(\frac{\mathrm{O}^{2+}}{\mathrm{H}^+}\right) = \log\left(\frac{\mathrm{I}_{[\mathrm{O\,III}]\ \lambda4959} + \mathrm{I}_{[\mathrm{O\,III}]\ \lambda5007}}{\mathrm{I}_{\mathrm{H}\beta}}\right) + 6.21 + \frac{1.21}{t_h} - 0.656 \cdot \log\left(t_h\right) \quad (2)$$

3.3.1. Starburst Metallicity

Figure 4. The positions of stellar associations lie in the EW space constructed by BEAGLE's mock galaxy spectra. The composite SFH model ranges from 10^6 to $10^{8.5}$ years. For both panels (*Left:* H γ ; *Right:* H δ), the EW of the emission portion is on the x-axis, and the EW of the absorption portion is on the y-axis. The marker for each stellar association is shown as a diamond (MEN), an inverted-triangle (NEN), a square (FEN), and a star (SB), respectively. For both panels, the absorption EWs of the starburst region cannot be accurately measured due to its weak absorption troughs. Therefore, we assume the absorption EWs of the BEAGLE mock profile at the corresponding age (i.e., $10^{6.48}$ years) to be the upper limits for those of the starburst region. The circular points are BEAGLE mock galaxies that are color-coded by their ages. Within each panel, the upper right corner displays the representative error bars of the measured emission and absorption EWs for mock galaxies.

Following the direct method described in Section 3.3, we can determine the electron density n_e , electron temperature $T_e[O III]$, and oxygen abundance for the starburst region. The second column of Table 5 summarizes these physical properties of the starburst region.

The $T_e[O III]$ temperature, however, cannot represent the temperature across the ionization zones. Previous studies use different approaches to tackle this issue. B16 utilize the calibration from Garnett (1992) to determines the low ionization zone temperature from $T_e[O III]$, which could underestimate the ionic abundance of O^+ (Section 3.3). If the galaxy is highly excited, then the impact should be negligible because the contribution of O^+ to the total oxygen abundance is subdominant. Due to this difference, even if we get similar electron density and temperature as B16, we find a relatively higher ionic abundance O^+/H^+ (Table 6). B21, instead, use different strong line ratios to determine T_e in different ionization zones (e.g., the [O II] $\lambda\lambda7320, 30/\lambda\lambda3726, 29$ line ratio is used in the lowionization zone).

Other than the temperature calibration, there were subtle differences between our "direct" method and those used in previous work. B16 utilizes the density-sensitive doublet [O II] $\lambda\lambda$ 7320, 30 instead of [O II] $\lambda\lambda$ 3726, 29 used in this study. B21 use [S II] $\lambda\lambda$ 6717, 6731, Si III] $\lambda\lambda$ 1883, 1892, C III] $\lambda\lambda$ 1907, 1909, and Ar IV] $\lambda\lambda$ 4711, 4740 line ratios to determine n_e in their four ionization zones respectively. We illustrate

the differences in determining intrinsic reddening values in Section 2.6. Moreover, the methods used by B16 and B21 to determine the oxygen abundance rely on SDSS and LBT/MODS spectra, respectively. However, according to Arellano-Córdova et al. (2022), the differences between the long-slit and IFU spectra are within the uncertainties when the high-ionization zone temperature $T_e[O III]$ is measured directly. These facts lead to the negligible deviation between our result and theirs (≤ 0.01 dex; Table 6).

3.3.2. Metallicity in the Post-starburst Region

We found that all eastern stellar associations (NEN: $7.52^{+0.03}_{-0.03}$, MEN: $7.37^{+0.03}_{-0.03}$, and FEN: $7.43^{+0.03}_{-0.03}$) have metallicities within three standard deviations of the starburst metallicity in terms of $12 + \log(O/H)$. Overall, the stellar-mass-weighted metallicity of the post-starburst region ($7.43^{+0.02}_{-0.02}$) is comparable to that of the starburst region.

The finding that these older stellar associations have similar metallicities as the starburst region is not surprising. Although the post-starburst region is old enough to explode supernovae and expel the produced metals to the ISM, this ejecta might reside in the hot ionized gas (i.e., $T \sim 10^6$ K), which needs to be traced by X-ray emissions (Martin et al. 2002). This gas would remain unmixed with the $\sim 10^4$ K gas until the radiative cooling is significant to detect these metals in the

