(Dated: November 5, 2024)

Electromagnetic resonant systems, such as cavities and LC circuits, are widely used to detect ultralight boson dark matter and high-frequency gravitational waves. However, the narrow bandwidth of single-mode resonators necessitates multiple scan steps to cover broad frequency ranges. By incorporating a network of auxiliary modes via beam-splitter-type and non-degenerate parametric couplings, we enable broadband detection with an effective bandwidth of each scan matching the order of the resonant frequency, while maintaining a strong signal response. In heterodyne upconversion detection, where a background cavity mode transitions into another due to a potential background source, multiple orders of the source frequency can be probed with high sensitivity without tuning the cavity frequency. Consequently, our method allows for significantly deeper exploration of the parameter space within the same integration time compared to single-mode detection.

I. INTRODUCTION

Axions [1–3] and dark photons [4] are compelling candidates for dark matter (DM) due to their natural prediction in the compactification of higher dimensional fundamental theories [5–8]. The QCD axion, in particular, provides a solution to the strong CP problem [9]. Experimental efforts are underway to detect these bosonic DM candidates through their electromagnetic coupling, using techniques like resonant microwave cavities [10, 11] and superconducting circuits [12–14]. In both cases, axion fields in the presence of a strong background magnetic field, or dark photon fields themselves, can induce effective currents that serve as signals in haloscope experiments [15–21].

On the other hand, gravitational waves (GW) with frequencies higher than kHz can offer insights into early universe cosmology and particle physics beyond the standard model [22]. Two noteworthy phenomena—the inverse Gertsenshtein effect [23], akin to axion electrodynamics, and mechanical resonance [24–27]—have the capability to convert GW into photons in the presence of a background electromagnetic field. The largely unexplored parameter space of high-frequency GW (HFGW) has gained significant attention, leading to the implementation of axion haloscope experiments aimed at detecting its signatures [27–33].

The scan rate, a critical figure of merit for covering broad frequency ranges [34–37], is influenced by the

trade-off between the bandwidth of each scan and its signal response during resonant detection. In single-mode resonators, responses to the signal and to the noise due to intrinsic fluctuations are identical, resulting in the effective bandwidth of each scan as the range where this intrinsic noise predominates over readout noise with a relatively flat power spectrum [38, 39]. Consequently, by adjusting the readout coupling, it is possible to optimize sensitivity and approach the standard quantum limit [34, 35, 37–43].

Exceeding the standard quantum limit in single-mode resonators involves broadening the effective bandwidth of each scan. A practical approach to achieve this is by reducing readout noise through squeezing techniques [34–37]. Recent studies have shown that a multi-mode resonant system with auxiliary non-degenerate parametric interactions can significantly increase the signal response at off-resonant frequencies, thereby considerably expanding the effective bandwidth [44–46].

In this study, we demonstrate the ultimate sensitivity limit achievable by a multi-mode resonator, which allows for a substantially increased quantum limit for the scan rate. This newly derived limit enables experiments to achieve a bandwidth as extensive as the resonant frequency for each scan. Notably, by applying multi-mode generalization to heterodyne upconversion detections—where bosonic fields and HFGWs induce transitions between two quasi-degenerate modes [33, 41, 42, 47]—it becomes feasible to realize a simultaneous resonant and broadband detector. This configuration achieves a significant signal response while obtaining an effective bandwidth that spans several orders in the frequency domain.

The structure of this paper is organized as follows: Section II briefly introduces resonant cavity and LC-circuit detectors, focusing on their mode quantization and response to effective currents. Section III discusses the effective currents induced by axions, dark photons, and HFGWs, as well as the mechanical vibration signals induced by HFGWs. Section IV applies the input-output formalism to derive the response and quantum limit of single-mode resonators. Section V explores multi-mode generalizations, presenting example configurations and detailing their responses and the enhanced response widths. Section VI discusses the practical realization and potential experimental challenges of these configurations. In Sec. VII, we apply the achieved bandwidth to three types of detection. Finally, section VIII summarizes the results and offers future outlooks.

II. RESONANT ELECTROMAGNETIC SYSTEMS

In this section, we introduce two electromagnetic resonant systems commonly used as detectors: resonant cavities and LC circuits. The left panel of Fig. 1 illustrates these detection schemes. We detail the parameterization

of the interaction between quantized resonant modes and an effective current signal. A cavity mode resonates when the current’s frequency falls within the resonant bandwidth and its wave function spatially overlaps with the cavity mode. Superconducting LC circuits utilize pickup loops to convert the magnetic flux, induced by the effective current in a shielded environment, into a voltage signal. Additionally, section II C presents equivalent circuit representations of a cavity mode.

FIG. 1: **Left:** An illustration depicting a resonant cavity and a superconducting LC circuit used to detect effective currents \vec{J}_{eff} originating from dark matter (DM) or high-frequency gravitational waves (HFGW). Background magnetic fields \vec{B}_0 are utilized for axion or GW detection. **Right:** A depiction of both detection scenarios unified within a single-mode resonant sensor, which probes the DM or HFGW, labeled as Ψ . The signal is then transmitted to the readout port.

A. Resonant Cavity

Electromagnetic fields can be generated in the presence of an effective current, denoted as J_{eff}^{μ} . A resonant cavity, characterized by a low dissipation quality factor Q_{int} , provides a straightforward means to amplify this weak signal. Within the cavity volume V , the electromagnetic fields become quantized bound states. Their wavefunctions, parameterized in the Weyl gauge, are expressed as: follows:

$$\vec{A} = \sum_n \frac{1}{\sqrt{2\omega_{\text{rf}}^n}} \hat{a}_n^{\dagger} \vec{\epsilon}_n(\vec{r}) e^{-i\omega_{\text{rf}}^n t} + h.c.. \quad (1)$$

In this equation, the discrete sum over the various modes n , with \hat{a}_n and \hat{a}_n^{\dagger} representing the annihilation and creation operators, respectively, each mode is characterized by an eigenfrequency ω_{rf}^n and a wavefunction $\vec{\epsilon}_n(\vec{r})$. With a perfect conductor as the boundary, each resonant mode arises from solving the vacuum Maxwell equations $\square \vec{A} = 0$, subject to the boundary conditions:

$$\hat{s} \times \vec{\epsilon}_n|_s = 0, \quad \hat{s} \cdot (\vec{\nabla} \times \vec{\epsilon}_n)|_s = 0. \quad (2)$$

Here, the subscript s denotes the surface of the cavity, with \hat{s} as the normal vector. Moreover, the wavefunctions

must satisfy the orthonormality condition:

$$\int_V \vec{\epsilon}_m^* \vec{\epsilon}_n d^3\vec{r} = \delta_{mn}. \quad (3)$$

Using Eq. 1, the free Hamiltonian for the modes within the cavity is given by:

$$H_0 = \frac{1}{2} \int_V (\vec{E}^2 + \vec{B}^2) d^3\vec{r} = \sum_n \omega_{\text{rf}}^n \left(\hat{a}_n^\dagger \hat{a}_n + \frac{1}{2} \right). \quad (4)$$

where $\vec{E} = -\partial\vec{A}/\partial t$ and $\vec{B} = \vec{\nabla} \times \vec{A}$ represent the electric and magnetic fields of the cavity modes, respectively.

We proceed by examining the interaction Hamiltonian concerning the spatial component of the effective current \vec{J}_{eff} . A linear coupling with the vector potential \vec{A} is established as follows:

$$\begin{aligned} H_{\text{int}} &= \int_V \vec{A} \cdot \vec{J}_{\text{eff}} d^3\vec{r} \\ &= \sum_n \sqrt{\frac{V}{2\omega_{\text{rf}}^n}} \eta_n \vec{J}_{\text{eff}} \hat{a}_n^\dagger e^{-i\omega_{\text{rf}}^n t} + h.c.. \end{aligned} \quad (5)$$

Here, η_n represents the geometric overlap function between $\vec{\epsilon}_n$ and \vec{J}_{eff} , defined as:

$$\eta_n \equiv \frac{\int_V \vec{\epsilon}_n \cdot \vec{J}_{\text{eff}} d^3\vec{r}}{\sqrt{\int_V |\vec{J}_{\text{eff}}|^2 d^3\vec{r}}}, \quad (6)$$

and \vec{J}_{eff} denotes the average current density within the cavity:

$$\vec{J}_{\text{eff}} \equiv \sqrt{\frac{1}{V}} \int_V |\vec{J}_{\text{eff}}|^2 d^3\vec{r}. \quad (7)$$

On the other hand, the time component of J_{eff}^μ , corresponding to the effective charge density ρ_{eff} , exclusively excites the irrotational mode, which does not experience resonant enhancement within the cavity context [48].

In addition to electromagnetic interactions involving the effective current, a cavity mode can also be excited by an external force applied to the cavity when a background mode is present. This force induces a displacement of the cavity walls, thereby instigating a power transition between the background and signal modes. This phenomenon can be characterized by a linear coupling resembling the expression in Eq. (5), which will be demonstrated in Sec. III B.

B. LC Circuit

The resonant frequency of a cavity is intrinsically linked to its spatial dimensions, which poses a challenge in achieving a wide frequency tuning range outside the GHz regime. This limitation can be mitigated through the utilization of an LC circuit, which allows for precise

tuning of the resonant frequency across different orders of magnitude below the GHz range. The LC circuit, comprising an inductor L and a capacitor C , forms a resonant system with a resonant frequency given by $\omega_{\text{rf}} = 1/\sqrt{LC}$. The system's free Hamiltonian, encompassing the energy stored within the inductor and the capacitor, is represented as follows:

$$H_0 = \frac{\Phi^2}{2L} + \frac{Q^2}{2C} = \omega_{\text{rf}} \left(\hat{a}^\dagger \hat{a} + \frac{1}{2} \right). \quad (8)$$

Here, Φ denotes the magnetic flux traversing the inductor, and Q signifies the charge accumulated in the capacitor. These serve as the canonical coordinate and its conjugate momentum, respectively, and are expressed in terms of annihilation and creation operators.

By introducing a pick-up loop, the LC circuit becomes capable of capturing an external magnetic flux Φ_Ψ and resonantly responding when the frequency of Φ_Ψ closely aligns with ω_{rf} . The interaction Hamiltonian, arising from a shift of the canonical coordinate $\Phi \rightarrow \Phi + \Phi_\Psi$ within Eq. (8), is presented as follows:

$$H_{\text{int}} = \frac{\Phi \Phi_\Psi}{L} = \sqrt{\frac{\omega_{\text{rf}}}{2L}} \Phi_\Psi \hat{a}_n^\dagger e^{-i\omega_{\text{rf}} t} + h.c.. \quad (9)$$

The magnetic flux in the pick-up loop originates solely from the spatial component of the effective current. The effective currents induce a magnetic field expressed as:

$$\vec{B}_\Psi(\vec{r}) \approx \int \frac{\vec{J}_{\text{eff}}(\vec{r}') \times (\vec{r} - \vec{r}')}{4\pi |\vec{r} - \vec{r}'|^3} d^3\vec{r}', \quad (10)$$

where we neglect the time derivative terms, assuming that the Compton wavelength of the source is much larger than the spatial scale of the detector. The existence of a conducting shield modifies the response magnetic field, which can be described as a geometric overlapping between the spatial distribution of \vec{J}_{eff} and all the eigenmodes of the shielding cavity [13]. We define a dimensionless geometric overlap function $\eta \sim \mathcal{O}(0.1)$ so that $\Phi_\Psi = \eta V \vec{J}_{\text{eff}}$, with \vec{J}_{eff} defined in Eq. (7).

