Abstract. In Chakraborti's *yard sale model* of an economy [6], identical agents engage in trades that result in wealth exchanges, but conserve the combined wealth of all agents and each agent's *expected* wealth. In this model, *wealth condensation*, that is, convergence to a state in which one agent owns everything and the others own nothing, occurs almost surely. We give a proof of this fact that is much shorter than existing ones and extends to a modified model in which there is a wealth-acquired advantage, i.e., the wealthier of two trading partners is more likely to benefit from the trade.

1 Background

The yard-sale model, first proposed in [6], is a caricature of a set of agents trading with each other. The agents are identical, and there are N of them. Time proceeds in discrete steps labeled 0, 1, 2, ..., and in the *n*-th step the *i*-th agent has wealth $X_n^i \ge 0$. We will write

$$X_n = \left[X_n^i\right]_{1 \le i \le N} \in \mathbb{R}^N.$$

Without loss of generality, we assume

$$\sum_{i=1}^N X_0^i = 1.$$

We think of X_0 as deterministic. The X_n with $n \ge 1$ are random, defined inductively as follows. Given X_{n-1} , choose a random pair of integers, (μ_n, ν_n) , uniformly distributed in the set of all pairs (i, j) with $1 \le i, j \le N$, $i \ne j$. Without loss of generality, assume $X_{n-1}^{\mu_n} \le X_{n-1}^{\nu_n}$. So agent ν_n is, at time n-1, at least as wealthy as agent μ_n . Imagine that agents μ_n and ν_n now engage in an economic transaction. As a result of errors (perhaps over- or underpayments occurring because of lack of complete information for instance), a random fraction $B_n \in (0, 1)$ of the wealth of agent μ_n (the poorer of the two) is transferred either from agent μ_n to agent ν_n , or vice versa. The B_n are assumed to be identically distributed. The direction of the transfer is determined by a fair coin flip. Formally, let $V_n = 1$ with probability 1/2, and $V_n = -1$ otherwise. Then

$$X_n^{\mu_n} = X_{n-1}^{\mu_n} + V_n B_n X_{n-1}^{\mu_n}$$
 and $X_n^{\nu_n} = X_{n-1}^{\nu_n} - V_n B_n X_{n-1}^{\mu_n}$

The pairs (μ_n, ν_n) , the fractions B_n , and the signs V_n are assumed to be independent of each other and of the X_k , B_k , and V_k with $k \le n-1$. In reference [6], and in much of the literature

on the yard-sale model, B_n is assumed to be a deterministic number $\beta \in (0,1)$. We use a random $B_n \in (0,1)$ more generally. Notice that wealth is conserved:

$$\sum_{i=1}^{N} X_n^i = 1$$

for all *n*. The model is known to have the following surprising property, which we will call the *yard-sale theorem*.

Yard-Sale Theorem. (a) *There almost surely exists an* $i \in \{1, ..., N\}$ *with* $\lim_{n \to \infty} X_n^i = 1$. (b) *For all* $i \in \{1, ..., N\}$,

$$P\left(\lim_{n \to \infty} X_n^i = 1\right) = X_0^i. \tag{1}$$

In the limit, one agent owns everything. This sort of maximal inequality is called *wealth condensation* in the literature. In the yard-sale model, wealth condensation is the inescapable result of random, statistically unbiased interactions.

For a version of the model in which there is a *continuum* of agents, rather than a finite number, a result of this kind was proved by Boghosian *et al* [3]. Chorro [7] pointed out that the theorem as stated above is an immediate consequence of Doob's martingale convergence theorem: For a fixed *i*, the sequence $\{X_n^i\}_{n=0,1,2,...}$ is a bounded martingale, and therefore must converge. It is clear from the definition of the model that the X_n^i cannot all converge unless one converges to 1 and the others converge to 0. Equation (1) follows from the fact that $E(X_n^i) = E(X_0^i)$ for all *n* and *i*.