Figure 5. The peculiar velocity map (*Top Left*), the FWHM map (*Top Right*), and the SNR([O III] λ 5007) map (*Bottom Middle*). The bins are obtained via our adaptive binning algorithm with a target SNR of 10 for [O III] λ 5007 line. For saturated regions, we simultaneously fit the strong emission lines, [O II] $\lambda\lambda$ 3726, 29, H β , H γ , H δ , and [O III] λ 4959, to find the peculiar velocity or FWHM. Instead, we only fit the [O III] λ 5007 line in the unsaturated regions. *Top Left:* Bins with SNR(v_p) < 3 have been masked out. Each bin is color-coded by its own v_p . The bins with reddish color mean they have values of v_p larger than 5 km s⁻¹. The bins with bluish color mean they have values of v_p less than -5 km s^{-1} . The bins with black color represent they have values of v_p ranging from -5 km s^{-1} to 5 km s⁻¹. The position of each stellar association is marked as the way in Figure 1. *Top Right:* Following the same binning procedure, each bin has SNR(v_p) \geq 3. Each bin is color-coded by its own FWHM value in velocity space. The white-square regions with labels 'E1', 'E2', and 'E3' represent the blue-shifted, zero-velocity, and redshifted regions, respectively, in Figure 6. *Bottom Middle:* Each bin is color-coded by its SNR of the [O III] λ 5007 line. For each panel, the photometric major axis is shown as a grey dashed line. To determine the major axis, the background-subtracted r-band DECalS image (see Section 2.3) is fitted using a 2D Gaussian function that aligns with the second-order moments of the source before the deblending process, implemented with Photutils. The estimated inclination of this source from Photutils is $i = \cos^{-1}(b/a) \approx 60^{\circ}$.

warm phase of the ISM (i.e., $T \sim 10^4$; K Tenorio-Tagle 1996).

Due to gravity, this gas may eventually fall onto the galactic disk and can be mixed with the ISM matter when the next generation of stars photoionize this gas. Consequently, these processes might take ~ 100 Myr for the chemical enrichment by the metal-rich gas to happen (Stasińska, G. et al. 2007). This mixing timescale is one order of magnitude larger than the estimated age of the post-starburst region. Therefore, this ejecta is subject

to a long mixing timescale to be well-mingled with the matters in the ISM.

3.3.3. Chemical Inhomogeneities

The majority of research indicates chemical homogeneity in ionized gas at scales $\gtrsim 100$ pc with spreads of $\lesssim 0.2$ dex (e.g., Kobulnicky & Skillman 1997; Lee & Skillman 2004; Kumari et al. 2019). It is crucial, however, to note that this argument does not hold in every instance (e.g., James et al. 2020; Fernández-Arenas et al.

Figure 6. Variations in [O III] λ 5007 line profiles along the minor axis around the post-starburst region. The [O III] λ 5007 line is extracted from the E1 or blueshifted (*left*), E2 or zero-velocity (*middle*), and E3 or redshifted (*right*) regions, respectively, in Figure 5. Only the double-Gaussian fitting is shown in each panel. In the panels for E1 and E3, the redshift and blueshift components are respectively represented by blue and cyan dashed lines. For E2, the broad and narrow components correspond to the dashed and cyan dashed lines, respectively. Their summation is shown as a red dashed line. The vertical grey dashed line represents the systemic velocity. The reduced χ^2 values for single- and double-Gaussian fittings are listed at the upper right corner of each panel. High absolute peculiar velocities in regions E1 and E3 are associated with an unresolved second velocity component confirmed by the F-test (Section 2.5). These two velocity component result in asymmetric line profiles and large FWHM values. In the context of a biconical morphology, each component is generated by the front and back sides of the outflow, respectively. The F-test results for E2 suggest a requirement for a second (broad) velocity component. The broad component, indicative of the turbulent outflowing gas, originates from the post-starburst (or the outflow launching) region. Because this broad component shares a velocity centroid similar to the narrow component, it does not significantly impact the line profile to increase its FWHM.

2023). Here we examine the chemical inhomogeneities of J1044+0353 by presenting the direct-based metallicity as a function of distance from the stellar-mass-weighted center of the four stellar associations (the cyan circular point in the left panel of Figure 7).

We applied the adaptive binning to a 2D narrow-band image of the faintest line, [O III] λ 4363, required by the oxygen abundance diagnostic at a SNR threshold of 5. We obtained 48 bins in total, shown in Figure 7 (and in Figure 3). After applying the binning algorithm to the 2D image, we follow the procedure outlined in Section 3.3 to determine the metallicity of each bin. To address three bins that show unphysical extinction values using the intrinsic Case A ratio (white contours in Figure 3), we assign these bins with $A_V = 0$ in the metallicity measurements.