C. Circuit Representation of Cavity Modes

Encapsulating an antenna within a cavity enables the investigation of specific cavity modes by analyzing the nodal flow across the antenna, expressed as:

$$\Phi = \int_{\text{Ant}} \vec{A}(\vec{r}, t) \cdot d\vec{l} = \sum_n \kappa_n \hat{a}_n^\dagger e^{-i\omega_{\text{rf}}^n t} + h.c.. \quad (11)$$

Here, the integration spans the spatial extent of the antenna. The zero-point uncertainty associated with a specific cavity mode is captured by κ_n , defined as:

$$\kappa_n \equiv \frac{1}{\sqrt{2\omega_{\text{rf}}^n}} \int_{\text{Ant}} \vec{\epsilon}_n(\vec{r}) \cdot d\vec{l}. \quad (12)$$

Given the harmonic oscillator behavior of the Hamiltonians in Eqs. (4) and (8), it is feasible to model a cavity mode using an equivalent LC circuit. In this model, the nodal flux is defined as in Eq. (11), and the resonant frequency is given by $\omega_{\text{rf}}^n = 1/\sqrt{L_n C_n}$. This analogy establishes a correspondence between the physical properties of cavity modes and circuit elements:

$$L_n = \frac{2\kappa_n^2}{\omega_{\text{rf}}^n}, \quad C_n = \frac{1}{2\kappa_n^2 \omega_{\text{rf}}^n}. \quad (13)$$

III. AXION, DARK PHOTON, AND GRAVITATIONAL WAVE-INDUCED SIGNALS

In this section, we explore the generation of effective current signals by axions, dark photons, and GWs. Additionally, we examine the mechanical vibrations induced by GWs, which can facilitate transitions between background and signal modes within cavities.

A. Effective Currents

The interaction Lagrangian between ultralight boson DM or HFGWs and electromagnetic fields can be reformulated as $A_\mu J_{\text{eff}}^\mu$ to identify the effective currents J_{eff}^μ . An example of this is the axion-photon interaction, which is expressed as follows:

$$\frac{1}{4} g_{a\gamma} a F_{\mu\nu} \tilde{F}^{\mu\nu} \rightarrow J_{\text{eff}}^{a\mu} = g_{a\gamma} \tilde{F}^{\mu\nu} \partial_\nu a. \quad (14)$$

Here, $g_{a\gamma}$ represents the axion-photon coupling constant, a is the axion field, and $F_{\mu\nu}$ and $\tilde{F}^{\mu\nu}$ are the electromagnetic field strength tensor and its dual tensor, respectively. The Bianchi identity ensures that the derivative in Eq. (14) affects only the axion field. In scenarios involving non-relativistic axion dark matter, the term with the time derivative primarily contributes to the axion's mass ($\omega_a \simeq m_a$), which is approximately 10^3 times greater than that from the spatial derivative [49]. Consequently, a background magnetic field \vec{B}_0 is typically employed in electromagnetic resonant detection, leading to the spatial current:

$$\vec{J}_{\text{eff}}^a = g_{a\gamma} \omega_a a \vec{B}_0. \quad (15)$$

Here, \vec{B}_0 may be static or oscillating, depending on the experimental setup. The latter corresponds to heterodyne upconversion, typically employing superconducting radio-frequency (SRF) cavities with significantly high quality factors ($Q_{\text{int}} \gg 10^9$) [27, 41, 47].

The subsequent example involves the kinetic mixing of the dark photon A'^μ , whose interaction in the interaction basis results in:

$$\epsilon m_{A'}^2 A'^\mu A_\mu \rightarrow J_{\text{eff}}^{A'\mu} = \epsilon m_{A'}^2 A'^\mu, \quad (16)$$

Here, ϵ represents the kinetic mixing coefficient, and $m_{A'}$ denotes the mass of the dark photon. Unlike the axion case, the effective current in Eq. (16) depends solely on the dark photon field, thus an electromagnetic background field is not relevant. Specifically, the spatial component of the current is directly proportional to \vec{A}' .

Finally, we consider the GW strain denoted as $h^{\mu\nu}$, which features a universal coupling to matter fields. Its interaction with electromagnetic fields yields:

$$\frac{1}{2} h^{\mu\nu} T_{\mu\nu}^{\text{EM}} \rightarrow J_{\text{eff}}^{h\mu} = \partial_\nu \left(\frac{1}{2} h F^{\mu\nu} + h^\nu{}_\rho F^{\rho\mu} - h^\mu{}_\rho F^{\rho\nu} \right). \quad (17)$$

Here, $T_{\mu\nu}^{\text{EM}}$ corresponds to the energy-momentum tensor of the electromagnetic field, and $h \equiv h^\rho{}_\rho$. Similar to the axion scenario, the generation of the effective current in Eq. (17) requires a background electromagnetic field, established within the proper detector frame. Notably, while the GW strain is often computed in the transverse-traceless (TT) frame characterized by the amplitude h_0 , transitioning from the proper detector frame to h_0 introduces a scaling factor of $\omega_h^2 V^{2/3}$ [29, 30].

In scenarios characterized by a stationary magnetic field background, the derivative in Eq. (17) pertains exclusively to the GW strain [29], resulting in:

$$\vec{J}_{\text{eff}}^h \simeq \omega_h^2 V^{1/3} B_0 h_0 \hat{j}(\vec{r}). \quad (18)$$

where we assume $\omega_h \sim V^{-1/3}$. The spatially-dependent dimensionless vector $\hat{j}(\vec{r})$ is related to the incoming direction and polarization of the GW. In the context of heterodyne upconversion detection, ω_{rf} typically significantly outweighs ω_h , consequently rendering the dominant component in Eq. (17) proportional to $\omega_{\text{rf}} \sim V^{-1/3}$, thus leading to approximately the same expression as in Eq. (18).

As elaborated in Sec. II, the spatial component of the effective currents exhibits coupling with either a cavity mode or a circuit, expressed in the following Hamiltonian:

$$H_\alpha = \alpha \Psi (\hat{a} e^{i\omega_{\text{rf}} t} + \hat{a}^\dagger e^{-i\omega_{\text{rf}} t}) / \sqrt{2}. \quad (19)$$

Here, the coupling coefficients α for the cavity and circuit scenarios are given by:

$$\alpha_{\text{cav}} \Psi = \sqrt{\frac{V}{\omega_{\text{rf}}}} \eta \vec{J}_{\text{eff}}, \quad \alpha_{\text{LC}} \Psi = \sqrt{\frac{\omega_{\text{rf}}}{L}} \Phi_\Psi, \quad (20)$$

respectively, derived in accordance with Eq. (5) and Eq. (9).

The average current density, \vec{J}_{eff} , can be directly inferred from Eq. (15), Eq. (16), and Eq. (18) for the respective source. The magnetic field strength, B_0 , is defined as the average magnitude over both space and time within the relevant volume. The magnetic flux Φ_Ψ , which traverses the pick-up loop of an LC circuit, is closely connected to the mean effective current density \vec{J}_{eff} by two factors: the spatial scale V and a dimensionless geometric parameter η , resulting in $\Phi_\Psi \sim \eta V \vec{J}_{\text{eff}}$. For simplicity,

Source \ Haloscope	Axion	Dark Photon	HFGW
LC circuit	$g_{a\gamma}\eta B_0 V^{5/6} \omega_a \sqrt{\omega_{\text{rf}}}$	$\epsilon\eta V^{5/6} m_{A'}^2 \sqrt{\omega_{\text{rf}}}$	$\eta B_0 V^{7/6} \omega_h^2 \sqrt{\omega_{\text{rf}}}$
Cavity	$g_{a\gamma}\eta B_0 V^{1/2} \omega_a / \sqrt{\omega_{\text{rf}}}$	$\epsilon\eta V^{1/2} m_{A'}^2 / \sqrt{\omega_{\text{rf}}}$	$\eta B_0 V^{5/6} \omega_h^2 / \sqrt{\omega_{\text{rf}}}$
SRF ^{EM}	$g_{a\gamma}\eta B_0 V^{1/2} \omega_a / \sqrt{2\omega_{\text{rf}}}$	$\epsilon\eta V^{1/2} m_{A'}^2 / \sqrt{\omega_{\text{rf}}}$	$\eta B_0 V^{7/6} \omega_h^2 \sqrt{\omega_{\text{rf}}/2}$
SRF ^{mech}	/	/	$\eta_p^t \eta_p^h L_p(\omega_h) B_0 V^{1/2} \omega_h^2 \sqrt{\omega_{\text{rf}}/2}$

TABLE I: Effective couplings α , defined in Eq. (19), between axions, dark photons, or HFGWs and sensor modes are listed for four detection schemes. Notably, SRF^{EM} for axions and HFGWs as well as SRF^{mech} refer to heterodyne upconversion using a background cavity mode.

the inductance L is assumed to be $V^{1/3}$. It is noteworthy that achieving optimal scaling for HFGW detection using an LC circuit necessitates a specialized design of the pick-up loops, as introduced in Ref. [30]. The values of the parameter α for each source and detection scheme are detailed in Table. I. Here, SRF^{EM} for axions and HFGWs refers to heterodyne upconversion using a background cavity mode. This setup differs from the cavity employing a static magnetic field background by a factor of $\sqrt{2}$, due to signal modes being created at two sidebands around the pump mode and the time-averaged magnitude being $\sqrt{2}$ smaller than the oscillation amplitude.

