We report on efforts to improve the speed of low-G far-infrared transition-edged-sensed bolometers. We use a fabrication process that does not require any dry etch steps to reduce heat capacity on the suspended device and measure a reduction in the detector time constant. However, we also measure an increase in the temperature-normalized thermal conductance (G), and a corresponding increase in the noise-equivalent power (NEP). We employ a new near-IR photon-noise technique using a near-IR laser to calibrate the frequency-domain multiplexed AC system and compare the results to a well-understood DC circuit. We measure an NEP white noise level of 0.8 aW/rtHz with a 1/f knee below 0.1 Hz and a time constant of 3.2 ms.

### <span id="page-1-0"></span>I. INTRODUCTION

Transition-edge sensed (TES) bolometers and their SQUID-based readout systems have been the detectors of choice for many recent ground-based astrophysics and cosmology experiments in the trans-millimeter bands [ACT  $(2015)^{1,2}$  $(2015)^{1,2}$  $(2015)^{1,2}$  $(2015)^{1,2}$  $(2015)^{1,2}$ , Bicep2<sup>[3](#page-18-1)</sup>, Bicep3<sup>[4](#page-18-2)</sup>, GISMO<sup>[5](#page-19-0)</sup>, HAWK+<sup>[6](#page-19-1)</sup>, Keck Experiment<sup>[7](#page-19-2)</sup>, PolarBear<sup>[8](#page-20-0)</sup>, SPI- $DER<sup>9</sup>$  $DER<sup>9</sup>$  $DER<sup>9</sup>$ , SPT<sup>[10](#page-20-2)</sup>, etc.].

TES bolometer arrays have generally demonstrated excellent systematic performance in deep microwave background measurements (BICEP-Keck/SPIDER Collaboration 2015<sup>[11](#page-21-0)</sup>, SPT 2018<sup>[12](#page-21-1)</sup>, BICEP-Keck Collaboration 2022<sup>[4](#page-18-2)</sup>,  $ACT<sup>2</sup>$  $ACT<sup>2</sup>$  $ACT<sup>2</sup>$ ). They are, thus, a strong candidate for tector systems exist. The far-IR is particularly ity in the released devices. Additionally, char-

compelling for a space mission because of the very low natural backgrounds across a full decade in wavelength from 25 to 300  $\mu$ m. A cryogenically-cooled telescope in this band offers large potential scientific gains for a range of astrophysical applications from planet formation to galaxy evolution<sup>[15](#page-23-0)[–18](#page-23-1)</sup>, particularly via moderate-resolution  $(\lambda/\delta \lambda \approx 100 - 500)$ spectroscopy<sup>[19](#page-24-0)</sup>. However, fully capitalizing on the low-background platform requires sensitivity matching the detector sensitivity to the photon shot noise in the narrow band - this results in a target noise equivalent power (NEP) of 0.1 aW/Hz<sup>1/2</sup> or lower.

future space missions, which would have lower challenges. The devices must have low therbackgrounds, both in the CMB bands  $(EPIC<sup>13</sup>$  $(EPIC<sup>13</sup>$  $(EPIC<sup>13</sup>$ , mal conductance  $(G)$  in the suspension, while Litebird<sup>[14](#page-22-1)</sup>) and also in the far-infrared (far-IR), maintaining sufficient speed; therefore, fabricawhere no commercial high-performance de- tion techniques must maintain low heat capac-The ultralow-noise requirement poses new

the electronics and the thermal radiation must be noise. Sec. [VI](#page-16-0) is the summary. heavily filtered. Early pioneering work in low-G far-IR TES sensors was made at  $JPL^{20-23}$  $JPL^{20-23}$  $JPL^{20-23}$ , where NEPs approaching 0.1 aW/Hz<sup>1/2</sup> were demonstrated with DC voltage bias<sup>[24](#page-24-3)[,25](#page-24-4)</sup>, albeit with the speed of response of several milliseconds. Subsequent work at SRON reported comparable sensitivity with speeds below  $1 \text{ ms}^{26-29}$  $1 \text{ ms}^{26-29}$  $1 \text{ ms}^{26-29}$ , using the SRON AC bias system $30,31$  $30,31$ .

