A Strategy for Identifying Periodic Sources Contributing to the Galactic Center Excess

The origin of the Galactic Center gamma-ray excess (GCE) has not been conclusively determined after over a decade of careful study. The two most widely discussed possibilities are a population of millisecond pulsars (MSPs), and annihilation of dark matter particles. In contrast with annihilating dark matter, MSPs are expected to produce periodic emission. We show that even though the number of photons contributing to the excess is small, there is potentially sufficient information in the data from *F*ermi to detect a periodic MSP signal. Such a detection would definitively prove that at least some fraction of the excess is due to MSPs. We argue that this conclusion is robust to potential timing perturbations of the gamma-ray photons, such as those due to Earth's orbit, even if the number of parameters that must be used to model the perturbations is ~ 7 .

Introduction. One of the most intriguing current puzzles in astrophysics is the origin of the Galactic Center excess (GCE) of GeV-range photons seen in Fermi-LAT data [1–4]. There have been a wide variety of approaches to determining if the GCE arises from dark matter (DM) annihilation, millisecond pulsars (MSPs) [5] or perhaps some other source. One such approach has been to search for non-Poisson fluctuations in the photon counts from the GC [6], which may be expected if some pixels host relatively rare but bright MSPs, which produce several detected photons. Simple estimates indicate that, in optimistic scenarios, ~ 10 photons in a pixel in the 1.9 – 12 GeV energy range might arise from a single pulsar whose luminosity is just below the Fermi-LAT point source threshold, with ~ 10 – 50 photons arising from other sources [6] in a pixel with size of roughly 0.5°.

We consider whether photon timing information can provide additional discriminating power between MSPs and dark matter annihilation. In particular, since MSPs produce photons directed at Earth on a characteristic $\sim 10^{-3}$ s timescale, while Fermi has a timing resolution of order 10^{-6} s [7], one might hope that Fermi could detect a telltale periodicity in photon arrival times in pixels from which a large excess of photons are seen. Such periodicity would not be be expected from dark matter annihilation, or from mismodeled astrophysical backgrounds. In this Letter, we consider in detail the prospects for this strategy.

A key advantage of this search strategy for exploring the nature of the GCE is that it does not rely on having correctly modeled the amplitude, energy dependence, or spatial distribution of the various astrophysical or exotic gamma-ray emission processes. Instead, one essentially analyzes the sum of all gamma-ray emission processes within a pixel, and determines if there is a component which is periodic in time. As such, this strategy is immune to the difficulties in background modeling which plague some other approaches to studying the GCE. The downside is that, although this strategy can potentially determine if a significant fraction of the GCE arises from bright MSPs, it cannot distinguish a contribution from numerous faint MSPs producing photons which are not correlated in time with each other. The time of arrival at *F*ermi-LAT of gamma rays from identified MSPs has previously been used to constrain gravitational waves [8] and wave dark matter [9, 10], using the MSPs as a pulsar-timing array. In this analysis, by contrast, we consider if photon timing can be used to detect the presence of a population of as-of-yet unidentified MSPs.

The GCE in the non-Poisson limit. We focus on the scenario in which the GCE is dominated by a relatively small number of bright pulsars which lie just below the Fermi-LAT threshold for identification as a point source. This scenario may be thought of as the "non-Poisson limit," because the resulting photon counts-in-pixels distribution will be non-Poisson: fluctuations in the photon counts will be dominated by the number of bright pulsars which happen to be in any pixel, rather than by Poisson fluctuations around the mean flux. In particular, we will take as a benchmark the scenario originally discussed in Ref. [6] as an explanation for the observed preference of the GCE for a non-Poisson photon count distribution.¹ In this scenario, the GCE is produced by ~ 300 – 400 unresolved MSPs. The luminosity function for these pulsars (in the 1.9 – 12 GeV range) is strongly peaked at ~ $1-2 \times 10^{-10} \text{ cm}^{-2} \text{s}^{-1}$, with ~ 100-150 MSPs lying just below the point source detection threshold. Given a Fermi-LAT exposure of ~ $7 \times 10^{10} \text{ cm}^2 \text{s}$, one would expect Fermi-LAT to have observed $\mathcal{O}(10)$ photons from each of these unresolved pulsars.

¹ There have been many subsequent refinements in the application of non-Poisson template fitting to the GCE (see, for example, [11–14]), but for the purposes of our study, this original scenario is a reasonable benchmark.