We first show the metallicity distribution of all bins in the right panel of Figure 7. To quantify the size of the spread in metallicity, we calculate an interquartile range (IQR) of 0.04. 45 out of 48 bins have metallicities within two standard deviations ($\sigma_Z = 0.05$) of the median value ($12 + \log(O/H) = 7.44$). Among the three outliers, two possess metallicities of 7.31, and one presents a metallicity of 7.60, signifying the largest spread of approximately 0.3 dex between individual bins. Although J1044+0353 is considered chemically homogeneous due to its relatively small IQR and σ_Z , the existence of spatial variations among these outlier regions, with a resolution element size of approximately 250 pc, cannot be disregarded, particularly in the post-starburst region where two of these outliers are located within this area.

We then divide the galaxy into four regions to see if the metallicity distributions vary with position angles. We present metallicity as a function of the distance to the spaxel closest to the stellar-mass-weighted center. The distance of each bin corresponds to the median projected distance of spaxels allocated to that bin. We find metallicity gradients are ranging from -0.026 ± 0.050 to 0.042 ± 0.043 dex kpc⁻¹ across four regions (Figure 8). The gradients in the South and West Regions could potentially be positive; however, their error bars are comparable to their respective values. The North and East Regions, centered around the post-starburst region, show slightly larger scatter compared to the other two regions (i.e., quantified by the values of residual sum of squares, or RSS, in Figure 8), suggesting potential chemical inhomogeneities along these two position angles. Overall, all regions exhibit relatively flat metallicity gradients considering error bars, indicating minor azimuthal metallicity variations. If we present metallic-

 Table 5. Physical Properties of Different Stellar Associations

NOTE—The first two rows show the intensities of [O II] $\lambda\lambda 3726, 3729$ doublet, whose ratio is used to derive the electron density n_e of each stellar association in row 3. The lower-density limit is set to be 10 cm⁻³. 4th and 5th (6th and 7th) rows show the intensities of narrow and broad components of [O III] $\lambda 4363$ ([O III] $\lambda 4959$) line. The narrow components of these two [O III] lines are used to determine the electron temperature T_e of each stellar association in row 8. The intensity of [O III] $\lambda 5007$ line is not shown here because its intensity is based on that of [O III] $\lambda 4959$ line (see Section 3.3). The gas phase oxygen abundance for each stellar association is shown in the 9th row. Rows 10 and 11 show the intensities of narrow and broad components of H β line. Rows 12 and 13 list the intensities of H γ and H δ . The equivalent widths, including both emission (EW (EM)) and absorption (EW (AB)) portions, of Balmer lines are shown from the rows 14 to 19. The intrinsic magnitude of extinction, A_V , is derived from the Balmer Decrement in the 20th row. All the intensities shown have been corrected for both Galactic and intrinsic extinction. The intensity units is 10^{-16} erg cm⁻² s⁻¹.

ity as a function of the distance to the center of the starburst region, the offsets in metallicity gradients (along all PAs) are well within the uncertainties.

4. DISCUSSION

Our stellar population age measurements (Section 3.1) and the velocity map (Figure 5) reveal the existence of a galactic outflow that appears to emanate from the poststarburst region. The metallicity map (Figure 7) and the corresponding gradients along different PAs (Figure 8), instead, reveal a considerable scatter of metallicities within the post-starburst region, indicating an induced inflow of low-metallicity gas by a merger or an interaction event. To better interpret the role of each mechanism, we can plot the relative positions of J1044+0353 to the mass-metallicity relation (MZR) and the SFRstellar mass relation (SFMR) (Section 4.1). We then discuss each mechanism respectively and quantify their impacts in this galaxy (Section 4.2).

4.1. Offset from MZR and SFMR

We determine J1044+0353's position in the massmetallicity plane using the median metallicity value presented in Figure 7 and the total stellar mass ascertained by B22. Due to the systematic offset between strongline-based and direct-based MZRs (e.g., López-Sánchez et al. 2012), we restrict our comparisons to the latter, as we employ the auroral line [O III] λ 4363 to derive the direct-based oxygen abundance in this study. As shown in Figure 9, J1044+0353 is situated below most direct-

	$n_{\rm e}~({\rm cm}^{-3})$	$T_e[O II]$ (K)	$T_{e}[O III] (K)$	O^+/H^+ (10 ⁵)	O^{2+}/H^+ (10 ⁵)	$12 + \log(O/H)$
STARBURST	193^{+34}_{-33}	14796^{+988}_{-988}	19313^{+158}_{-157}	$0.28^{+0.06}_{-0.06}$	$2.56^{+0.05}_{-0.05}$	7.45 ± 0.01
B16	260	$16300{\pm}300$	19600 ± 500	$0.17 {\pm} 0.10$	$2.62{\pm}0.03$	7.45 ± 0.02
B21	200 ± 40	19100 ± 1500	19200 ± 200	$0.114{\pm}0.025$	$2.70 {\pm} 0.067$	$7.44 {\pm} 0.01$