Here, we report the development of a lowheat-capacity wet-release process for fabricating low-G far-IR TES sensors and characterization of these devices. We employ both AC and DC biasing schemes and present a novel absolute power calibration technique using near-IR (1550 nm) shot noise, which overcomes uncertainties in the electrical transfer through the system. We find a two to four times improvement in device speeds relative to our previous dryrelease devices, but thermal conductances and associated noise-equivalent powers are five to ten times higher than the previously published ones for devices with similar geometries $^{23}$  $^{23}$  $^{23}$ .

This paper is organized as follows: following the introduction in Sec. [I](#page-1-0) is the array design and

acterization is challenging at the very low load-and [V](#page-11-0) describe the detail of AC and DC meaings (of order 1 aW or less), since bolometers surements, respectively. These measurements are susceptible to all forms of radiation; both include time constants, optical responsivity, and

## <span id="page-2-0"></span>II. ARRAY DESIGN AND FABRICATION

Each TES sensor consists of a free-standing low-stress silicon nitride (LSN) membrane  $(0.25 \times 400 \times 300 \ \mu m^3)$  which connects to the substrate through four 0.25  $\mu$ m thick s 1000  $\mu$ m long s  $0.4 \mu m$  wide LSN support beams. Niobium wires (30 nm thick) run along two of the support beams and electrically connect to an 80 x 8  $\mu$ m<sup>2</sup> high-T<sub>c</sub> titanium thermistor (100 nm) in series with a 50 x 50  $\mu$ m<sup>2</sup> low-T<sub>c</sub> bilayer consisting of titanium (50 nm) and gold (150 nm). A grid of titanium nitride wires  $(1.5 \mu m)$  wide x 12  $\mu$ m long x 30 nm thick) with a T<sub>c</sub> of ~ 1 K define the optical absorber, which has an effective sheet resistance of  $\sim$  400  $\Omega$ /sq. Each TES sensor is arranged in an array with a format size of 5 x 12 with a column and row spacing of 3.73 and 0.99 mm, respectively. ### <span id="page-5-0"></span>III. EXPERIMENTAL SETUP

setup is described in Sec. [III B.](#page-6-0)

The TESs were tested in a BlueFors LD250 Dilution Refrigerator (DR) system<sup>[33](#page-25-4)</sup> at JPL. The temperature is controlled using a PID loop with a Lake Shore Cryotronics Model 372 AC Resis-tance Bridge<sup>[34](#page-25-5)</sup>. The thermometer and heater are mounted on the mixing chamber plate near the TES sample box. The temperatures presented in this paper are measured using the same thermometer as the PID loop. The TESs are biased with a Tektronix AFG 31000 Series Arbitrary Function Generator<sup>[35](#page-25-6)</sup>. The bias voltage is reduced with a voltage divider before entering the cryostat. The bias and readout lines in the cryostat are phosphor-bronze shielded twisted pairs. The cabling connects to the TES housing box shown in Fig. [3](#page-5-1) using a 37-pin micro-D connector. The TES housing box and the mixing chamber plate are gold-plated copper, and the fasteners are brass to ensure good thermal contact while cold. The bias lines pass through a 20 MHz RC low-pass filter on a printed circuit board and are wirebonded into a chip contain-ing a Magnicon 2-stage SQUID<sup>[36](#page-25-7)</sup>. The SQUID is fed back and read out with Magnicon XXF-1 electronics $37$ . The output of the SQUID electronics is recorded with a Pico Technology PicoScope 6403E[38](#page-25-9) USB oscilloscope. The bias and readout system is set up in either a DC or an AC mode depending on the measurement. The the Netherlands Institute for Space Research

setup are presented in Sec. [V.](#page-11-0)

#### C. Near-IR Laser Setup

To overcome the uncertainties in the electrical power calibration of low-G TESs, we have developed a near-IR photon-noise calibration technique. For this measurement, six 0.5-mm hole array is located above the four detectors are given in Table [I.](#page-12-0) Current vs voltage curves

are measured for each TES, and bias voltages for the subsequent response and noise measurements are chosen such that the TES is at 1/2 the normal resistance. DC current vs voltage curves are presented in Sec. [V A.](#page-11-1)

### <span id="page-8-0"></span>A. Photon-noise Calibration

#### *1. Approach*

The absolute current and voltage scales in the AC setup are not known accurately due to uncertainty in the shunt resistor value, difficulty in establishing the open-loop MHz SQUID response, and reactive effects in the TES resonant circuit. To overcome these obstacles and provide absolute electrical power calibration, we have developed a technique using shot noise from a 1550 nm laser. When the laser is turned off, the current is  $I_0$  and the NEI is NEI<sub>0</sub>. Shot noise in the near-IR photon stream incident on the TES has a noise-equivalent power (NEP) of  $42$ 