Photon Emission Model. We will consider a simple pulsar emission model, in which the flux from the MSP is described by a periodic train of Gaussians, with the period τ and Gaussian pulse width, w. As pulsar emission in gamma-rays is expected to be sharply peaked in time [15], we will assume that $w \ll \tau$. The total flux (photons per time) at time t contributing to the pixel is then

$$r(t;\theta) = \sum_{z=-\infty}^{z=\infty} r_s \exp\left[-\frac{(t-z\tau-t_0)^2}{2w^2}\right] \Theta(t,z,\tau) + r_b,$$
(1)

where θ represents the model parameters, and

$$\Theta(t, z, \tau) = \begin{cases} 1 & \text{if } z\tau + t_0 - \tau/2 < t < z\tau + t_0 + \tau/2 \\ 0 & \text{otherwise} \end{cases}$$
(2)

is a tophat function that cuts off the pulse so that it has no flux outside of a time period of length τ . In general, since w is significantly smaller than τ , truncating the tails of the pulse has negligible impact. The sum over z in Eq. 1 runs over all integers, but in practice we truncate the sum to the regime relevant to the finite time of the observations. The factors r_s and r_b control the amplitude of the MSP signal and the (time-independent) flux from background sources, respectively. For convenience, we will treat the total expected number of photons observed over time T, from the MSP, N_s , and from backgrounds, N_b , as the free parameters rather than r_s and r_b . In other words, $N_b = r_b T$. This simple model has five parameters: the expected number of photons over the Fermi exposure from the pulsar (N_s) and from time-invariant sources (N_b) , the period τ of the pulsar, the width of the pulse (w) and the phase (t_0) . We will refer to this set of parameters as θ_{simple} .

Likelihood. Assuming the distance between the detector and the emitters remains fixed (we will return to this assumption below), the above model enables us to calculate a likelihood for the observed photon times given θ_{simple} . Consider a time interval T divided into small subintervals Δ such that the number of photons received in each subinterval is either zero or one. The expectation value of the number of photons during $(t, t+\Delta)$ is then $\mu(t) = r(t)\Delta$. The Poisson probability of detecting zero photons in the interval is

$$P(0) = \exp(-r(t)\Delta) \tag{3}$$

and the Poisson probability of detecting one photon is

$$P(1) = (r\Delta) \exp\left(-r(t)\Delta\right). \tag{4}$$

The total likelihood for the data vector, \vec{d} , consisting of ones and zeros representing photon detection/nondetection is then

$$\mathcal{L}_{\text{simple}}(\theta_{\text{simple}}|\vec{d}) = \prod_{i} [\delta_{0d_{i}}P(0) + \delta_{1d_{i}}P(1)] = \prod_{i}^{N_{T}-N} \exp(-r(t_{i})\Delta) \prod_{i}^{N} (r(t_{i})\Delta) \exp(-r(t_{i})\Delta)$$
$$= e^{-\int_{T} r(t_{i})dt} \prod_{i}^{N} r(t_{i})\Delta, \tag{5}$$

where N is the number of intervals that have a detected photon, N_T is the total number of intervals, δ is a Kronecker δ , and the final product runs over all detected photons. This likelihood was first derived in Gregory and Loredo [16].

 $^{^{2}}$ It would be rare for two or more bright pulsars to lie in the same pixel, so we will ignore that possibility, as it will not affect our results significantly.

Of course, there are several effects that are not encapsulated by the simple model we have introduced. For example, the motion of the Earth around the Sun will induce a perturbation to the photon arrival times as the distance between the detector and the emission source is modulated.

The effect of some perturbations is to shift the arrival of the photons times in a completely deterministic and invertible way. By this we mean that given some set of parameters, θ_{pert} describing the perturbation, the perturbed detection time, t' is related to the unperturbed time, t, by

$$t' = f(t; \theta_{\text{pert}}), \tag{6}$$

where f is some function which can depend on θ_{pert} , and which is invertible. We restrict our consideration here to perturbations for which $dt'/dt = \dot{f} \sim 1$.

Perturbations of this type would include, for instance, perturbation to photon arrival times caused by Earth's orbit and by the orbit of Fermi around the Earth. The effect of such perturbations is to add or subtract some additional time delay to the photons; this perturbation could be inverted by simply subtracting off this time delay. Moreover, for such perturbations, $\dot{f} - 1 \sim \mathcal{O}(v/c) \ll 1$, where v is a velocity scale characteristic of Fermi, the Earth, the Sun, or the MSP. As another example, note that MSPs can have a gamma ray pulse profile with two repeating pulses which are not equally spaced in time; such a perturbation is also of this type, with a constant shift in time for every other pulse. But not all perturbations to the photon arrival times can be written in this way, as we will discuss below.