Some interesting variations can be handled immediately using the same reasoning. For instance, different agents can be assumed to have different degrees of risk tolerance [5]. The amount of wealth transferred during the trade between agents μ_n and ν_n might be taken to be $V_n B_n \lambda_{\mu_n} X_{n-1}^{\mu_n}$, where the λ_i , $1 \le i \le N$, are fixed numbers in (0, 1); if λ_i is smaller, agent *i* is more risk averse. Obviously but remarkably, eq. (1) still holds for the modified model; risk aversion does not make an agent less or more likely to end up owning everything.

Cardoso *et al.* [5] have recently proposed a different argument, based on the Gini index, to derive related results for a broader class of models. Their analysis relies on what they call the *fair rule hypothesis* [5, Equation (8)]. For wealth-conserving models, it is the martingale property. Most, but not all, examples in [5] are wealth-conserving. The result in [5] is that the Gini index is monotonically increasing, and stationary if and only if it is 1.

An interesting extension is obtained by adding a *wealth-acquired advantage* [4]. The coin flips that determine in which direction the wealth will flow in each interaction is biased in favor of the wealthier agent: $V_n = 1$ with probability p, and $V_n = -1$ otherwise, where p is no longer required to be $\frac{1}{2}$, but is allowed to be anywhere in $\left[\frac{1}{2}, 1\right)$. One should certainly expect wealth condensation for $p > \frac{1}{2}$ if there is wealth condensation for $p = \frac{1}{2}$. However, proofs that rely on the martingale property no longer work; the model is still wealth-conserving, but $\{X_n^i\}_{n\geq 0}$ is no longer a martingale, nor a sub- or super-martingale.

To the model with a (possible) wealth-acquired advantage, Boghosian *et al.* [1,2] added *wealth taxation*. Each agent is taxed a fraction $\chi \in (0,1)$ of their fortune in each time step, uniformly re-distributing the total amount taken in:

$$\tilde{X}_{n}^{\mu_{n}} = X_{n-1}^{\mu_{n}} + V_{n} B_{n} X_{n-1}^{\mu_{n}} \quad \text{and} \quad \tilde{X}_{n}^{\nu_{n}} = X_{n-1}^{\nu_{n}} - V_{n} B_{n} X_{n-1}^{\mu_{n}},$$
$$X_{n}^{i} = (1 - \chi) \tilde{X}_{n}^{i} + \frac{\chi}{N} \quad \text{for all } i \in \{1, \dots, N\}.$$

It is clear that wealth taxation, no matter how small $\chi \in (0,1)$ may be, prevents wealth condensation: We now have

$$X_n^i \ge \frac{\chi}{N}$$

for all $n \ge 1$ and $i \in \{1, ..., N\}$, which precludes the existence of the limits $\lim_{n \to \infty} X_n^i$.

For a version of the model with wealth-acquired advantage and taxation in which there is a continuum of agents, Boghosian *et al* [4] have shown that for each $p \in (\frac{1}{2}, 1)$, there is a threshold value χ_c depending on p, such that there will be *oligarchy* for $\chi < \chi_c$, but not for $\chi > \chi_c$. Here *oligarchy* means that a vanishingly small fraction of the population will own, in the long run, a non-vanishing fraction of total wealth.

In this brief note, we propose a new probabilistic proof of part (a) of the Yard-Sale Theorem, which applies also if $p \in (\frac{1}{2}, 1)$. Our proof does not use the martingale property, and therefore applies when $p \in (\frac{1}{2}, 1)$. The tools used in our analysis are much lighter than those used in previously published proofs of the Yard-Sale Theorem or similar results. Instead of the Gini index, we use $||X_n||^2$ as the measure of concentration, where $|| \cdot ||$ denotes the Euclidean norm. We note that the idea of using the Euclidean norm of a probability vector as a measure of concentration is not new; it appears in quantum physics [8], political science [9], ecology [10], and antitrust regulation [11].