<span id="page-8-4"></span>NEP<sub>photon</sub> = 
$$
\sqrt{2P_{photon}h v_{photon}}
$$
. (1)

Here *P* is the photon power absorbed by the detector,  $h$ *v*<sub>photon</sub> is the photon energy, and the expression has units of  $W/Hz^{1/2}$ . The corresponding noise-equivalent current (NEI) generated by the fluctuating photon power absorbed by the TES is

<span id="page-8-2"></span>
$$
NEI_{photon} = -S(v)NEP_{photon}, \qquad (2)
$$

where  $S(v) = dI/dP$  is the current to power responsivity. The frequency dependence of the responsivity is given by

<span id="page-8-6"></span>
$$
S(v) = \frac{S(v=0)}{\sqrt{1 + (2\pi v \tau)^2}},
$$
\n(3)

where the rolloff is produced by the time constant of the TES,  $\tau$ . The mean value of the current also changes as the near-IR power is introduced, creating an additional constraint

<span id="page-8-3"></span>
$$
I - I_0 = S(v)P_{\text{photon}},\tag{4}
$$

which is an excellent approximation for a voltage-biased TES so long as the responsivity is constant. The power of absorbed photons is eliminated by combining Eqs. [2](#page-8-2) and [4](#page-8-3) with Eq. [1](#page-8-4)

<span id="page-8-5"></span>
$$
NEI_{photon}^2 = 2h v_{photon} S(v)(I - I_0)
$$
 (5)

<span id="page-9-2"></span>FIG. 7. TES response to a laser power sweep. The laser power values are the measured laser power at the entrance to the cryostat. Left: TES current vs time. Right: NEI vs frequency. Both current and NEI are averaged in bins for visibility.

quadrature addition of the photon NEI and the constant multiplicative factor. NEI with the laser off,  $NEI_0$ 

where  $NEI_{photon}^2$  is the photon shot-noise con- absolute NEI is not known, assuming that the tribution to the NEI. The measured NEI is the NEP is proportional to the measured NEI with a

$$
NEImeasured2 = NEIphoton2 + NEI02.
$$
 (6)

Combining Eqs. [5](#page-8-5) and [6](#page-9-0) yields

$$
NEI_{measured}^2 = \alpha I + \beta \tag{7}
$$

where

$$
\alpha = 2h v_{\text{photon}} S(v) \tag{8}
$$

$$
\beta = -\alpha I_0 - \text{NEI}_0^2. \tag{9}
$$

The responsivity of the TES can be calculated from a fit to Eq. [7](#page-9-1) without knowledge of the tocalibration allows for a measurement of the absolute NEP from the measured NEI, even if the for this example are 0.3-3 Hz. The squared aver-

#### <span id="page-9-3"></span><span id="page-9-1"></span><span id="page-9-0"></span>*2. Measurements*

tal laser power incident on the detector. This and the corresponding NEI is plotted in Fig. [7.](#page-9-2) With the bias voltage fixed, a timestream of the TES current is measured for a range of laser powers. The TES current is the mean of the timestream data. The NEI is calculated from an FFT of the timestream data and is averaged over frequencies below the rolloff, but above any low-frequency excess, to capture the white noise value. An example of a TES timestream The frequencies over which the NEI is averaged

aged NEI and the current corresponding to this example are plotted in Fig. [8,](#page-10-0) with a linear fit. The fit parameter  $\alpha$  is used to extract  $S(v)$  using Eq. [8.](#page-9-3) This calibration technique works for the TESs with and without absorbers. We see a factor of 5 higher absorption at 1550 nm in the TESs with absorbers.

<span id="page-10-0"></span>FIG. 8. NEI<sup>2</sup> vs current with a linear fit. These data are extracted from the dataset presented in Fig. [7.](#page-9-2) The responsivity for this dataset is -70.1 nA/fW.

To ensure that power fluctuations in the laser source (Thorlabs SLD) are not corrupting the measurement somehow, we repeated the experiment with a different source, a Thorlabs S3FC1550 distributed-feedback (DFB) laser<sup>[43](#page-26-4)</sup>. We obtained the same results to within the measurement uncertainty.

<span id="page-10-1"></span>FIG. 9. Example of time constant data and fits for ABS 1 (time constant  $= 6.4$  ms). At each transition, the TES shows an short electrical transient followed by the thermal response in the opposite direction, the latter being the relevant time constant.