The key point is that if the perturbation can be written in this way, then it is in principle possible to solve for t given the observed time t' and the parameters θ_{pert} : $t = f^{-1}(t'; \theta_{pert})$.

A key simplification now arises in the calculation of the likelihood. In particular, since the perturbation can be exactly undone, we find

$$\mathcal{L}(\theta_{\text{pert}}, \theta_{\text{simple}} | \vec{d}) = \mathcal{L}_{\text{simple}}(\theta_{\text{simple}} | f^{-1}(\vec{d}; \theta_{\text{pert}})).$$
(7)

In other words, the likelihood of obtaining data \vec{d} , given a model parameterized by θ_{simple} and θ_{pert} , is the same as the likelihood of obtaining data \vec{d} but with the effect of the perturbations on the data removed, given the simple pulsar model with parameters θ_{simple} . Note that we have implicitly used the fact that $dt'/dt \sim 1$. Generally, perturbations of this form will not only shift the photon arrival time, but will also rescale the probability density by a Jacobian factor; we consider perturbations for which this factor is close to $1.^3$

In Eq. 7, every photon is assumed to have originated from the pulsar, and their arrival times are modified by removing the effect that the perturbation (parameterized by θ_{pert}) had. Of course, many, if not most photons may have originated with the time-invariant background. However, Eq. 7 is nevertheless true: since the background is time-invariant, the probability of a background photon arriving in one time bin is the same as in any other time bin. Thus, as long as perturbations to the MSP photons can be written as in Eq. 6, we can relate the likelihood of the data given these perturbations to the likelihood in their absence.

Measuring feasibility of detection. Our goal is now to determine if there is enough information in the Fermi-LAT photon timing data to distinguish a preference for the model with a pulsar in the pixel over a model with no pulsar, and only a time-invariant background. For this purpose, we will generate mock datasets with the expected statistical power of the Fermi data. To assess a preference for the model with a MSP over the model without a MSP we will utilize the Bayesian Information Criterion (BIC), which is given by

$$BIC = k \ln n - 2\mathcal{L}^{\max}, \tag{8}$$

where k is the number of parameters in the model, n is the number of data points, and \mathcal{L}^{\max} is the maximum likelihood of the data under the corresponding model.

We would like to compute the BIC for the model with a pulsar in the pixel (BIC^{signal}) and the BIC for the model with no pulsar in the pixel (BIC^{bgd}) . A smaller BIC implies a greater preference for the model, so we consider the quantity

$$\Delta BIC \equiv BIC^{\text{signal}} - BIC^{\text{bgd}},$$

= $\Delta k \ln n - 2\Delta \mathcal{L}^{\text{max}}.$ (9)

³ More generally, perturbations of this form will rescale the width of pulse by the inverse of the Jacobian factor. Assuming the pulse width is small compared to the time binning, the Jacobian factors will in any case cancel.

If $\Delta BIC \leq -10$, when summed over all pixels with anomalously high photon count, then Fermi-LAT data has, at least in principle, enough information to distinguish the presence of a periodic source in those pixels. Note, however, that since we expect about a hundred such pixels hosting bright MSPs, ΔBIC averaged over all such pixels need only be slightly negative.

Unfortunately, we do not have a precise model for the perturbations to the periodic pulsar timing signal. However, even without such a model, we can set an upper limit on ΔBIC with the following argument. The maximum likelihood of the data over the full parameter space ($\theta_{pert}, \theta_{simple}$) is necessarily greater than or equal to the maximum likelihood of the same data over the restricted space θ_{simple} , with θ_{pert} fixed to the true values. But we argued above that when the perturbation can be exactly undone, the likelihood for the perturbed data can be related to the likelihood of unperturbed data under the simple model. We therefore find

$$\mathcal{L}_{\max}^{\text{signal}} = \max_{(\theta_{\text{simple}}, \theta_{\text{perturb}})} \mathcal{L}(\theta_{\text{simple}}, \theta_{\text{perturb}} | \vec{d}) > \max_{\theta_{\text{simple}}} \mathcal{L}(\theta_{\text{simple}} | f^{-1}(\vec{d}; \theta_{\text{perturb}}^{\text{true}})).$$
(10)