B. Mechanical Deformation

In addition to the microscopic interaction between GWs and electromagnetic fields, an alternative mechanism for inducing cavity mode transitions involves the deformation of the cavity's inner surface driven by GWs, as explored in Ref. [27] for the SRF cavity configuration. This deformation is characterized by local displacements from the equilibrium position, represented as:

$$\vec{U}(\vec{r}, t) = \sum_p x_p(t) \vec{U}_p(\vec{r}), \quad (21)$$

where the subscript p corresponds to a mechanical normal mode with a time-dependent mode function $x_p(t)$, and \vec{r} denotes a point within the cavity shell with volume V_S . The function $\vec{U}_p(\vec{r})$ describes the dimensionless spatial profile of the p -mode, satisfying the normalization condition:

$$\int_{V_S} \vec{U}_p^*(\vec{r}) \cdot \vec{U}_q(\vec{r}) \rho_S(\vec{r}) d^3\vec{r} = \delta_{pq} M_S, \quad (22)$$

where $\rho_S(\vec{r})$ and M_S denote the mass density and total mass of the cavity shell, respectively. These mechanical normal modes can be excited by an external force, described by the following equation of motion:

$$\ddot{x}_p + \frac{\omega_p}{Q_p} \dot{x}_p + \omega_p^2 x_p = \frac{1}{M_S} \int_{V_S} \vec{f}(\vec{r}, t) \cdot \vec{U}_p^*(\vec{r}) d^3\vec{r} \equiv \frac{F_p}{M_S}. \quad (23)$$

Here, ω_p and Q_p represent the resonant frequency and mechanical quality factor of the p -mode, respectively. The force density is denoted as $\vec{f}(\vec{r}, t)$, and F_p represents the total force applied to the p -mode. The solution to this equation in the frequency domain is straightforwardly obtained as $x_p(\omega) = L_p(\omega) F_p(\omega) / M_S$, with $L_p(\omega)$ being the response function given by $(\omega^2 - \omega_p^2 + i\omega\omega_p/Q_p)^{-1}$.

GW strain acts as a tidal force on the cavity shell, exerting a force density $f_i = -\rho_S R_{i0j0} r^j$ in the long-wavelength regime, where r_j is defined in a coordinate system originating at the center of mass of the cavity. The Riemann curvature tensor is typically expressed in terms of the strain in the TT gauge, $R_{i0j0} = -\dot{h}_{ij}^{\text{TT}}/2 + \mathcal{O}(h^2)$. The strain-induced force on the p -mode, labeled as F_p^h , is then characterized through an overlapping function η_p^h between the strain polarization basis H_{ij}^{TT} and the mechanical mode profile:

$$F_p^h(\omega) = M_S V^{1/3} \eta_p^h \omega^2 h_0(\omega), \quad (24)$$

$$\eta_p^h \equiv \frac{H_{ij}^{\text{TT}}}{2V^{1/3} M_S} \left| \int_{V_S} \rho(\vec{r}) U_p^{i*}(\vec{r}) r^j d^3\vec{r} \right|.$$

Here, $h_0(\omega)$ represents the strain amplitude, satisfying the relation $h_{ij}^{\text{TT}} \equiv h_0 H_{ij}^{\text{TT}}$.

The deformation of the inner cavity surface leads to deviations from the orthonormality condition of the cavity modes in Eq. (3), enabling the transition from the pump mode to the signal mode. The effective coupling between these modes in the frequency domain is identified as per the following equation [27, 50]:

$$\alpha\Psi(\omega) = \frac{\sqrt{2} \omega_{\text{rf}}^{1/2} B_0 V^{1/6}}{2 M_S} \sum_p \eta_p^t L_p(\omega - \omega_0) F_p^h(\omega - \omega_0). \quad (25)$$

Here, η_p^t represents the transition form factor given by

$$\eta_p^t = V^{1/3} \int_S \left(\vec{\epsilon}_0 \cdot \vec{\epsilon}_1^* - \frac{1}{\omega_{\text{rf}}^2} (\mathbf{curl}\vec{\epsilon}_0) \cdot (\mathbf{curl}\vec{\epsilon}_1^*) \right) d\vec{s} \cdot \vec{U}_p, \quad (26)$$

where the integral is performed over the inner surface of the cavity. The subscripts 0 and 1 denote the pump and signal modes, respectively. For simplicity, it is assumed that the dominant contribution from GW is manifested

in a single quadrupolar mechanical mode possessing the lowest ω_p , as $\eta_p^h \propto 1/\omega_p^2$. The expression of the effective coupling is listed in Table I as well.

IV. QUANTUM LIMIT FOR SINGLE-MODE RESONATORS

This section begins with a brief introduction to the input-output formalism used to derive the scattering matrix elements of single-mode resonators. From these elements, one can calculate the signal and noise power spectral densities (PSDs). We then explore how to optimize the scan rate by adjusting the readout coupling and distributing the integration time within the e -fold time. Additionally, we discuss how the optimized scan rate translates into the physics reaches of various detection schemes for the three sources outlined in Sec. III.

A. Input-Output Formalism

The Hamiltonian governing a resonant mode \hat{a} is given by

$$H = H_{\text{free}} + H_{\text{int}}, \quad (27)$$

where $H_{\text{free}} = \omega_{\text{rf}}(\hat{a}^\dagger \hat{a} + 1/2)$ represents the free Hamiltonian, and H_{int} includes the interaction terms. Utilizing the Heisenberg equation in the interaction picture,

$$\frac{d}{dt}\hat{a} = -i[\hat{a}, H_{\text{int}}], \quad (28)$$

leads to the derivation of the system's dynamics.

Before exploring specific interaction forms, it is essential to consider environmental factors that become relevant when the system is coupled to an external port, as described by the quantum Langevin equation:

$$-i[\hat{a}, H_{\text{env}}^{\text{P}}] = -\gamma_{\text{p}}\hat{a} + \sqrt{2\gamma_{\text{p}}}\hat{u}_{\text{p}}, \quad (29)$$

where $H_{\text{env}}^{\text{P}}$ represents the interaction with the environment via port p, γ_{p} denotes the dissipation coefficient, and \hat{u}_{p} corresponds to incoming noise as dictated by the fluctuation-dissipation theorem. The input-output relation is then derived from the port boundary condition:

$$\hat{v}_{\text{p}} = \hat{u}_{\text{p}} - \sqrt{2\gamma_{\text{p}}}\hat{a}, \quad (30)$$

where \hat{v}_{p} designates the outgoing mode.

For a single-mode resonant detection system, two noise-contributing ports are relevant: intrinsic dissipation and readout. Together with the interaction with a potential signal, H_α introduced in Eq. (19), the interaction Hamiltonian becomes:

$$H_{\text{int}} = H_\alpha + H_{\text{env}}^\gamma + H_{\text{env}}^{\gamma_r}. \quad (31)$$

Utilizing Eq. (28) and Eq. (29), the equation of motion for \hat{a} in the frequency domain can be solved as follows:

$$\hat{a} = \frac{-i\alpha\Psi e^{-i\omega_{\text{rf}}t}/\sqrt{2} + \sqrt{2\gamma}\hat{u}_a + \sqrt{2\gamma_r}\hat{u}_r}{\gamma + \gamma_r - i\Omega}, \quad (32)$$

where $\Omega \equiv \omega - \omega_{\text{rf}}$ represents the frequency shift in the interaction picture, and γ and γ_r denote the dissipation coefficients of the two ports, with corresponding incoming modes \hat{u}_a and \hat{u}_r , respectively. The intrinsic dissipation can alternatively be expressed in terms of the quality factor Q_{int} , which is related to γ by $Q_{\text{int}} \equiv \omega_{\text{rf}}/(2\gamma)$.

The observable is obtained from the readout port's outgoing mode, as per the input-output relation in Eq. (30):

$$\hat{v}_r = S_{0r} \left(\hat{u}_a - \frac{i\alpha e^{-i\omega_{\text{rf}}t}}{2\sqrt{\gamma}}\Psi \right) + S_{rr}\hat{u}_r, \quad (33)$$

The two scattering matrix elements, characterizing the propagation from the input to the output of different ports, are given by:

$$S_{0r} = -\frac{2\sqrt{\gamma\gamma_r}}{\gamma + \gamma_r - i\Omega}, \quad S_{rr} = \frac{\gamma - \gamma_r - i\Omega}{\gamma + \gamma_r - i\Omega}. \quad (34)$$

Here, the subscript 0 represents the probing sensor, such as a cavity or a circuit discussed in Sec. III, and r indicates the readout port.

When the integration time significantly exceeds the signal's correlation time, the PSD of the outgoing mode is typically taken to be the observable, defined by:

$$S_{v_r}(\Omega)\delta(\Omega - \Omega') \equiv \langle \hat{v}_r(\Omega)\hat{v}_r^*(\Omega') \rangle, \quad (35)$$

incorporating PSDs of both the signal and noise.

B. Physics Reach

According to Eq. (31), apart from the signal port H_α , fluctuations are induced by intrinsic dissipation and the readout port. The readout PSD in Eq. (35), expressed as $S_{v_r}(\Omega) = S_{\text{sig}} + S_{\text{noise}}$, can be separated as:

$$S_{\text{sig}} = |S_{0r}|^2 \frac{\alpha^2}{4\gamma} S_\Psi, \quad (36)$$

$$S_{\text{noise}} = |S_{0r}|^2 n_{\text{occ}} + |S_{rr}|^2 \frac{1}{2} + \frac{1}{2}.$$

Here, S_Ψ represents the source PSD, which is related to its energy density ρ_Ψ as follows:

$$S_\Psi = \frac{2\pi}{\omega^2} \frac{d\rho_\Psi}{d\omega}. \quad (37)$$

The three noise terms in Eq. (36) represent intrinsic fluctuation noise, the readout port noise, and additional amplifier noise, respectively. n_{occ} represents the intrinsic noise occupation number, for example, the thermal fluctuation of a cavity mode gives $n_{\text{occ}}^{\text{th}} = 1/2 + 1/(e^{\omega/T} - 1)$,

where ω is the frequency and T is the temperature. In the zero-temperature limit, the sum of the noise precisely equals one due to unitarity, leading to the standard quantum limit of single-mode resonant detection [38, 39].

The sensitivity reach of each scan can be estimated by requiring that the signal-to-noise ratio (SNR) be of order one [38, 39, 41–43, 45], as described by the Dicke radiometer equation [51]:

$$\text{SNR}^2 = \frac{t_{\text{int}}}{2\pi} \int_0^\infty \left(\frac{S_{\text{sig}}}{S_{\text{noise}}} \right)^2 d\omega. \quad (38)$$

Here, t_{int} represents the integration time. The integrand in Eq. (38) is decomposed into the product of two distributions: the signal PSD distribution $\alpha^4 S_\Psi^2 / \gamma^2$ and the sensitive response function of the detector, characterized by $(|S_{0r}|^2 n_{\text{occ}} / S_{\text{noise}})^2$, which quantifies the ratio of intrinsic fluctuation noise against the total noise.