### B. Time Constant

Time constants are measured from a detector response to a modulated electrical signal. A small square-wave modulation is applied to the TES bias voltage. The function generator time constant is sufficiently fast to measure the detector response. The response is fitted to an exponential function to extract the time constant. An example of the detector response to the modulated signal is plotted in Fig. [9](#page-10-1) with exponential fits. 64 time constants are fitted and averaged for each TES (32 ascending and 32 descending). The averaged time constants for each of the four detectors are given in Table [I.](#page-12-0) Our devices are

slower than those from  $SRON^{27-29}$  $SRON^{27-29}$  $SRON^{27-29}$ . Those measurements were obtained while biased deeper in the transition ( $R \sim 0.25R_n$ ), and were generally at bath temperatures of 40-60 mK, both of which increase the electrothermal feedback and, thus, the speed relative to the conditions of our measurements: biased at  $R_n/2$  and a bath temperature of 100 mK. We may also have excess heat capacity on these devices. The fact that our devices with absorbers are slower than those without suggests additional heat capacity in the superconducting film, an aspect that is anomalous and may indicate excess heat capacity in the metallic components generally.

### <span id="page-11-3"></span>C. AC Setup NEP

The responsivity is calculated using the photon-noise calibration method described in Sec. [IV A.](#page-8-0) The responsivities are presented in Table [I,](#page-12-0) along with the time constants that are used to calculate the frequency dependence of the responsivities. The spread in responsivities is an artifact of the laser calibration: the responsivities include the frequency-dependent gain of the system, an aspect that is removed from the NEP through the calibration. The calculated NEPs for the four TESs are shown in Fig. [10.](#page-11-2) The NEPs show a white noise of  $1 \times 10^{-18}$  and rolloffs of 30 Hz set by the measured time constant.

<span id="page-11-2"></span>FIG. 10. Calculated NEPs of four TESs, with the frequency response from Eq. [3](#page-8-6) and the measured time constants from Table [I.](#page-12-0)

#### <span id="page-11-0"></span>V. DC SETUP MEASUREMENTS

As a check on the AC measurements and the inference from the near-IR shot noise, we employed the well-understood DC bias setup (Sec. [III B\)](#page-6-0) to both directly measure the TES properties and to repeat the laser shot-noise calibration measurement. For the DC measurements, we focused on the single device labeled ABS1 in Sec. [IV.](#page-7-0)

### <span id="page-11-1"></span>A. Current vs voltage

The total current through the parallel combination of the shunt resistor and TES is defined as *I*bias. *I*bias is calculated from the applied function generator voltage using the circuit model in Fig. [5.](#page-7-1) The TES current  $I_{\text{TES}}$  is measured

<b>TES</b>			Frequency (MHz) $R/R_{\text{normal}}$ Time constant (ms) $S(v=0)$ (nA / fW)

#### B. Resistance vs temperature

For a range of temperatures, the TES resistance can be measured from the TES voltage vs current. For each temperature, a linear fit to current vs voltage (in the regime where heating is negligible) determines the resistance at each temperature. The resistance vs temperature is presented in Fig. [13.](#page-13-0)

<span id="page-13-0"></span>FIG. 13. TES resistance vs temperature.

### <span id="page-13-4"></span>C. Thermal Conductance

The temperature dependence of the thermal conductance  $G = dP/dT$  is modeled as<sup>[20](#page-24-1)</sup>

<span id="page-13-2"></span>
$$
G = G_c \left(\frac{T_{\text{bath}}}{T_c}\right)^{\beta}.
$$
 (10)

<span id="page-13-3"></span>FIG. 14. TES power vs temperature on transition with a fit to Eq. [11.](#page-13-1)

The power vs temperature relation can be calculated by integrating  $dP = GdT$  with  $G(T)$  defined in Eq. [10.](#page-13-2) The integrated equation is

<span id="page-13-1"></span>
$$
P = \frac{G_c}{(\beta + 1)T_c^{\beta}} \left( T_c^{\beta + 1} - T_{\text{bath}}^{\beta + 1} \right) - P_{\text{dark}}.
$$
 (11)

The power vs temperature data are extracted from the TES current vs voltage curves by averaging the power for each temperature in the transition. The power is plotted in Fig. [12.](#page-12-2) The negative slope in some of the power vs voltage curves is due to a small error in the current calibration. This error is negligible for our purpose of calculating the thermal conductance. The data are fit to Eq. [11.](#page-13-1) The data and fit are presented in Fig. [14.](#page-13-3) The fit parameters are pre-sented in Table [II.](#page-14-0) Note that *P*<sub>Dark</sub> is not a reliable measurement of the actual dark power because an accurate fit to *P*<sub>Dark</sub> requires a dark

measurement of  $T_c$  and the measurement of  $T_c$ was under the same loading conditions as the power vs temperature data.