 Table 6. Comparison to Previous Studies on J1044+0353

NOTE—Comparison of n_e , $T_e[O II]$, $T_e[O III]$, and gas phase oxygen abundance with previous studies conducted by B16 and B21. Row 1 shows these physical quantities of the starburst region obtained in this study (Table 5). Row 2 is extracted from Table 3 in B16. Row 3 is extracted from Table 3 and 5 from B21, which is based on a four-ionization-zone model. The n_e in our study is based on $[O II] \lambda\lambda 3726, 3729$ line ratio; however, the n_e in B16 is based on $[S II] \lambda\lambda 6717, 6731$ line ratio. B21, instead, use $[S II] \lambda\lambda 6717, 6731$, $Si IIII \lambda\lambda 1883, 1892$, CIII] $\lambda\lambda 1907, 1909$, and Ar IV] $\lambda\lambda 4711, 4740$ line ratios to determine n_e in different ionization zones. The low-ionization-zone temperature $T_e[O II]$ is estimated using the AR20 (or Garnett (1992)) calibration between $T_e[O II]$ and $T_e[O III]$ in our study (or in B16). B21 directly measure $T_e[O II]$ by using the $[O II] \lambda\lambda 7320, 30/\lambda\lambda 3726, 29$ line ratio.

Figure 7. Left: The gas-phase metallicity map with the metallicities measured from the direct method. The bins are obtained via our adaptive binning algorithm with a target SNR = 5 for [O III] λ 4363 line. This map is divided into four regions (by two black dashed lines) with different position angles so we can find out how metallicity gradients change with position angles (shown in Figure 8). The crossing of these two black dashed lines is the stellar-mass-weighted center (marked by the cyan circular point). Each bin is color-coded by its own metallicity in terms of 12 + log(O/H). Right: Distribution of the gas-phase metallicity of each bin obtained by the direct method. The median, mean, and standard deviation of the metallicity distribution are shown in the upper right corner. 45 out of 48 bins have metallicities within two standard deviations ($\sigma_Z = 0.05$) of the median value. Two of the other three bins have metallicities of 7.31, and one has a metallicity of 7.60.

based MZRs. However, it could fall within the MZR from Andrews & Martini (2013) (hereafter AM13) upon extrapolating this relationship to the low-mass regime $(M_* \leq 10^7 M_{\odot})$. A key limitation of this argument is the omission of systematic differences in sample selections, stellar mass determination methods, and various approaches to measuring T_e, which result in slight deviations in slopes and normalizations of these MZR curves. Nevertheless, we can assert that J1044+0353 is more metal-depleted than most dwarf galaxies at this stellar mass.

To explain this offset from the MZR, prior research (e.g., Mannucci et al. 2010; Curti et al. 2020) highlights the existence of a more general relation (the fundamental metallicity relation or FMR) among stellar mass, gas-phase metallicity, and SFR. These studies reveal a more pronounced secondary dependence of metallicity on SFR in the low-mass-end regime of the MZR, suggesting that low-metallicity galaxies exhibit higher SFRs at a fixed stellar mass. Given the steep low-mass slope of the MZR from AM13 ($Z \propto M_*^{1/2}$; compared to other direct-based MZRs in Figure 9 with $Z \propto M_*^{1/3}$), the position of J1044+0353 is well-explained by extrapolating this MZR. Sanders et al. (2021) ascribe this steep slope to a sample bias characterized by increasing SFR as M_* declines, implying that this regime allows galaxies with varying SFRs to generate MZRs with distinct slopes.

This anti-correlation between metallicity and SFR suggests that J1044+0353's SFR is relatively higher than the typical SFRs at its stellar mass. J1044+0353's

Figure 8. Metallicity gradients in different position angles. The galaxy is divided into four regions with corresponding position angles (shown in the title of each panel; see Figure 7). For each panel, the black solid line is the best-fitting linear function. The RSS (residual sum of squares) of each best-fitting linear model is presented in each panel. The green and orange areas represent the 68% and the 95% confidence bands of the best-fitting line. The gradients in the South and West Regions could potentially be positive; however, their error bars are comparable to their respective values. The North and East Regions, centered around the post-starburst region, show slightly larger scatter compared to the other two regions. Overall, all regions exhibit relatively flat metallicity gradients considering error bars, indicating minor azimuthal metallicity variations.

position in the SFR- M_* (SFMR) plane verifies this point (shown in the right panel of Figure 9). At its total stellar mass, it lies roughly 2 dex higher in SFR compared to the LMLVL samples in Berg et al. (2012). This point is also illustrated in B22. The SFMR trend of the CLASSY (COS Legacy Archive Spectroscopic SurveY) galaxy sample, including J1044+0353, has a similar slope as the LMLVL trend at $z \sim 0$, but its SFR is more typical for galaxies around $z \sim 2$ (Whitaker et al. 2014).