For convenience, we introduce the concept of the average source frequency as:

$$\bar{\omega}_\Psi \equiv \frac{\int \omega^2 S_\Psi \alpha^2 / \gamma d\omega}{\int \omega S_\Psi \alpha^2 / \gamma d\omega}, \quad (39)$$

and define the source bandwidth as:

$$\Delta\omega_\Psi \equiv \frac{\int \omega^2 S_\Psi \alpha^2 / \gamma d\omega}{\bar{\omega}_\Psi^2 S_\Psi(\bar{\omega}_\Psi) \alpha^2(\bar{\omega}_\Psi) / \gamma(\bar{\omega}_\Psi)}. \quad (40)$$

The quality factor of the source is defined as $Q_\Psi \equiv \bar{\omega}_\Psi / \Delta\omega_\Psi$, which is 10^6 for non-relativistic DM. For HFGWs, we parameterize the PSD as $S_h(\omega) = \Theta(\Delta\omega_h/2 - |\omega - \omega_h|) h_0^2 / \Delta\omega_h$, where Θ is the Heaviside function and $\Delta\omega_h$ denotes the GW bandwidth.

Due to the common factor $|S_{0r}|^4$ of the signal and intrinsic fluctuation in Eq. (38), the detector's effective sensitive width is approximately

$$\Delta\omega_r \equiv \int_0^\infty \left(\frac{|S_{0r}|^2 n_{\text{occ}}}{S_{\text{noise}}} \right)^2 d\omega, \quad (41)$$

within which the sensitivity to a source remains approximately the same order.

The integral width in Eq. (38) is determined by the minimum of $\Delta\omega_\Psi$ and $\Delta\omega_r$. Moreover, their maximum controls how the integration time t_{int} of each scan is distributed within the total amount of time t_e spent covering each e -fold of $\bar{\omega}_\Psi$:

$$t_{\text{int}} \simeq t_e \max[\Delta\omega_\Psi, \Delta\omega_r] / \bar{\omega}_\Psi. \quad (42)$$

By considering only the dominant intrinsic noise within $\Delta\omega_r$, SNR^2 for a given hypothesis of $\bar{\omega}_\Psi$ is simplified to

$$\text{SNR}^2(\bar{\omega}_\Psi) \simeq \frac{t_e}{\bar{\omega}_\Psi} \Delta\omega_\Psi \Delta\omega_r \frac{\alpha^4 S_\Psi^2}{32\pi\gamma^2 n_{\text{occ}}^2} \Big|_{\omega=\bar{\omega}_\Psi}. \quad (43)$$

From the expression in Eq. (43), the key factor for a scan search is the response width $\Delta\omega_r$, defined in

FIG. 2: Sensitivity reach of axion and dark photon DM, and HFGW, depicted with solid lines for single-mode and dashed lines for multi-mode detection limits. The sensitivity thresholds for single-mode are based on requiring Eqs. (44, 45, 46) to reach 1, while for multi-mode, the thresholds are derived from Eqs. (72, 73, 74, 76, 77). The integration time allocated for each e -fold of the target source frequency is $t_e = 10^7$ s. Benchmark parameters for different experimental setups are discussed in Sec. IV.

Eq. (41), which is proportional to the scan rate as discussed in Refs. [34–37]. This parameter can be optimized by adjusting the readout coupling. Specifically, setting $\gamma_r = 2\gamma$ in the zero-temperature limit [40], or $\gamma_r \simeq 2n_{\text{occ}}\gamma$ when $n_{\text{occ}} \gg 1$ [38, 39, 41–43], results in $\Delta\omega_r \simeq 3\gamma$ and $2n_{\text{occ}}\gamma$, respectively. Substituting these values back into

Eq. (43) yields the sensitivity limit of single-mode resonators.

By incorporating the optimized γ_r and the couplings detailed in Table I into Eq. (43), the resulting SNR² can be calculated for each instance of single-mode resonant detection, as well as for the three target sources:

- Axion:

$$\begin{aligned} \text{LC Circuit} &: \frac{\pi}{2} g_{a\gamma}^4 \rho_{\text{DM}}^2 \eta^4 B_0^4 V^{10/3} Q_a Q_{\text{int}} t_e / T, \\ \text{Cavity} &: 3\pi \frac{g_{a\gamma}^4}{m_a^5} \rho_{\text{DM}}^2 \eta^4 B_0^4 V^2 Q_a Q_{\text{int}} t_e, \\ \text{SRF}^{\text{EM}} &: \frac{\pi}{8} \frac{g_{a\gamma}^4}{m_a^2} \rho_{\text{DM}}^2 \eta^4 B_0^4 V^2 Q_a Q_{\text{int}} t_e / (\omega_{\text{rf}}^2 T). \end{aligned} \quad (44)$$

- Dark Photon:

$$\begin{aligned} \text{LC Circuit} &: \frac{\pi}{2} \epsilon^4 m_{A'}^4 \rho_{\text{DM}}^2 \eta^4 V^{10/3} Q_{A'} Q_{\text{int}} t_e / T, \\ \text{Cavity} &: 3\pi \frac{\epsilon^4}{m_{A'}} \rho_{\text{DM}}^2 \eta^4 V^2 Q_{A'} Q_{\text{int}} t_e, \\ \text{SRF}^{\text{EM}} &: \frac{\pi}{2} \epsilon^4 m_{A'}^2 \rho_{\text{DM}}^2 \eta^4 V^2 Q_{A'} Q_{\text{int}} t_e / (\omega_{\text{rf}}^2 T). \end{aligned} \quad (45)$$

- HFGW:

$$\begin{aligned} \text{LC Circuit} &: \frac{1}{8\pi} h_0^4 \omega_h^8 \eta^4 B_0^4 V^{14/3} Q_h Q_{\text{int}} t_e / T, \\ \text{Cavity} &: \frac{3}{4\pi} h_0^4 \omega_h^3 \eta^4 B_0^4 V^{10/3} Q_h Q_{\text{int}} t_e, \\ \text{SRF}^{\text{EM}} &: \frac{1}{32\pi} h_0^4 \omega_h^6 \eta^4 B_0^4 V^{14/3} Q_h Q_{\text{int}} t_e \omega_{\text{rf}}^2 / T, \\ \text{SRF}^{\text{mech}} &: \frac{h_0^4 \omega_h^6 |\eta_p^t \eta_p^h L_p(\omega_h)|^4 B_0^4 V^2 Q_h Q_{\text{int}} t_e \omega_{\text{rf}}^2}{16\pi T N_M} \\ &\quad \times \min\left(1, \frac{Q_{\text{int}} \omega_h}{T N_M}\right). \end{aligned} \quad (46)$$

In these expressions, we assume the thermal occupation number for the cavity to be $n_{\text{occ}}^{\text{th}} = 1/2$, and for the LC circuit and SRF^{EM/mech}, $n_{\text{occ}}^{\text{th}} = T/\omega$, which applies respectively when $T \ll \omega$ or $T \gg \omega$. For mechanical resonance, the SRF cavity is designed to maximize mechanical vibrations, which may cause the thermal vibrations of the cavity shell to transition the pump mode at frequency ω_0 into the signal mode. This mechanism significantly contributes to n_{occ} , surpassing the intrinsic cavity mode thermal noise at low frequencies, expressed as [27]:

$$n_{\text{occ}}^{\text{mech}} = \frac{Q_{\text{int}}}{4\pi} \frac{B_0^2 V^{1/3}}{M_S^2} \frac{\omega_0^5}{\omega^3 \omega_{\text{rf}}^2} \sum_p S_{F_p^T} |\eta_p^t L_p(\omega - \omega_0)|^2. \quad (47)$$

Here, F_p^T represents the thermal vibration force, whose PSD is given by $S_{F_p^T} = 4\pi M_S \omega_p T / Q_p$, according to the equipartition theorem. In Eq. (46), a dimensionless function $N_M(\omega_h)$ is defined as:

$$N_M(\omega_h) \equiv 1 + Q_{\text{int}} \omega_{\text{rf}} B_0^2 S_{F_p^T} |\eta_p^t L_p(\omega_h)|^2 V^{1/3} / (\pi T M_S^2), \quad (48)$$

where the first term corresponds to the intrinsic thermal noise of the cavity modes, and the second term is the noise induced by mechanical resonance. At frequencies below $\mathcal{O}(100)$ kHz, the total contribution to $n_{\text{occ}} = N_M n_{\text{occ}}^{\text{th}}$ increases significantly, causing the optimized bandwidth $\Delta\omega_r$ to exceed ω_h . To address this, we impose a cutoff such that t_{int} remains below t_e , achieved by applying the min-function at the end of Eq. (46). We further assume that $\omega - \omega_0 \approx m_a$ or ω_h , and that $\omega \approx \omega_0 \approx \omega_{\text{rf}} \gg m_a$ or ω_h for setups involving heterodyne upconversion. For setups without heterodyne upconversion, including dark photon searches with SRF^{EM}, we assume $\omega_{\text{rf}} \approx \omega \approx m_a, m_{A'}$, or ω_h .

Requiring each case in Eqs. (44,45,46) to reach $\mathcal{O}(1)$, we can establish the sensitivity reach for the single-mode resonant detection, as illustrated in solid lines in Fig. 2. The e -fold time is set at $t_e = 10^7$ s. The relevant benchmark parameters of experiments are as follows:

- LC circuit: $B_0 = 4$ T, $Q_{\text{int}} = 10^6$, $T = 0.01$ K, $V = 1$ m³;
- Cavity: $B_0 = 4$ T, $Q_{\text{int}} = 10^4$, $T = 0.01$ K, $V = 1$ m³;
- SRF: $B_0 = 0.2$ T, $Q_{\text{int}} = 10^{12}$, $T = 1.8$ K, $V = 1$ m³, $\omega_{\text{rf}} \approx \omega_0 = 2\pi$ GHz.

We consider the frequency ranges for traditional and SRF cavities used in dark photon searches to be between GHz and 10 GHz, LC circuits between kHz and 100 MHz, and heterodyne upconversion involving the SRF cavity between kHz and GHz. The axion-photon coupling $g_{a\gamma}$ and the dark photon kinetic mixing coefficient ϵ are included in α , while S_Ψ incorporates h_0^2 . For axion and dark photon dark matter, we set both Q_a and $Q_{A'}$ at 10^6 and assume a local dark matter density of $\rho_{\text{DM}} = 0.45$ GeV/cm³. The HFGW spectrum is generally model-dependent; we assume a quality factor, $Q_h = 10^3$, aligned approximately with the predictions for primordial black hole binary inspiral, considering frequency shifts within t_{int} [30, 52]. This assumption can be generalized to other sources by scaling Q_h according to Eq. (46). The geometric overlapping factor η is set to 1 for the axion and $1/\sqrt{3}$ for the dark photon, reflecting the projections of their random polarizations onto an axis. For GW detection involving electromagnetic coupling, η is set to $1/10$, as outlined in Refs. [29, 30]. In contrast, for mechanical coupling, a specialized cavity shape is designed to maximize deformation-induced transitions, with selected parameters including $Q_p = 10^6$, $\omega_p = 10$ kHz, $M_S = 10$ kg, $\eta_p^t = 1$, and $\eta_p^h = 0.18$ [27].