	$G_c$ (fW/K)	$P_{\text{Dark}}$ (fW)
0.682	313	0.1411

<span id="page-14-0"></span>TABLE II. Power vs temperature fit parameters.

### D. Photon-Noise Calibration

The photon-noise calibration was repeated with the DC setup. The DC electrical responsivity  $S(v = 0)$  is equal to the inverse of the TES voltage, which is calculated from the circuit model in Fig. [5.](#page-7-1) The photon-noise calibration was repeated at several bias voltages at 100.10 mK. The results are plotted in Fig. [15](#page-14-1) with the electrical responsivity. The error bars are propagated from the uncertainty in the linear fits to  $NEI<sup>2</sup>$  vs *I*.

### E. NEP Common-Mode Reduction

In order to determine whether the 1/f noise is intrinsic to the detector or due to the measurement setup, an array was tested with a timedomain readout system at the Goddard Spaceflight Center. The time-domain system allows for common-mode reduction in the noise spectra of multiple detectors that were measured simultaneously. Four detectors without absorbers were measured.

<span id="page-14-1"></span>FIG. 15. DC responsivity: comparison of electrical responsivity estimated from the applied voltage and the circuit, and via the photon-noise-calibration technique. *V*<sub>TES</sub> is calculated from the circuit model in Fig. [5,](#page-7-1) where  $R_{shunt}$  is set to the nominal shunt resistor value of 1.8 m $\Omega$ . The vertical error bars are propagated from the fits to  $NEI<sup>2</sup>$  vs *I*.

### *1. Experimental Setup*

The laboratory Dewar is a custom-built cryostat designed at Goddard. It is a combination of parts from Simon Chase Cryogenics (4He sorption Cooler), High Precision Devices (ADR) and CryoMech ( PT-407). A custom-built set of readout electronics is used to read and run all of the thermometers and control the PID loop for the ADR at a level of less than 200 nK/ $\sqrt{Hz}$ .

Clocking and grounding are controlled and synchronized for electrical noise performance.

Vibrational dampers are used to control acoustic on each row. Thus, there were 33.33 Msamples noise that can be introduced from floor and air for each row/run. vibration.

The thermal and electrical control provides a clean environment for bolometer testing. To provide a regime that makes it possible to test low-noise bolometers, a specially designed package was developed at Goddard. This package utilizes superconducting thermal filters that isolate the SQUID readout chips (the timedomain SQUID multiplexers and series arrays were provided by NIST/Boulder) from the detector chip under test. Both regions in the package are darkened with a special EMI/Thermally black paint developed at Goddard<sup>[44](#page-26-5)</sup> and then closed out with a metal to metal stepped edge to block external light from getting in. The multiplexed detector signals were read out using the Multi Channel Electronics (MCE) from UBC<sup>[45](#page-26-6)</sup>.

### *2. Measurements and Data Reduction*

The data for the plots were taken with a base temperature of 88 mK. The data were taken still individual points in the FFT. The frequenat night to minimize interference from other cies were averaged to get an average frequency sources. There were three runs with different for each bin. This has the effect of smoothing bias settings, each operating the detector on a the data at high frequency although some sharp different place on the transition. Data were lines still appear. The lowest frequency is limtaken for ∼ 800 s each of those runs. The sample ited by the duration (800 s) of the data. The PID rate is 50 MHz and there were 4 pixels (rows) controller was turned on but was not properly with a dead time of 4.8  $\mu$ s (240 samples) for tuned for the temperature setting. We show resettling and a dwell time of 1.2  $\mu$ s (60 samples) sults for three of the devices (there was a data

In two of these row/runs a single jump was noted. The data before the jump were averaged and the mean was subtracted. The data after the jump were also averaged and the mean was subtracted. Then, for each row/run, a straight line fit (offset and slope) was removed. The slope is minimal and probably not important. There is an arbitrary offset set in at the time the feedback is locked. The data were then Fourier transformed, the absolute value was applied, and half the results were binned into frequency bins. The remaining half is a mirror image and, thus, redundant. This forms a standard power spectrum. The gain was determined by the voltage setting on the TES and the counts to generate a  $\Phi_0$  in the feedback. The current to power responsivity is given as the standard *V*bias. The shunt resistor is 250  $\mu$ Ω.