Mannucci et al. (2010) illustrate multiple approaches to explain the anti-correlation between metallicity and SFR discovered in the FMR. For example, galactic outflows are considered the primary mechanism for the dependence of abundances on mass and SFR in the local universe, especially for dwarf galaxies with shallower gravitational potential wells. If we extrapolate Figure 12 in AM13 to this low-mass regime, we find this directbased FMR significantly overestimates the metallicity value at this specific SFR and stellar mass (i.e., larger than the median metallicity value in Figure 7 by ~ 0.25 dex). This large deviation suggests outflow cannot be the sole mechanism that dominates in this galaxy.

Given the presence of localized chemical heterogeneities (Section 3.3.3), we cannot exclude the possible impacts of mergers or interactions in J1044+0353's elevated SFR and diluted metallicity. Several studies find that merger-type galaxies are not consistent with the FMR (Ellison et al. 2008; Bustamante et al. 2018, 2020). Even though the FMR predicts a dilution of metallicity for weakly-interacting galaxies (i.e., projected separation $\gtrsim 50$ kpc), the measured metallicity offset for galaxies at the end stage of interaction is stronger than the FMR's prediction (Bustamante et al. 2020). This metallicity offset or the SFR enhancement might be due to the induced radial inflow of low-metallicity gas (by

Figure 9. Left: The direct-based MZRs. Solid lines in various colors depict MZRs with direct-based metallicity measurements from multiple sources (Lee et al. 2006; Berg et al. 2012; Andrews & Martini 2013; Ly et al. 2016; Yates et al. 2020). The yellow dashed line illustrates the MZR extrapolation from Andrews & Martini (2013) to the low-mass regime of J1044+0353. The total stellar mass of J1044+0353 is represented by a blue circle and extracted from B22, with the median metallicity value and 1- σ uncertainty ($\sigma = 0.05$) from Figure 7. Right: Total star formation rates versus total stellar mass (SFMR). J1044+0353's position is indicated by a blue circle based on values from B22, while the overall CLASSY sample trend is represented by a blue solid line (B22). The $z \sim 0.5 - 2.5$ SFMR trends from Whitaker et al. (2014) (orange lines) and $z \sim 0$ trends from Chang et al. (2015) (SDSS; cyan dashed line) and Berg et al. (2012) (LMLVL; green solid line) are included for comparison.

mergers or interactions) from the outskirts to the galactic center (Rupke et al. 2010a,b; Rich et al. 2012; Torrey et al. 2012). These studies indicate that J1044+0353 is an FMR outlier (i.e., the FMR is not universal) due to its interaction history.

4.2. Spatial Variations in Metallicity

The conventional perspective that low-metallicity star-forming dwarf galaxies are chemically homogeneous is contested by several recent studies (Bresolin 2019; James et al. 2020, and references therein). These studies propose that chemical inhomogeneities might arise in these systems under certain critical conditions, such as: (i) the presence of metal-enriched outflows stemming from supernovae and (ii) the induction of metal-poor gas inflows due to interactions and mergers. We elaborate on each circumstance to account for the localized spatial variations in metallicity surrounding the post-starburst region (Section 3.3.3).

4.2.1. Potential Explanations

Mergers or interactions could be the primary driver to localized chemical inhomogeneities. Numerical studies suggest that the induced inflows of less-enriched gas by mergers or strong interactions might lower the central metallicity (Rupke et al. 2010a; Rich et al. 2012; Torrey et al. 2012). Although these numerical simulations have different treatments of the chemical enrichment by star formation, gas consumption rate, and efficiency of galactic wind, all agree that nuclear metallicity is diluted after the first pericenter. This change in nuclear metallicity is not a monotonic function as the progress of a merger. Chemical enrichment and metal redistribution by galactic outflows would partially wipe out the dilution of metal-poor gas inflows. The metallicity dilution by mergers or interactions is also emphasized in observational studies (Rupke et al. 2010b; Kewley et al. 2010; Grossi et al. 2020). Rich et al. (2012) observe that this dilution effect is prevalent across all stages of interaction, with the degree of dilution increasing from the weakly-interacting stage to the final coalesced stage for their luminous infrared galaxies, indicating that this effect is sensitive to the galaxy's interaction stage.

To specify a particular interaction stage for this galaxy, we first need to understand whether the chemical inhomogeneities are due to a strong encounter with a dark gas cloud or a dwarf-dwarf merger. The age difference (~ 20 Myr) between the starburst and the post-starburst regions can constrain the parameters of these two scenarios.