V. BROADENED RESPONSE WIDTH IN MULTI-MODE RESONATORS

As discussed in Sec. IV, the scan rate of a detector is reflected in the effective response width, defined in Eq. (41) as the range where intrinsic fluctuation noise dominates over readout noise. One method to exceed the quan-

tum limit for scan rates involves squeezing techniques that reduce readout noise levels [34–37]. However, because the single-mode resonant response is a Lorentzian function that decreases quadratically as $|\Omega|$ increases in off-resonant regions, significantly extending the response width is challenging.

Alternatively, by incorporating multiple auxiliary modes connected to the probing sensor, the direct response to signals can be significantly broadened and amplified without increasing the readout noise level [44–46]. For instance, consider the non-Hermitian chain structure modeled as a chain of modes with the interaction Hamiltonian [53, 54]:

$$H_{\text{ch}} = \sum_{k=0}^{N-1} \left(i g \hat{a}_k \hat{a}_{k+1}^\dagger + i G \hat{a}_k \hat{a}_{k+1} + h.c. \right), \quad (49)$$

where the parameters g and G represent the couplings for beam-splitter-type and non-degenerate parametric interactions, respectively [55–59]. This system comprises $N + 1$ modes denoted by \hat{a}_k , with each adjacent pair linked by the two types of interactions. The dynamics described by Eq. (49) can be interpreted as two copies of the Hatano-Nelson model, where two groups of quadratures are amplified in opposite directions [54]. We designate \hat{a}_0 as the probing sensor, while the readout port is connected to the last mode \hat{a}_N , as illustrated in the top panel of Fig. 3. The application of the $N = 1$ model of Eq. (49) for axion DM was previously discussed in Refs. [46, 60].

This section will focus on two examples of multi-mode systems, including the chain described in Eq. (49), and a binary tree structure that amplifies both quadratures [45]. We will derive the corresponding input-output formalism and demonstrate that their response width can be significantly broadened to as large as the order of the resonant frequency.

A. Scattering Matrices For Non-Hermitian Chain

We begin with a chain of resonant modes, where each neighboring pair is linked through both beam-splitter-type interactions and non-degenerate parametric interactions. The system is governed by the Hamiltonian:

$$\begin{aligned} H_{\text{ch}} &= \sum_{k=0}^{N-1} \left(i |g| e^{i\varphi_k^g} \hat{a}_k \hat{a}_{k+1}^\dagger + i |G| e^{i\varphi_k^G} \hat{a}_k \hat{a}_{k+1} + h.c. \right) \\ &= \sum_{k=0}^{N-1} \left[(|g| - |G|) X_k \tilde{Y}_{k+1} - (|g| + |G|) \tilde{X}_{k+1} Y_k \right], \end{aligned} \quad (50)$$

where $\varphi_k^{g/G}$ denote the relative phases of the couplings. Quadrature operators are introduced as follows:

$$\begin{aligned} X_k &\equiv \frac{e^{i\varphi_k^+}}{\sqrt{2}} \hat{a}_k + h.c., & Y_k &\equiv \frac{e^{i\varphi_k^+}}{\sqrt{2i}} \hat{a}_k + h.c., \\ \tilde{X}_k &\equiv \frac{e^{i\varphi_{k-1}^-}}{\sqrt{2}} \hat{a}_k + h.c., & \tilde{Y}_k &\equiv \frac{e^{i\varphi_{k-1}^-}}{\sqrt{2i}} \hat{a}_k + h.c., \end{aligned} \quad (51)$$

where $\varphi_k^\pm \equiv (\varphi_k^G \pm \varphi_k^g)/2$. As depicted in the top panel of Fig. 3, the probe sensor mode and the readout port are strategically positioned at the two opposing termini of the chain, specifically labeled as \hat{a}_0 and \hat{a}_N , respectively.

Assuming zero relative phases $\varphi_k^{g/G} = 0$, we simplify the system's dynamics, leading to decoupled equations of motion for $Y_k = \tilde{Y}_k$:

$$\begin{aligned} (\gamma - i\Omega) Y_0 + (|g| - |G|) Y_1 &= \sqrt{2\gamma} \hat{u}_0, \\ (\gamma - i\Omega) Y_k + (|g| - |G|) Y_{k+1} - (|g| + |G|) Y_{k-1} &= \sqrt{2\gamma} \hat{u}_k, \\ (\gamma + \gamma_r - i\Omega) Y_N - (|g| + |G|) Y_{N-1} &= \sqrt{2\gamma} \hat{u}_N + \sqrt{2\gamma_r} \hat{u}_r, \end{aligned} \quad (52)$$

where all intrinsic dissipation coefficients are simplified as γ . Recursive relations for Y_k are derived from the first two lines of Eq. (52):

$$Y_k = y_k \sum_{j=0}^k \prod_{m=j}^{k-1} \mathcal{G}^{k-j} y_m \sqrt{2\gamma} \hat{u}_j - \mathcal{G} y_k Y_{k+1}, \quad (53)$$

where the series y_k , \mathcal{J} , and \mathcal{G} are defined as:

$$\begin{aligned} y_0 &\equiv 1/(\gamma - i\Omega), & y_k &\equiv 1/(\gamma - i\Omega + \mathcal{J}^2 y_{k-1}), \\ \mathcal{J} &\equiv (|g|^2 - |G|^2)^{1/2}, & \mathcal{G} &\equiv |g| + |G|. \end{aligned} \quad (54)$$

Consequently, the solution for the last mode Y_N is expressed as:

$$Y_N = \frac{\sqrt{2\gamma_r} \hat{u}_r + \sum_{k=0}^N \prod_{j=k}^{N-1} \mathcal{G}^{N-k} y_j \sqrt{2\gamma} \hat{u}_k}{\gamma + \gamma_r - i\Omega + \mathcal{J}^2 y_{N-1}}, \quad (55)$$

which provides the scattering matrix elements entering the readout port:

$$S_{kr} = \frac{-2\sqrt{\gamma\gamma_r} \mathcal{G}^{N-k} f_k}{\gamma_r f_N + f_{N+1}}, \quad S_{rr} = \frac{-\gamma_r f_N + f_{N+1}}{\gamma_r f_N + f_{N+1}}, \quad (56)$$

where f_k is defined as:

$$f_k \equiv \prod_{j=0}^{k-1} \frac{1}{y_j} = \sum_{j=0}^{\lfloor k/2 \rfloor} C_{k-j}^j (\gamma - i\Omega)^{k-2j} \mathcal{J}^{2j}. \quad (57)$$

Here, $\lfloor \dots \rfloor$ denotes the floor function that takes the integer part, and C_{x-j}^j is the binomial coefficient. The stability condition $|g| > |G|$ [53] arises from the poles of the scattering matrix elements, assuming negligible γ .

Similarly, the equations of motion for $X_k = \tilde{X}_k$ differ from those for Y_k only by the sign change in $|G|$, turning

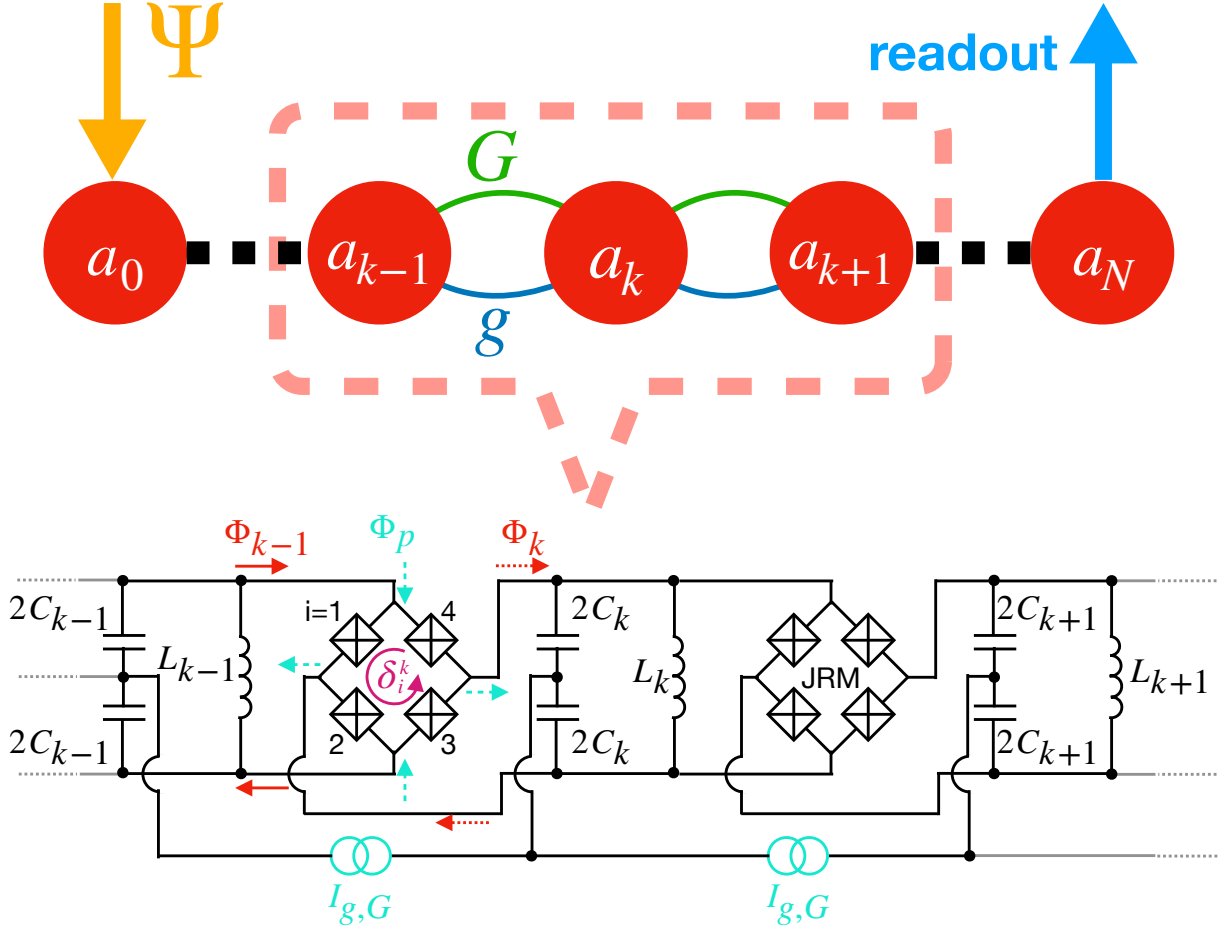

FIG. 3: **Top:** Illustration of a chain of resonant modes as described by Eq. (49). The lowest mode a_0 serves as the probing sensor, and the highest mode a_N functions as the readout. Each pair of adjacent modes is interconnected through both beam-splitter-type (blue) and non-degenerate parametric (green) interactions. **Bottom:** Circuit diagrams showing modes a_{k-1} , a_k , and a_{k+1} connected via Josephson Ring Modulators (JRMs), detailed in Sec. VI A. Each JRM consists of four Josephson junctions (boxes), labeled $i = 1, 2, 3, 4$. The phases δ_i^k of these junctions are defined in a counter-clockwise direction within each JRM (purple). These JRMs facilitate three-wave mixing among Φ_{k-1} (solid red), Φ_k (dashed red), and the pumping mode Φ_p (dashed cyan), driven by a current source $I_{g,G}$ at the bottom.