For the time-invariant background model, perturbations to the photon times do not change the likelihood. The maximum likelihood under the background-only model, \mathcal{L}_{bgd}^{max} , can thus be computed by simply maximizing Eq. 5 over r_b with r_s fixed to zero:

$$\mathcal{L}_{\max}^{\text{bgd}} = \max_{r_b} \mathcal{L}_{\text{simple}}(r_b, r_s = 0 | \vec{d}) = \max_{r_b} \mathcal{L}_{\text{simple}}(r_b, r_s = 0 | f^{-1}(\vec{d}; \theta_{\text{perturb}}^{\text{true}})).$$
(11)

We then have

$$\Delta \mathcal{L}^{\max} = \mathcal{L}^{\text{signal}}_{\max} - \mathcal{L}^{\text{bgd}}_{\max}$$
(12)

$$> \max_{\theta_{\text{simple}}} \mathcal{L}_{\text{simple}}(\theta_{\text{simple}} | f^{-1}(\vec{d}; \theta_{\text{perturb}}^{\text{true}})) - \max_{r_b} \mathcal{L}_{\text{simple}}(r_b, r_s = 0 | f^{-1}(\vec{d}; \theta_{\text{perturb}}^{\text{true}}))$$
(13)

$$\equiv \Delta \mathcal{L}_{\text{simple}}^{\text{max}}.$$
(14)

This last term is just the difference in maximum likelihoods between the simple model and background-only model, evaluated on data with no perturbations. The arguments above demonstrate that this difference sets a lower limit on the true $\Delta \mathcal{L}^{\text{max}}$.

We constrain $\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$ by simulating unperturbed data, and finding the maximum likelihood over the θ_{simple} parameter space and over the background-only parameter space. Finally, our constraint on $\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$ translates into a limit on ΔBIC :

$$\Delta BIC < \Delta k \ln n - 2\Delta \mathcal{L}_{\text{simple}}^{\text{max}}.$$
(15)

Results. We generate mock data sets from the simple model, fixing the true parameters to $(\tau, w, t_0) = (5 \text{ ms}, 0.5 \text{ ms}, 0)$. A ratio $w/\tau \sim 0.1$ is typical of known MSP gamma ray pulse profiles [17]. We set the time resolution to 5×10^{-4} s, the same as the pulse width, and easily achievable given the performance of Fermi. Fermi's time resolution is significantly better than 5×10^{-4} s, and in principle finer binning could be used. Our choice of coarse binning means that the pulses are highly under-sampled. The motivation for this choice is to reduce our sensitivity to perturbations to pulse shape, etc. We explore the sensitivity of our results to these choices in the Appendix. We set the total observation time to 10^8 s. We will consider several choices of N_s and N_b .

For a given mock data set, we maximize the likelihood over θ_{simple} using the basin hopping algorithm [18]. We also compute the maximum likelihood for the background-only model, varying only r_b . The difference between these maximum likelihood values is then $\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$. Finally, we repeat this process many times to build a distribution for $2\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$. The condition $\Delta k \ln n < 2\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$ will then allow us to estimate the maximum number of parameters θ_{pert} which can perturb our simple periodic model, while still guaranteeing that there is sufficient information in the data to determine the presence of periodic sources. Note that since we are only setting a lower limit on $\Delta \ln \mathcal{L}^{\text{max}}$, it is possible that a detection could be achieved with more than this number of parameters. Our results can therefore be viewed as conservative. We plot the distributions of $2\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$ in Figure 1 (red histograms) for data generated assuming $(N_s, N_b) = (10, 30)$ (far left), (10, 50) (middle left), (250, 750) (middle right) and (250, 1250) (right). In each panel, we also plot the distribution of $2\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$ when the true data includes no signal contribution, but is background-only with an expected number of photons given by the value of $N_s + N_b$ used in each panel (blue histograms, labelled 'Null test'). For $N_s = 10$ (and $N_b = 30$ or 50) we find that the distribution of $2\Delta \mathcal{L}_{\text{simple}}^{\text{max}}$ for a pixel containing a bright MSP is essentially indistinguishable from one with only time-invariant backgrounds, indicating that there is clearly not enough information in the timing data to detect evidence of the periodic MSP (left two panels of Fig. 1). However, we may consider the possibility of increasing the energy range of the photons included in our analysis in order to

FIG. 1: Histograms of $2\Delta \ln \mathcal{L}_{\text{simple}}^{\text{max}}$ from the mock data analysis. In each case, we have generated 100 mock data sets at the true parameter values indicated in the text, and for the values of N_b, N_s indicated at the top of each panel (red). The blue histograms are similar, but describe the case in which the parameter values used to generate the mock data are for the background-only model, with $N_s + N_b$ held fixed.

increase the number of photons arising from a periodic source. It was estimated above that an MSP lying just below the point source detection threshold would produce ~ 10 photons in the energy range 2 – 12 GeV. However, Fermi can detect photons up to an order of magnitude lower in energy. Since an MSP gamma-ray energy spectrum scales roughly as $E^{-1.5}$ [19], one might expect that up to $N_s \sim 250$ could be reasonably obtained, for an MSP just below the point source detection threshold, with current Fermi exposure, given an energy window above the Fermi energy threshold. If we assume that this increase in the energy range increases N_b proportionally, then our most optimistic benchmarks would be $(N_s, N_b) = (250, 750)$ or (250, 1250).