If the age difference is roughly the time it takes the gas cloud to pass through these two regions (separated by ~ 1 kpc), the velocity of this gas cloud is 1 kpc/20 Myr \approx 49 km/s. This value is a factor of three larger than the measured circular velocity of this galaxy (15.6^{+3.0}_{-3.7} km/s) by Xu et al. (2022).

Alternatively, the age gradient might reflect the first and second pericenter of a dwarf-dwarf merger. If each of these two dwarf galaxies has a stellar mass of $10^6 M_{\odot}$ with a roughly $10^{9.5} M_{\odot}$ halo (i.e., extrapolate the stellar mass-halo mass relation from Moster et al. (2012) to the lower stellar-mass regime; Wheeler et al. 2019), the estimated separation between them is 0.86 kpc based on the assumption that they revolve in a circular orbit. This estimated separation is close to the projected distance between the starburst and the post-starburst regions.

Galactic outflows can also lead to spatial chemical variations. Observing the kinematic indicators of outflow gas in Knot C of the local blue compact dwarf (BCD) Haro 11, James et al. (2013) attribute its depleted metallicity to a metal-enriched galactic outflow. Wang et al. (2019) discover two $z \sim 2$ dwarf galaxies with positive metallicity gradients due to strong outflows triggered by central starbursts. Intrinsically, the extent of metal enrichment probably depends on the fraction of supernovae-produced metals that mix with the ISM matter instead of being lost in metal-enriched galactic winds (Sharda et al. 2021).

4.2.2. Analytical Chemical Evolution Model

To disentangle the roles of induced inflows (by merger or interaction) and galactic outflows played in this galaxy, we can apply the chemical evolution model of Erb (2008) to find out the mass accretion factor, $f_i = \dot{M}_{\rm acc}/{\rm SFR}$, and the mass loading factor, $f_o = \dot{M}_{\rm out}/{\rm SFR}$, needed to explain its metallicity and gas fraction μ .

We first convert the SFR surface densities of the starburst and the post-starburst region to the gas surface densities by inverting the Kennicutt-Schmidt law (Kennicutt 1998). This approach delineates rough constraints on gas fractions for both regions: $\mu_{\rm SB} \gtrsim 0.98$ and $0.70 \lesssim \mu_{\rm PSB} \lesssim 0.85$, with the latter representing the stellar-weighted gas fraction in PSB. Assuming a return fraction of R = 0.45 and a true stellar yield of y = 0.038 for the Chabrier (2003) IMF and at metallicity ~ $0.08Z_{\odot}$ (Vincenzo et al. 2016), we then calculate the evolution curves of metallicity with gas fraction at fixed $f_{\rm o}$ (0 or 30) using Equation (11) and (13) from Erb (2008). This model assumes a homogeneous wind that the outflowing gas has the same metallicity as the gas in the ISM. The left panel of Figure 10 shows inflow-only models (i.e., the solid lines) can explain the position of the starburst region, which is consistent with Figure 5 that v_p is low around this region. These models converge to a single curve in the high- μ regime, so it is hard for us to assign an exact value of f_i for the starburst region.

The property of the post-starburst region can only be reproduced by a high- f_i -high- f_o model (e.g., $f_i = 28$ and $f_o = 30$; the red dashed line in the left panel of Figure 10) given the constraint on its gas fraction. This unrealistic inflow rate questions the validity of the assumption of homogeneous wind in this dwarf galaxy. Our metallicity measurement also suggests metals ejected in the outflowing gas are not well-mixed with the ISM, which is compatible with previous studies (e.g., Chisholm et al. 2018). To relax this assumption, we parametrize the wind metallicity $Z_{\rm W}$ as Equation (41) of Forbes et al. (2019) in Equation 3.

$$Z_{\rm W} = Z + \xi \frac{y}{\max(\mu, \mathbf{R})} \tag{3}$$

We use a fiducial value of $\xi = 0.4$ ($0 \le \xi \le 1$) that is appropriate for log(M_*/M_{\odot}) ~ 8 galaxies in Curti et al. (2020) (Sharda et al. 2021). $\xi = 0$ corresponds to the homogeneous wind model, whereas $\xi = 1$ represents the scenario that all supernova ejecta are lost in winds.

Following this non-homogeneous wind model (see the right panel of Figure 10), we find that a reasonable range of f_i (i.e., $2 \leq f_i \leq 8$) at a physical outflow rate $f_o = 10$ can explain the position of the post-starburst region. Therefore, as long as the wind from the post-starburst region is metal-enriched, we do not require unphysically high outflow and inflow rates to reproduce our observations. We should also keep in mind this finding is based on the fiducial value of ξ that is poorly constrained by both theory and observations, and it is degenerate with f_i and f_o . As a result, accurate measurements of ξ and μ would help us break the degeneracy among these physical quantities.