$|G| \rightarrow -|G|$. When the magnitude of $|g|$ significantly surpasses both γ and \mathcal{J} , the progression of Y_k or X_k results in consecutive increments or decrements, respectively.

In the presence of nonvanishing relative phases $\varphi_k^{g/G}$, the amplification of the k -th mode to the $(k+1)$ -th mode, denoted as Y_k , experiences a misalignment with the previously amplified \tilde{Y}_k . Instead, as defined earlier, they are related by a linear transformation:

$$\tilde{X}_k = X_k \cos \theta_k - Y_k \sin \theta_k, \quad \tilde{Y}_k = X_k \sin \theta_k + Y_k \cos \theta_k. \quad (58)$$

Here, $\theta_k \equiv (\varphi_{k-1}^G - \varphi_{k-1}^g - \varphi_k^G - \varphi_k^g)/2$. Consequently, the amplification process experiences a sequence of attenuation factors expressed as the product $\prod_{k=1}^{N-1} \cos \theta_k$. It is important to observe that even with an initial calibration of all the relative phases, fluctuations in the phase of the pumping modes have the potential to contribute

to $\varphi_k^{g/G}$ [61].

B. Scattering Matrices For Binary Tree

We also consider a multi-mode resonator with a binary tree structure [45]. The corresponding Hamiltonian, denoted as H_{BT} , is formulated as:

$$\begin{aligned} H_{\text{BT}} = & \sum_{i=2}^N \sum_{j=1}^{2^{N-i}} i \hat{a}_{ij} \left(g \hat{a}_{i-1,2j-1}^\dagger + G \hat{c}_{i-1,2j-1} \right) \\ & + \sum_{i=2}^N \sum_{j=1}^{2^{N-i}} i \hat{c}_{ij} \left(g \hat{a}_{i-1,2j}^\dagger + G \hat{c}_{i-1,2j} \right) \\ & + i \hat{b} \left(g \hat{a}_{N1}^\dagger + G \hat{c}_{N1} \right) + h.c., \end{aligned} \quad (59)$$

Similar to the chain-like structure in Eq. (50), the binary tree encompasses both beam-splitter-type interactions and non-degenerate parametric interactions. However, it introduces auxiliary modes and connect every two adjacent modes by either one coupling only. An illustrative example of the model with $N = 3$ is presented in Fig. 4.

FIG. 4: An illustration of a multi-mode resonator with a binary tree structure for $N = 3$. Black lines indicate beam-splitter-like interactions, and blue dashed lines represent non-degenerate parametric interactions. At the lowest level, a network of 2^N sensors is positioned, facilitating the probing of Ψ . The remaining modes are auxiliary modes.

The equation of motion for a mode situated within the middle of the network can be expressed as:

$$\hat{c}_{ij} = \frac{\sqrt{2\gamma} \left[\hat{u}_{ij}^c - \left(g^* \hat{u}_{i-1,2j}^a + G^{r*} \hat{u}_{i-1,2j}^{c\dagger} \right) / (\gamma - i\Omega) \right]}{\gamma - i\Omega + \mathcal{J}^2 / (\gamma - i\Omega)} + \dots, \quad (60)$$

where \dots accounts for terms involving modes not directly connected to \hat{c}_{ij} as well as the coupling with the higher-level mode. The equations of motion for \hat{a}_{ij} differ from Eq. (60) only in the subscript, changing from $2j$ to $2j - 1$. For $|g| \approx |G| \gg \gamma$, the propagation from $\hat{u}_{i-1,2j}^a$ or $\hat{u}_{i-1,2j}^{c\dagger}$ to \hat{c}_{ij} in Eq. (60) is amplified by a factor of $|g/(\gamma - i\Omega)|$, achieving significant amplification similar to the non-Hermitian chain model.

Notably, in the binary tree configuration, both quadratures of each mode within this structure are equally amplified, thus mitigating the issues of phase fluctuations encountered in the non-Hermitian chain [45].

In this setup, approximately 2^N sensors can be positioned at the bottom level to probe Ψ , each undergoing

successive amplification as they propagate toward \hat{b} . The coherent nature of the source background can thus be leveraged to increase the sensitivity.

C. Response Width in Multi-Mode Resonators

As discussed in Sec. IV, the response width governs the sensitivity reach of detectors. This width can be optimized numerically using Eq. (41), or approximated by the range in which intrinsic noise in \hat{a}_0 dominates over other noise contributions, as given by:

$$|S_{0r}|^2 n_{\text{occ}} \gtrsim |S_{rr}|^2 \frac{1}{2} + \frac{1}{2} + \sum_{k=1}^N |S_{kr}|^2 n_{\text{occ}}. \quad (61)$$

To proceed, we first determine the range that satisfies a necessary condition from Eq. (61): the dominance of the left-hand side, representing intrinsic noise, over the readout noise on the right-hand side. This condition is characterized by a nearly constant PSD of approximately 1 for sufficiently small γ . By keeping g , γ , and n_{occ} fixed, we then adjust γ_r to match \mathcal{J} . According to Eq. (56), the condition $|S_{0r}|^2 \gg 1$ holds within the region where $\Omega \ll \gamma_r$, but diminishes swiftly beyond this boundary. Leveraging this observation, we make the following substitutions: \mathcal{J} , γ_r , and Ω are substituted with $\Delta\omega_r$, leading to an optimized response width:

$$\Delta\omega_r^{\text{opt}} \simeq \left(\gamma n_{\text{occ}} \mathcal{G}^{2N} \right)^{1/(2N+1)}, \quad (62)$$

which converges to $2|g|$ for large N . Figure 5 depicts numerical instances of noise PSDs, with $\gamma_r = \Delta\omega_r^{\text{opt}}$ held constant and \mathcal{J} varied. In these scenarios, the remaining condition from Eq. (61)—that intrinsic noise in \hat{a}_0 surpasses other intrinsic noise sources—is inherently fulfilled. The figure demonstrates that a smaller value of \mathcal{J} mildly affects $\Delta\omega_r$, despite compressing the PSD within a narrower Ω range. By setting $\gamma_r = \mathcal{J} = \Delta\omega_r^{\text{opt}}$, we achieve a relatively flat PSD within $\Delta\omega_r$, rendering it robust against potential variations in \mathcal{J} , in light of the reasonable demands for dynamic range.

The binary tree scenario, as introduced in Sec. VB, along with numerical computations based on optimized conditions, exhibits the same scaling of the response width as demonstrated in Eq. (62) [45].

Compared to single-mode resonators, the inclusion of both beam-splitter and non-degenerate parametric interactions with comparable interaction strengths $|g| \sim |G|$ effectively suppresses off-resonant phase shifts, as seen in the denominators of Eqs. (55, 60). This leads to a sequential broadening of the response width. Consequently, by extending the response width from an order of $n_{\text{occ}}\gamma$ to $2|g|$, multi-mode resonators significantly enhance the scan rate beyond that of single-mode resonators, as demonstrated in Fig. 5.

FIG. 5: Noise PSDs for chain detectors with assumptions of $g/\gamma = 10^6$, $n_{\text{occ}} = 10$, and $\gamma_r = \Delta\omega_r^{\text{opt}}$. The black line represents readout noise, while the other solid lines depict the dominant contribution from \hat{a}_0 , which surpasses the remaining intrinsic noise shown by the dashed lines. A decrease in \mathcal{J} results in a squeezed spectrum. The gray arrow line highlights the range where Eq. (61) is applicable, specifically for $N = 5$. For comparison, the intrinsic noise of a single-mode resonator is shown in orange.

VI. REALIZATION OF MULTI-MODE RESONATORS

This section demonstrates the realization of multi-mode resonators that feature significantly broadened response widths, focusing particularly on the beam-splitter-type and non-degenerate parametric interactions between modes, as derived in Sec. V and illustrated in Fig. 3. We will also discuss potential challenges associated with their implementation. Notably, within a multi-mode resonator setup, only one mode at the lowest level needs to function as the probing sensor, as discussed in Secs. II and III. The remaining auxiliary modes may be circuit modes that do not require pick-up loops and are not embedded in a magnetic field background, or they can be other resonant cavity modes within the same cavity.

One method to achieve the necessary couplings is through three-wave mixing, where one pumping mode's frequency matches the sum or difference of the other two, thereby enabling non-degenerate parametric and beam-splitter-type interactions, respectively. Feasible implementations of three-wave mixing include the use of a Josephson Ring Modulator (JRM) [56], Superconducting Nonlinear Asymmetric Inductive eLement (SNAIL) [59], and DC-driven Josephson junction effects [55]. Notably, the JRM structure has recently been utilized to demonstrate response width broadening in a $N = 1$ res-

onator composed of two circuit modes [60]. Thus, we use JRMs as the benchmark for constructing multi-mode resonators, as illustrated in the bottom panel of Fig. 3.

A. Multi-Mode Resonators Connected by Josephson Ring Modulators

The use of a JRM to connect two modes with a third pumping mode is illustrated in the bottom panel of Fig. 3. Each JRM consists of four Josephson junctions, each with the same critical current I_0 , labeled by $i = 1, 2, 3, 4$. This results in a total Hamiltonian given by [56]:

$$H_{\text{ch}} = \sum_{k=1}^N H_{\text{JRM}}^k = \sum_{k=1}^N \sum_{i=1}^4 -I_0 \varphi_0 \cos \delta_i^k, \quad (63)$$

where the sum over k labels the JRM connecting the $(k-1)$ -th and the k -th modes with Hamiltonian H_{JRM}^k , and each junction contributes a cosine potential. $\varphi_0 \equiv 1/(2e)$ is the reduced flux quantum, where e is the elementary charge. δ_i^k represents the phase difference across the i -th Josephson junction of the k -th JRM, with the direction of phase difference defined as counter-clockwise within the JRM, as indicated by the purple arrow in the figure.

The resonant modes Φ_{k-1} and Φ_k are related to δ_i^k through a basis transformation, as mandated by Kirchhoff's voltage law, resulting in:

$$\begin{aligned} \frac{\Phi_{k-1}}{\varphi_0} &= \frac{\delta_1^k + \delta_2^k - \delta_3^k - \delta_4^k}{2}, \quad \frac{\Phi_k}{\varphi_0} = \frac{-\delta_1^k + \delta_2^k + \delta_3^k - \delta_4^k}{2}, \\ \frac{\Phi_p}{\varphi_0} &= \frac{\delta_1^k - \delta_2^k + \delta_3^k - \delta_4^k}{2}, \quad \frac{\Phi_L}{\varphi_0} = -(\delta_1^k + \delta_2^k + \delta_3^k + \delta_4^k). \end{aligned} \quad (64)$$

Here, Φ_L represents the loop flux threading through the JRM, and Φ_p serves as the pumping mode for the three-wave mixing. In the bottom panel of Fig. 3, solid and dashed arrows in red represent Φ_{k-1} and Φ_k , respectively, while dashed arrows in cyan denote Φ_p .