2 Proof of almost sure wealth condensation

We consider, from here on, the yard-sale model, possibly with a wealth-acquired advantage: $\frac{1}{2} \le p < 1$, but without taxation. Write $M_n = \max_i X_n^i$. We will prove $M_n \to 1$ almost surely, which is part (a) of the Yard-Sale Theorem. We have no analogue of part (b) for $p > \frac{1}{2}$.

We begin with a preliminary calculation in which we determine the expected change in the concentration measure $||X_n||^2$ in a single step. (As before, $|| \cdot ||$ is the Euclidean norm.) Suppose that X_{n-1}^i , $1 \le i \le N$, are given, μ_n and ν_n have been chosen, with $X_{n-1}^{\mu_n} \le X_{n-1}^{\nu_n}$, and B_n has been chosen as well. We write $\omega_n = B_n X_{n-1}^{\mu_n}$; this is the amount of wealth at stake in the trade between agents μ_n and ν_n . We also write $p = \frac{1}{2} + \delta$, with $0 \le \delta \le \frac{1}{2}$. Then the (conditional) expectation of $||X_n||^2 - ||X_{n-1}||^2$ equals

$$\left(\frac{1}{2} + \delta\right) \left(\left(X_{n-1}^{\mu_{n}} - \omega_{n}\right)^{2} - \left(X_{n-1}^{\mu_{n}}\right)^{2} + \left(X_{n-1}^{\nu_{n}} + \omega_{n}\right)^{2} - \left(X_{n-1}^{\nu_{n}}\right)^{2} \right) + \left(\frac{1}{2} - \delta\right) \left(\left(X_{n-1}^{\mu_{n}} + \omega_{n}\right)^{2} - \left(X_{n-1}^{\mu_{n}}\right)^{2} + \left(X_{n-1}^{\nu_{n}} - \omega_{n}\right)^{2} - \left(X_{n-1}^{\nu_{n}}\right)^{2} \right) = 2\omega_{n}^{2} + 4\delta\omega_{n} \left(X_{n-1}^{\nu_{n}} - X_{n-1}^{\mu_{n}}\right) \ge 2\omega_{n}^{2}.$$

This implies

$$E(\|X_n\|^2) - E(\|X_{n-1}\|^2) \ge 2E(\omega_n^2)$$
(2)

where *E* denotes *unconditional* expectations.

We now proceed to the main argument, which makes use of inequality (2) at the end. To show $M_n \rightarrow 1$ almost surely, it is enough to show that $\omega_n \rightarrow 0$ almost surely. Therefore we have to show that for any $\varepsilon > 0$, it almost surely happens only finitely many times that $\omega_n \ge \varepsilon$. By the Borel-Cantelli lemma, it is enough to show

$$\sum_{n=1}^{\infty} P(\omega_n \ge \varepsilon) < \infty$$

for any $\varepsilon > 0$. Since $E(\omega_n^2) \ge P(\omega_n \ge \varepsilon)\varepsilon^2$, we have

$$\sum_{n=1}^{\infty} P(\omega_n \ge \varepsilon) \le \frac{1}{\varepsilon^2} \sum_{n=1}^{\infty} E(\omega_n^2).$$

Using (2),

$$\sum_{n=1}^{\infty} E(\omega_n^2) \le \frac{1}{2} \sum_{n=1}^{\infty} \left(E(\|X_n\|^2 - E(\|X_{n-1}\|^2)) \right) \le \frac{1}{2} \left(\limsup_{n \to \infty} E(\|X_n\|^2) - E(\|X_0\|^2) \right) \le \frac{1}{2} \sum_{n=1}^{\infty} E(\|X_n\|^2) - E(\|X_0\|^2) \le \frac{1}{2} \sum_{n=1}^{\infty} E(\|X_n\|^2) - E(\|X_n\|^2) \le \frac{1}{2} \sum_{n=1}^{\infty} E(\|X_n\|^2) \le \frac{1}{$$

This completes the proof.