5. CONCLUSION

The dwarf galaxy J1044+0353 provides an ideal testbed for understanding high-redshift galaxies during the Epoch of Reionization. Previous studies have drawn attention to the extreme physical properties (e.g., low metallicity, high ionization, and high specific star formation rate) of the starburst region. In this paper, we used integral field spectroscopy to map the metallicity and gas kinematics over spatial scales much larger than the compact starburst. We also examined stellar spectral features and their spatial variations. Our results provide insight into the origin of the starburst and its feedback on the surrounding interstellar medium. These gas flows strongly influence the galaxy's chemical evolution during this phase of rapid mass assembly.

We summarize our specific results from this work as follows:

1. We discovered a post-starburst region which we divided into partially resolved associations of stars: MEN, NEN, and FEN. We found significant differences among the emission-line and absorption-line equivalent widths of these regions. We proposed a composite SFH using BEAGLE to constrain their stellar ages. Specifically, we constructed EW grids (i.e., x-axis: EW of the emission portion of a line profile; y-axis: EW of the absorption portion of a line profile) for the Balmer lines $H\gamma$ and $H\delta$. Based on each region's position in the EW grids, we estimate the log(Age/year) of each stellar association

Figure 10. Analytical evolution of metallicity with gas fraction from Erb (2008) compared to the observed values of the starburst (SB) and the post-starburst (PSB) regions. Left: Homogeneous wind models such that $Z_W = Z$. Evolution curves are shown at fixed outflow rates ($f_o = 0$ or 30), color-coded by inflow rate f_i ranging from 0 to 28. Inflow-only models (i.e., the solid lines) can explain the position of the starburst region ($\mu_{SB} \gtrsim 0.98$), which is consistent with Figure 5 that v_p is low around this region. The property of the post-starburst region ($0.70 \leq \mu_{PSB} \leq 0.85$) can only be reproduced by a high- f_i -high- f_o model (e.g., $f_i = 28$ and $f_o = 30$), which is unrealistic. Right: Non-homogeneous wind models such that Z_W is defined in Equation 3. Evolution curves are shown at fixed outflow rates ($f_o = 0$ or 10), color-coded by inflow rate f_i ranging from 0 to 10. Compared to the homogeneous model, a reasonable range of f_i (i.e., $2 \leq f_i \leq 8$) at a physical outflow rate $f_o = 10$ can explain the position of the post-starburst region. In each panel, the horizontal black (or grey) dashed line denotes the gas-phase metallicity for the starburst (or post-starburst) region.

to be 6.480 ± 0.005 (SB), 7.2 ± 0.1 (MEN & NEN), and 7.30 ± 0.05 (FEN), respectively. Our age estimation for the starburst is consistent with the one derived by Olivier et al. (2022) from the FUV spectrum. The time interval between the poststarburst and the starburst may reflect the propagation of a disturbance across the galaxy, e.g., an encounter with a gas cloud or a mini-halo. Alternatively, the age gradient might reflect the first and second passage of a dwarf-dwarf merger.

- 2. We also used the mass-to-light ratios of mock galaxies to determine the stellar mass of each region. The $\log(M_*/M_{\odot})$ was measured at $5.82^{+0.39}_{-0.12}$, $6.26^{+0.05}_{-0.18}$, $6.08^{+0.05}_{-0.18}$ and $5.57^{+0.10}_{-0.04}$ for SB, MEN, NEN, and FEN, respectively.
- 3. The intrinsic extinction A_V of each stellar association is determined from the Balmer decrement. SB $(0.20^{+0.10}_{-0.10})$, FEN $(0.20^{+0.04}_{-0.04})$, and NEN $(0.21^{+0.13}_{-0.12})$ are found to have similar dust attenuation. However, the intrinsic extinction is significant in MEN $(0.56^{+0.09}_{-0.09})$, implying a dust lane, perhaps a relic of a galaxy merger.
- 4. Using the temperature sensitive auroral line [O III] $\lambda 4363$, we derived the "direct" gas-phase oxygen abundance of 7.45 ± 0.01 (SB), 7.37 ± 0.03 (MEN), 7.52 ± 0.03 (NEN), and 7.43 ± 0.03 (FEN) in terms

of 12 +log(O/H) respectively. The stellar-massweighted metallicity of the post-starburst region $(12 + \log(O/H) = 7.43 \pm 0.02)$ is comparable to that of the starburst region, which indicates metalenriched wind. There were subtle differences between our "direct" method and the ones used in B16 and B21 to measure metallicity, including the calibration between T[O III] and T[O II], the electron density diagnostics, the Balmer lines chose to determine the intrinsic reddening value, the intrinsic reddening law, and the ionization-zone model (two or four ionization zones). The deviations of metallicity in the starburst region are ≤ 0.01 dex among our work and previous studies.