Substituting the basis transformation from Eq. (64) into the Hamiltonian Eq. (63) yields:

$$\begin{aligned} H_{\text{JRM}}^k &= -4I_0\varphi_0 \left(\cos \frac{\Phi_k}{2\varphi_0} \cos \frac{\Phi_{k-1}}{2\varphi_0} \cos \frac{\Phi_p}{2\varphi_0} \cos \frac{\Phi_L}{4\varphi_0} \right. \\ &\quad \left. + \sin \frac{\Phi_k}{2\varphi_0} \sin \frac{\Phi_{k-1}}{2\varphi_0} \sin \frac{\Phi_p}{2\varphi_0} \sin \frac{\Phi_L}{4\varphi_0} \right) \\ &\approx \frac{\sqrt{2}I_0}{4\varphi_0} \left[(\Phi_k^2 + \Phi_{k-1}^2 + \Phi_p^2) - \frac{\Phi_k \Phi_{k-1} \Phi_p}{\varphi_0} \right]. \end{aligned} \quad (65)$$

We universally set the loop flux threading through the JRM as $\Phi_L = \pi\varphi_0$. In the last line, we consider the leading order expansions where $\Phi_k, \Phi_{k-1}, \Phi_p \ll \varphi_0$. This approximation requires operation in the weak signal and low noise limit, where the flux in the resonant modes, Φ_k and Φ_{k-1} , is significantly less than φ_0 . To activate Φ_p as a pump mode, a current source labeled $I_{g,G}$, illustrated

in Fig. 3, is injected at the bottom of the JRM, resulting in:

$$\Phi_p = \frac{\sqrt{2}\varphi_0}{I_0} I_{g,G}, \quad I_{g,G} \equiv I_g \psi_-^k + I_G \psi_+^k, \quad (66)$$

where $\psi_{\pm}^k \equiv \cos[(\omega_{\text{rf}}^{k-1} \pm \omega_{\text{rf}}^k)t]$, and the current amplitudes I_g and I_G are set to values smaller than I_0 . These terms carry the frequencies of the sum and difference between the two resonant modes connected, simultaneously generating beam-splitter-type and non-degenerate parametric interactions.

Taking the currents from Eq. (66) into Eq. (65), the three-wave mixing term proportional to $\Phi_k \Phi_{k-1} \Phi_p$ facilitates both the beam-splitter-type and non-degenerate parametric interactions as described in Eq. (49). Under the rotating wave approximation (RWA), the coupling strengths are given by:

$$|g| = \frac{I_0}{4\varphi_0} \tilde{I}_g \kappa_k \kappa_{k-1}, \quad |G| = \frac{I_0}{4\varphi_0} \tilde{I}_G \kappa_k \kappa_{k-1}, \quad (67)$$

where $\tilde{I}_g \equiv I_g/I_0$, $\tilde{I}_G \equiv I_G/I_0$, and κ_k, κ_{k-1} are the zero-point uncertainties of the respective resonators, defined in Eq. (12).

Note that in addition to the desired couplings, the first term in the last line of Eq. (65) results in frequency shifts $\delta\omega_{\text{rf}}^k$ on the two resonant modes, expressed as

$$\delta\omega_{\text{rf}}^k = \frac{\sqrt{2}I_0}{4\varphi_0} \kappa_k^2. \quad (68)$$

To avoid disrupting the resonator's function, these shifts should remain smaller than the resonant frequencies ω_{rf}^k .

In practice, the amplitudes $|g|$ and $|G|$ dictate the response width $\Delta\omega_r$, as explored in Sec. V. Their magnitudes can be approximated as:

$$|g|, |G| \sim I_0 \tilde{I}_{g/G} \kappa_k \kappa_{k-1} / \varphi_0 \sim e^2 \tilde{I}_{g/G} \kappa_k \kappa_{k-1} E_J, \quad (69)$$

where $E_J \equiv I_0 \varphi_0$ denotes the Josephson energy. Achieving E_J significantly higher than $\mathcal{O}(1)$ GHz has been demonstrated in experiments [62, 63], ensuring that both $|g|$ and $|G|$ can be engineered to be comparable to, but not exceeding, ω_{rf}^k due to the consideration of frequency shifts. We will adopt $\Delta\omega_r \approx 2|g| \approx \omega_{\text{rf}}^k$ of the probing sensor as the operational limit for multi-mode resonators. Before discussing the physics reach, we briefly outline several challenges to realization and experimental operation.

B. Potential Challenges

The implementation of three-wave mixing, as discussed above, has been previously demonstrated in Ref. [56]. Additionally, a prototype that realizes both g and G types of couplings simultaneously using a Josephson Ring Modulator (JRM) has shown the potential to amplify

a mimicking axion signal, achieving a 5.6-fold enhancement in SNR^2 with $N = 1$ [60]. However, constructing a multi-mode resonator capable of significantly broadening the response bandwidth presents several challenges, which we will briefly address along with potential solutions below.

- The foremost challenge is the compatibility of Josephson junctions with strong magnetic fields. Josephson junctions, being superconducting elements, require isolation from background magnetic fields to maintain superconductivity. One approach involves using a transmission line to connect the cavity or circuit with the Josephson junctions, thereby shielding them from direct magnetic exposure [46]. Moreover, the operation of Josephson junctions in magnetic fields up to $\mathcal{O}(1)$ T has been successfully demonstrated [64]. Thus, the apparent incompatibility between Josephson junctions and strong magnetic fields can be effectively mitigated.
- In implementing three-wave mixing as outlined in Eq. (63), with pumping modes defined in Eq. (66), higher-order terms such as $\Phi_k^2 \Phi_p^2$ and $\Phi_{k-1}^2 \Phi_p^2$ could potentially destabilize the resonator. The pumping mode Φ_p^2 oscillates at frequencies $2\omega_{\text{rf}}^k$ or $2\omega_{\text{rf}}^{k-1}$, resulting in terms under the RWA that involve \hat{a}_k^2 and \hat{a}_{k-1}^2 [65]:

$$H_{\text{JRM}}^k \supset \frac{\sqrt{2}I_0}{32\varphi_0} \tilde{I}_g \tilde{I}_G (\kappa_k^2 \hat{a}_k^2 + \kappa_{k-1}^2 \hat{a}_{k-1}^2 + \text{c.c.}), \quad (70)$$

which are known as the self-squeezing terms. These effects can be suppressed by detuning the pumping frequencies from $\omega_{\text{rf}}^{k-1} \mp \omega_{\text{rf}}^k$ [65]. However, a slight deviation from the optimal setting could destabilize the system, particularly when $|g|$ and $|G|$ are large. Notably, in alternative configurations like the binary tree structure discussed in Sec. VB, self-squeezing issues are naturally avoided by using only one type of coupling in each connection, facilitated by the introduction of auxiliary modes.

- Another potential challenge is the phase fluctuation of the pump mode Φ_p , which deviates from the frequencies at $\omega_{\text{rf}}^{k-1} \pm \omega_{\text{rf}}^k$. In the non-Hermitian chain model discussed in Sec. VA, resultant phase fluctuations $\varphi_k^{g/G}$ can quench the amplification [61]. Additionally, misalignment of these phases can suppress the amplification of quadratures as described in Eq. (58). However, the binary tree model in Sec. VB completely circumvents this issue, as both quadratures are equally amplified.
- A large noise occupation number n_{occ} can challenge the assumption $\Phi_k \ll \varphi_0$, as $\Phi_k \sim \sqrt{n_{\text{occ}}} \kappa_k$. According to Eqs. (12) and (13), zero-point uncertainties κ_k are adjustable by modifying the structure of the readout antenna in a cavity or manipulating

the inductance and capacitance of an LC circuit. However, reducing κ_k excessively will diminish the magnitudes of $|g|$ and $|G|$ as defined in Eq. (69), necessitating a higher Josephson energy E_J to compensate.

- The optimized response width discussed in Sec. V assumes that the intrinsic noise levels across all modes are comparable, allowing the contribution from the lowest mode to dominate. This assumption may not hold if the auxiliary modes have lower quality factors Q_{int} than the probing sensor. To maintain dominance of the lowest mode, it is necessary that $(|g| + |G|)^2 \gamma_0 n_{\text{occ}}^0 > \Delta\omega_r^2 \gamma_1 n_{\text{occ}}^1$, where $\gamma_{0/1}$ and $n_{\text{occ}}^{0/1}$ represent the dissipation coefficients and thermal occupation numbers of the probing sensor and the auxiliary mode, respectively. This condition becomes particularly challenging in an SRF cavity with a high Q_{int} and low γ_0 , necessitating that the auxiliary modes also maintain low $\gamma_1 n_{\text{occ}}^1$. To achieve this, one might consider employing other SRF cavities or different cavity modes within the same cavity as auxiliary modes.
- Additionally, when connections are made via JRMs and transmission lines, there is a potential for increased dissipation, which could lower the quality factor of the probing sensors. Consequently, precise noise control and calibration of γ are necessary.

VII. SIMULTANEOUS RESONANT AND BROADBAND DETECTION

As demonstrated in Sec. V and Sec. VI, the response width $\Delta\omega_r$ covered by each scan can be of the same order as ω_{rf} for a multi-mode resonator. In this section, we apply this broadened width to the various detection schemes mentioned previously in Sec. III, establishing how the physics reach can be significantly deepened through multi-mode generalizations.

For both axion and HFGW detection using static magnetic fields, as well as dark photon detection without background fields, the reachable source frequency $\bar{\omega}_\Psi$ typically lies within the bandwidth $\Delta\omega_r$ centered around ω_{rf} . For these cases, Eq. (43) serves as a reliable approximation for estimating the sensitivity reach, with the integration time t_{int} for each scan extending up to t_e as $\Delta\omega_r$ approaches $\omega_{\text{rf}} \sim \bar{\omega}_\Psi$. Compared to single-mode resonators, multi-mode systems exhibit enhanced sensitivity. This enhancement is quantified by the ratio of their respective $\Delta\omega_r$, where for single-mode resonators it is $2n_{\text{occ}}\gamma$ for LC circuits and SRF cavities, and 3γ for traditional cavities, resulting in:

$$\frac{\text{SNR}_{\text{MM}}^2}{\text{SNR}_{\text{SM}}^2} = \frac{\Delta\omega_r^{\text{MM}}}{\Delta\omega_r^{\text{SM}}} \sim \frac{Q_{\text{int}}}{n_{\text{occ}}}. \quad (71)$$

Here, ‘MM’ and ‘SM’ denote multi-mode and single-mode, respectively.