If $N_s = 250$ (for either $N_b = 750$ or 1250) the distribution is peaked at $2\Delta \ln \mathcal{L} \sim 70$, implying that if the number of parameters needed to describe the pulsar model is $\Delta k \leq 70/\ln(1500) \approx 10$, then there will be sufficient information in the data to detect the periodic MSP signal (right two panels of Fig. 1). Beyond N_b and the Gaussian width (which does not affect the likelihood when the time binning is sufficiently coarse), the simple pulsar model has 3 parameters, implying that perturbations to the arrival times described by less than roughly 7 parameters are still guaranteed adequate detection prospects.

In Figure 2 in the Appendix, we repeat this analysis for a few other choices of N_s , N_b , ΔT and w, in order to determine how the distribution of $2\Delta \mathcal{L}_{simple}^{max}$ changes with these parameters. We see that increasing N_b has a relatively mild effect on the likelihood, compared to increasing N_s . Evidently, our ability to detect the presence of a periodic source is limited less by the size of the time-invariant background than by the necessity of having enough periodic photons to constrain the model parameters. We also see that reducing the size of the pulse width, in comparison to the period, tends to lead to greater discriminating power. Thus, the presence of pulsars with smaller gamma-ray pulse widths than our benchmark assumption can lead to improved sensitivity.

Other perturbations. Some perturbations to photon arrival times may not be expressible in a form like Eq. 6. One such perturbation, for example, is a possible spin down of the pulsar. Spin down will change the times of the pulses, but it will also change their widths. More generally, beyond changes to the arrival time of a pulse, perturbations can change the pulse width, or the expected number of photons per pulse. Since we use time bins that are comparable in width to the pulses, changes to the pulse widths over the observation time would have to be O(1) in order to significantly impact our results. But we are justified in assuming that the effects of spin down cannot be large on the timescale of Fermi observation. Given that the age of a typical MSP is $O(10^9)$ yr, it is unlikely that a pulsar from which gamma rays can be detected with a $O(10^{-3})$ s period today, could have either a luminosity in gamma-rays which is decreasing rapidly, or a width which is increasing rapidly with respect to the bin size, over the period of observation.

For radio pulsars, an additional source of perturbations to pulse timing is propagation of the pulses through plasma, leading to a pulse delay that is related to the dispersion measure. This effect would not be of the form Eq. 6 because of its stochastic nature: the dispersion measure can vary with time as the relative positions of the Earth, plasma, and MSP change. For gamma-rays, however, such propagation effects are expected to be negligible [8].

Discussion. We have considered a strategy for testing if a sizeable contribution to the Galactic Center GeV excess arises from a population of bright millisecond pulsars, which each produce several photons seen by Fermi-LAT. Such a population of MSPs may be responsible for non-Poisson fluctuations in the photon counts in pixels found in some recent analyses of the GC excess. Our strategy is to use the fact that the timing resolution of Fermi-LAT ($\mathcal{O}(10^{-6})$ s) is much smaller than period of these sources, suggesting that Fermi-LAT data may contain enough information to

We have found that if a typical bright pulsar produces ~ 250 photons seen by Fermi-LAT within the energy range of interest, then there is, in principle, enough information in the photon timing data to identify the presence of $\sim 1 \text{ ms}$ periodicity in the photon arrival times, even if these times are perturbed via a perturbation model with ~ 7 free parameters.

detect the presence of periodic sources with a high degree of confidence.

Our analysis has essentially been a proof of principle. It would be interesting to apply this type of analysis to current *F*ermi-LAT data. A first step would be the development of a robust pulsar gamma-ray emission model, including a detailed parameterization of the effects which could perturb the timing of gamma ray emission.

In this analysis, we have only considered the timing of photons in a pixel, not the detailed energy spectrum. Since the energy spectrum of pulsar gamma-ray emission will differ from that of other astrophysical backgrounds, additional information may be contained in correlations between the photon energy and photon arrival times. A more detailed study of this possibility would be an interesting topic for future work.