5. Applying an adaptive binning algorithm to the strongest emission line $[O \text{ III}] \lambda 5007$, we created a line-of-sight velocity map. We discovered a strong velocity gradient along the galaxy's minor axis, up to 50 km/s over 1.5 kpc. If this gradient represents rotation, the stellar system would have the shape of a prolate spheroid rotating about its long axis, a scenario that is highly unlikely. We argue that the galaxy is better described as an oblate spheroid, essentially a gas disk viewed at a fairly high inclination; then, we explain the minor-axis velocity gradient by a bipolar outflow erupting perpendicular to the gas disk. A closer examination of the

velocity field supports the outflow interpretation. The outflow cones converge at a vertex near FEN, the oldest stellar association, that marks the location where the most supernova explosions have occurred. In addition, the regions with high absolute peculiar velocities also have the largest line widths. This correspondence supports the outflow interpretation because the skew of the line profiles matches expectations for an inclined cone. The outflow speed is higher than the estimated escape velocity for such a low-mass galaxy, suggesting a possible escape from the gravitational potential.

- 6. The asymmetric velocity field around the starburst region is notable, indicating the systematic velocity offset between the starburst's southern regions and the entire galaxy. This velocity offset reveals the existence of induced inflows fueling the starburst region during mergers or interactions, a hypothesis awaiting future H I mapping for confirmation.
- 7. For its stellar mass, the metallicity of J1044+0353 lies below most MZRs in the literature. Its diluted metallicity is qualitatively consistent with its elevated SFR, and the galaxy lies on the extrapolation of the MZR defined by (Andrews & Martini 2013). From the direct-based metallicity map, J1044+0353 is considered chemically homogeneous due to its relatively small IQR and $\sigma_{\rm Z}$. However, we observe a relatively large scatter of metallicities within the post-starburst region compared to the starburst region, with the largest spread of approximately 0.3 dex between individual regions. This increased scatter in the poststarburst region suggests an induced inflow of lowmetallicity gas, potentially caused by mergers or interactions.
- 8. To quantify the outflow and the induced inflow rates, we first applied the Erb (2008) chemical evolution model, which includes a pristine-gas inflow and a homogeneous wind. For the starburst metallicity, we found that inflow-only models require a near-unity gas fraction, consistent with the high SFR surface density and Kennicutt-Schmidt law; the inflow rate is not well constrained. Models with outflows have lower gas fractions when they reach the SB metallicity. Quantitatively, however, even high mass loss rates, $f_{\rm o} = \dot{M}_{\rm out}/{\rm SFR} =$ 30, are not ruled out; for inflow rates $f_{\rm i} =$

 $M_{\rm acc}/{\rm SFR} \lesssim 5$, the required gas fraction still exceeds 96%, which is roughly within observational constraints.

9. Because the gas fraction is arguably lower in the post-starburst region, homogeneous models require enormous gas outflow and inflow rates to reduce the gas fraction below $\sim 95\%$ at its gas-phase metallicity. One plausible solution is that the metals in the outflowing gas are not well-mixed with the gas in the ISM. We demonstrated that a chemical evolution model with a metal-enriched wind reaches the post-starburst metallicity at a significantly lower gas fraction. We prefer this metal-enriched wind model for the chemical evolution of J1044+0353 because it requires reasonable outflow and inflow rates in the post-starburst region.

Our analysis provides detailed insight into the physical processes that shape early galaxy assembly. If J1044+0353 were at high redshift, only the compact starburst would be detected. While the young age of the starburst would suggest relatively little supernova feedback, our study shows a different picture. The duration of the starburst is extended over roughly a dynamical timescale, long enough for supernova feedback to create holes in the surrounding neutral gas reservoir before all the O stars die off, causing ionizing photons to escape and reionize the intergalactic gas.

Future KCRM or archived VLT/MUSE observations could cover the H α line. A H α /H β map would substantially improve the accuracy of the reddening map and offer additional constraints on the optically thin regions. These regions, corresponding to holes in the H I distribution, might shed light on the escape direction of ionizing photons.

Software: PyNeb (v1.1.14, Luridiana et al. 2013, 2015), LMFIT (Newville et al. 2021), BEAGLE (Chevallard & Charlot 2016), Photutils (Bradley et al. 2022), Petrofit (Geda et al. 2022)

Z.P. would like to acknowledge Giovanni Cresci, Xin Wang, Zuyi Chen, and Zhuyun Zhuang for helpful discussions and Christophe Morisset for technical assistance in PyNeb. The authors are grateful to the anonymous referee for constructive suggestions. We gratefully acknowledge support for this work by NSF grant AST-1817125.