From Eq. (71), we can generalize the SNR^2 calculations from single-mode resonators in Eqs. (44, 45, 46) to multi-mode limits, expressed as follows:

- Axion:

$$\begin{aligned} \text{LC Circuit} &: \frac{\pi}{2} g_{a\gamma}^4 m_a \rho_{\text{DM}}^2 \eta^4 B_0^4 V^{10/3} Q_a Q_{\text{int}}^2 t_e / T^2, \\ \text{Cavity} &: 2\pi \frac{g_{a\gamma}^4}{m_a^5} \rho_{\text{DM}}^2 \eta^4 B_0^4 V^2 Q_a Q_{\text{int}}^2 t_e, \end{aligned} \quad (72)$$

- Dark Photon:

$$\begin{aligned} \text{LC Circuit} &: \frac{\pi}{2} \epsilon^4 m_{A'}^5 \rho_{\text{DM}}^2 \eta^4 V^{10/3} Q_{A'} Q_{\text{int}}^2 t_e / T^2, \\ \text{Cavity} &: 2\pi \frac{\epsilon^4}{m_{A'}} \rho_{\text{DM}}^2 \eta^4 V^2 Q_{A'} Q_{\text{int}}^2 t_e, \\ \text{SRF}^{\text{EM}} &: \frac{\pi}{2} \epsilon^4 m_{A'} \rho_{\text{DM}}^2 \eta^4 V^2 Q_{A'} Q_{\text{int}}^2 t_e / T^2. \end{aligned} \quad (73)$$

- HFGW:

$$\begin{aligned} \text{LC Circuit} &: \frac{1}{8\pi} h_0^4 \omega_h^9 \eta^4 B_0^4 V^{14/3} Q_h Q_{\text{int}}^2 t_e / T^2, \\ \text{Cavity} &: \frac{1}{2\pi} h_0^4 \omega_h^3 \eta^4 B_0^4 V^{10/3} Q_h Q_{\text{int}}^2 t_e. \end{aligned} \quad (74)$$

We utilize the same benchmark experimental parameters as those used for single-mode resonators, detailed in Sec. IV. In Fig. 2, we illustrate the multi-mode physics reach using dashed lines, requiring that Eqs. (72, 73, 74) reach an SNR of 1. Notably, Eq. (71) demonstrates a significant enhancement in SRF^{EM} detection of dark photons, attributable to a high quality factor, $Q_{\text{int}} = 10^{12}$.

On the other hand, for heterodyne upconversion-type detection, operating a pump mode with frequency ω_0 in an SRF cavity allows for the excitation into a signal mode at $\omega_{\text{rf}} = \omega_0 + \bar{\omega}_\Psi$, where $\bar{\omega}_\Psi$ can be significantly lower than ω_{rf} . Notably, when employing the multi-mode extension to SRF cavities, a wide range of $\bar{\omega}_\Psi$ spanning several orders of magnitude can be covered in a single scan. For example, setting $\omega_{\text{rf}} - \omega_0 = 2\pi$ kHz allows probing up to six orders of $\bar{\omega}_\Psi$, ranging from 2π kHz to $\omega_{\text{rf}} - \omega_0 + \Delta\omega_r \approx 2\pi$ GHz, as illustrated in Fig. 6. In principle, even lower frequencies could be explored by further reducing $\omega_{\text{rf}} - \omega_0$, although this would introduce more intrinsic noise [41, 47]. The SNR can be estimated by setting $t_{\text{int}} = N_e t_e$ in Eq. (38), where $N_e = 6 \ln 10$ represents the number of e -folds between kHz and GHz. This yields the ratio:

$$\frac{\text{SNR}_{\text{HUMM}}^2}{\text{SNR}_{\text{HUSM}}^2} \simeq N_e \frac{\bar{\omega}_\Psi Q_{\text{int}}}{\omega_{\text{rf}} n_{\text{occ}}}, \quad (75)$$

where ‘HU’ denotes heterodyne upconversion detection. This enhancement is particularly evident in SRF detection for axion DM and HFGW, thanks to the high-quality factor.

From Eq. (75), the SNR^2 expressions for the multi-mode generalization of heterodyne upconversion detection are as follows:

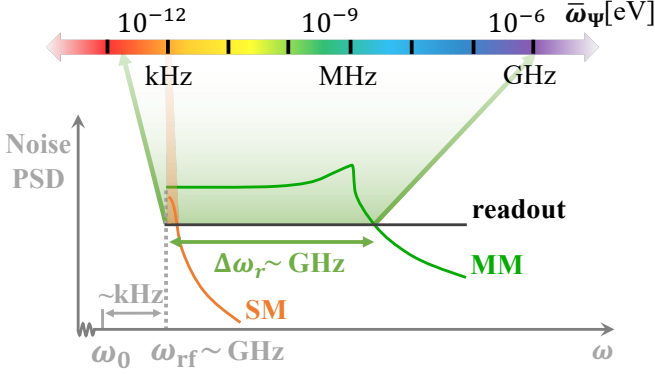

FIG. 6: A schematic plot illustrating the response width, $\Delta\omega_r$, for single-mode (SM) and multi-mode (MM) generalizations of heterodyne upconversion detection. The corresponding coverages of the source frequency, $\bar{\omega}_\Psi$, are shown with shaded areas in orange for SM and green for MM, respectively. The noise PSDs follow the definitions outlined in Fig. 5.

- Axion:

$$\text{SRF}^{\text{EM}} : \frac{3\pi \ln 10}{4} \frac{g_{a\gamma}^4}{m_a} \rho_{\text{DM}}^2 \eta^4 B_0^4 V^2 Q_a Q_{\text{int}}^2 t_e / (\omega_{\text{rf}}^2 T^2). \quad (76)$$

- HFGW:

$$\begin{aligned} \text{SRF}^{\text{EM}} &: \frac{3 \ln 10}{16\pi} h_0^4 \omega_h^7 \eta^4 B_0^4 V^{14/3} Q_h Q_{\text{int}}^2 t_e \omega_{\text{rf}}^2 / T^2. \\ \text{SRF}^{\text{mech}} &: \frac{3 \ln 10}{16\pi} \frac{h_0^4 \omega_h^7 |\eta_p^t \eta_p^h L_p(\omega_h)|^4 B_0^4 V^2 Q_h Q_{\text{int}}^2 t_e \omega_{\text{rf}}^2}{T^2 N_M^2}. \end{aligned} \quad (77)$$

We depict the corresponding physics reach with dashed lines in Fig. 2. The electromagnetic coupling cases of SRF^{EM} demonstrate significant enhancement across various frequencies. However, in the mechanical coupling case, SRF^{mech} , there is negligible enhancement below $\mathcal{O}(100)$ kHz, as the response width in the single-mode case can already cover the order of ω_h at these frequencies.

Notably, apart from the sensitivity enhancement described in Eq. (75), the multi-mode upgrade eliminates the need to tune $\omega_{\text{rf}} - \omega_0$ for each scan step, resulting in a broadband detector. Compared to traditional broadband setups in Refs. [14, 47], the multi-mode design significantly enhances the response to the signal, combining the advantages of resonant detection. In the standard SRF broadband setup, $\omega_0 = \omega_{\text{rf}}$, and an over-coupled readout coupling γ_B is employed, enabling the probing of $\bar{\omega}_\Psi / (2\pi)$ above 10 kHz in the off-resonant region [47] with $|S_{0r}|^2 \approx 4\gamma_B / \bar{\omega}_\Psi^2$. The corresponding signal and noise PSDs are $S_{\text{sig}} \simeq \gamma_B \alpha^2 S_\Psi / \bar{\omega}_\Psi^2$ and $S_{\text{noise}} \simeq 1$, re-

spectively, leading to the following SNR ratio:

$$\frac{\text{SNR}_{\text{HUMM}}^2}{\text{SNR}_{\text{BB}}^2} \simeq \frac{\bar{\omega}_\Psi^4 Q_{\text{int}}^2}{16 \gamma_B^2 \omega_{\text{rf}}^2 n_{\text{occ}}^2}, \quad (78)$$

where ‘BB’ denotes broadband detection. The significant enhancement factor in Eq. (78) is primarily due to the severely suppressed off-resonant response in the standard broadband SRF. For other types of broadband searches, such as those using LR circuits proposed in Ref. [14], the sensor consistently responds to the PSD of effective currents induced from bosonic fields. Consequently, the resultant SNR^2 is substantially lower than that achieved with heterodyne upconversion, reduced by a factor of $Q_{\text{int}}^2 / n_{\text{occ}}^2$.

VIII. DISCUSSION AND CONCLUSIONS

This work demonstrates the efficacy of multi-mode resonators in achieving the advantages of both resonant and broadband detection. These resonators exhibit significant responses to signals across a sensitive bandwidth, spanning one or several orders in the frequency domain of the sources. This capability is achieved by employing both beam-splitter and non-degenerate parametric interactions to connect adjacent modes. By tuning these interactions to comparable magnitudes, off-resonant phases are effectively canceled sequentially, thereby enhancing both the bandwidth and the overall response of the system. Consequently, both the peak value and bandwidth of the scattering matrix increase sequentially during propagation towards the readout port, while the readout noise, which sets the standard quantum limit of the sensitive response width, remains unaffected. By upgrading to multi-mode detectors, the scan rate can be increased by a factor of approximately $Q_{\text{int}} / n_{\text{occ}}$ compared to single-mode detectors. Moreover, the need for frequency tuning and calibration in single-mode resonators is eliminated, saving valuable time and enabling the scanning of large, unexplored regions of axion and dark photon DM, along with HFGWs, within a reasonably short timeframe. Notably, this includes the exploration of the well-motivated QCD axion [9] DM mass window above kHz.

The practical implementation of this concept relies on utilizing Josephson junctions, achievable with mature superconducting technology. The stability of the sensitive response width to variations in the two coupling values ensures the robustness of the quantum network. In the chain model described by Eq. (49), calibration of the relative phases of the two couplings is necessary, and potential decoherence may arise from self-squeezing and phase fluctuations of the pumping modes [61]. However, such issues are circumvented in the binary tree model described in Eq. (59), where the two quadratures are equally amplified [45]. Another crucial consideration is the intrinsic dissipation of the probing sensors,

which requires precise control once the multi-mode array is formed.

Note that the multi-mode resonators discussed in this work are compatible with squeezing technology employed at the readout port [34–37]. Both approaches aim to increase the range in which intrinsic noises dominate over readout noise. To further enhance sensitivity, additional probing sensors can be incorporated [45, 66], which can be naturally embedded into a multi-mode network like the binary tree. Utilizing spatially distributed sensors and sensors with different sensitive directions can reveal both macroscopic properties and the microscopic nature of potential sources, such as angular distribution and polarization [67, 68].