The resulting power spectra were then averaged (RMS) into equal log bins in frequency. Those at the lower end of the spectrum are glitch during the measurements of the fourth device). The noise data are presented in Fig. [16.](#page-16-1) The white noise level is 0.8 aW/ $Hz^{1/2}$ , and the single-pole rolloff is at 50 Hz (3.2 ms time constant). NO ABS 2 and 3 have a 1/f knee below 0.1 Hz, and NO ABS 1 has a higher 1/f knee of below 1 Hz. The 1/f noise is reduced from the measurements in Sec. [IV C](#page-11-3) by up to a factor of 10.

The noise model in Fig. [16](#page-16-1) includes the G noise, the Johnson noise, and the SQUID noise. The G noise is  $NEP_G = \sqrt{4kT^2G}$ 0.53 aW/ $\sqrt{Hz}$ , where G is measured in Sec. [V C.](#page-13-4) The SQUID noise was measured using an off-resonance bias, and matches the Magnicon datasheet. The SQUID noise divided by the average responsivity of the TESs is 0.08 aW/ $\sqrt{Hz}$ . The Johnson noise is calculated from NEI<sub>Johnson</sub> =  $\sqrt{\frac{4kT}{R}}$  $\frac{kT}{R}$ , where *T* and *R* are the operating temperature and resistance of the TESs. The average value of the Johnson noise divided by the average responsivity is 0.19 aW/ $\sqrt{Hz}$ . The sum of the G, SQUID, and Johnson noise is 0.57 aW/ $\sqrt{\text{Hz}}$ .

#### <span id="page-16-0"></span>VI. SUMMARY

We present development and testing of low-

<span id="page-16-1"></span>FIG. 16. Calculated NEP of three TESs without absorbers, with the common-mode noise removed. The noise model includes the G noise, the SQUID noise, the Johnson noise, and the response rolloff.

thermal-conductance transition-edge-sensed confirms an increase in speed with fixed G (TES) bolometers for far-IR space astrophysics. relative to the dry process; therefore, the heat Our new wet-release process is compatible capacity improvements are real. The higher G with large arrays of devices with 1-mm long in our low-G wet-release devices may be due to legs on 1/4-micron silicon nitride, and yields an improved speed of response (3–10 ms) relative to previous low-G devices developed at the JPL Microdevices Lab  $(10\n-30 \text{ ms})^{21-23}$  $(10\n-30 \text{ ms})^{21-23}$  $(10\n-30 \text{ ms})^{21-23}$ . However, in a careful calibration in both AC and DC bias schemes and multiple experimental setups, we find that the thermal conductances (Gs) are ten times higher than previously measured with the same leg geometries in the old dry-release process. We do note that a similar wet-release approach used for higher-G, higher-temperature devices (not presented here)

a reduction in phonon scattering along the legs visioned for the cryogenic space missions. due to the smoothness associated with the wet release.

In characterizing these devices, we have developed a near-IR photon-shot-noise calibration technique which offers a rapid and unambiguous measure to total power on the TESs. While not a replacement for far-IR optical characterifor assessing electrical properties. This is especially useful when the bias transfer is uncertain, as is often the case in AC bias systems. It works ford. We would like to thank Jonathan Hunacek in the regime in which the power to current responsivity is constant, the bulk of the operating regime for TES devices. In future experiments, stray light could be reduced using a simple near-IR bandpass filter.

The time-domain multiplexing system at Goddard yields better sensitivities than the AC setup, a fact we attribute to improved filtration and stray light blockage, rather than a fundamental difference in the approach. Through a careful 1/f reduction, the noise is further reduced to an electrical noise-equivalent power as low as  $0.8$  aW/Hz<sup>1/2</sup>. This is only modestly larger than the 0.57 aW/Hz<sup>1/2</sup>, which is expected from the fluctuations in the thermal transport (the G noise), the Johnson noise, and the SQUID noise. The floor is very white, suggesting that it may be due to stray light. We measure a 1/f knee frequency as low as 0.1 Hz, ample for large-scale mapping experiments en-
