#### ABSTRACT

ASASSN-14ko was identified as an abnormal periodic nuclear transient with a potential decreasing period. Its outbursts in the optical and UV bands have displayed a consistent and smooth "fast-rise and slow-decay" pattern since its discovery, which has recently experienced an unexpected alteration in the last two epochs, as revealed by our proposed high-cadence *Swift* observations. The new light curve profiles show a bump during the rising stages and a rebrightening during the declining stages, making them much broader and symmetrical than the previous ones. In the last two epochs, there is no significant difference in the X-ray spectral slope compared to the previous one, and its overall luminosity is lower than those of the previous epochs. The energy released in the early bump and rebrightening phases (~  $10^{50}$  erg) could be due to collision of the stripped stream from partial tidal disruption events with an expanded accretion disk. We also discussed other potential explanations, such as disk instability and star-disk collisions. Further high-cadence multiwavelength observations of subsequent cycles are encouraged to comprehend the unique periodic source with its new intriguing features.

#### 1. INTRODUCTION

Quasiperiodicity is a phenomenon that is often observed in active galactic nuclei (AGNs). OJ 287 is a well-known example of this, exhibiting a 12 vr quasiperiodic oscillation (QPO) in its optical light curve (Sillanpaa et al. 1988). This QPO is thought to be caused by a supermassive black hole binary (SMBHB; Lehto & Valtonen 1996; Valtonen et al. 2008). Furthermore, PG 1553 + 113 (Ackermann et al. 2015) and SDSS J143016.05 + 230344.4 (Jiang et al. 2022) have both been observed to show OPOs, and are likely to host SMB-HBs. However, some AGNs display short-term QPOs in their X-ray emission, such as RE J1034+396, which has a QPO of the order of 1 hr (Gierliński et al. 2008). These short-term QPOs in X-rays may be generated by the inner disk (Jin et al. 2021), while long-term QPOs may be the result of SMBHBs (Huang et al. 2021).

Recently, another quasiperiodic phenomenon in Xrays known as quasiperiodic eruption (QPE) has been discovered in GSN 069 (Shu et al. 2018; Miniutti et al. 2019). This signal is only present in the low state and disappears in the high state (Miniutti et al. 2023b,a). Five other sources with QPEs have been identified, such as RXJ1301.9+2747 (Sun et al. 2013; Giustini et al. 2020), eRO-QPE1, eRO-QPE2 (Arcodia et al. 2021), XMMSL1 J024916.6-041244 (Chakraborty et al. 2021), AT2019vcb (Quintin et al. 2023) and Swift J023017.0+283603 (Evans et al. 2023; Guolo et al. 2023). Additionally, a smaller type of recurrent X-ray eruption sources, called ultraluminous X-ray bursts (UXBs), were discovered by Irwin et al. (2016).

ASASSN-14ko is a nuclear transient located in the Seyfert 2 galaxy ESO 253–G003, which was discovered in 2014 (Holoien et al. 2014). It has been observed to have a strong periodicity in its UV/optical light curves, with a period of 115 days and a negative period derivative of -0.0026 (Payne et al. 2021, 2023). The light curves of each outburst have a "fast rise and slow decay" pattern, and the optical spectra show a blue wing in  $H\beta$  during the flare that is absent in the quiescent state (Payne et al. 2021). It is thought to be related to a partial tidal disruption event (TDE; Payne et al. 2021, 2022; Tucker et al. 2021), which is caused by an evolved star on an eccentric orbit (Liu et al. 2023a). Additionally, Cufari et al. (2022) suggest that the disrupted star originated from a binary system via the Hills mechanism. Metzger et al. (2022) propose that the periodic behavior may be due to the mass transfer in a coorbiting extreme mass ratio inspiral system consisting of a supermassive black hole (SMBH) and a binary. King (2023) believes that mass transfer between the white dwarf and SMBH can induce such periodic variability, which was previously suggested by Shen (2019) to explain UXBs. However, it should be noted that ASASSN-14ko has a black hole mass of  $10^{7.85} M_{\odot}$  (Payne et al. 2021), and such a black hole would swallow a white dwarf without disrupting it. Alternatively, Suková et al. (2021) argue that the periodic outburst could also be produced by the periodic perturbation of a star in the accretion flow. Similarly, star-disk interaction is also thought to could produce this phenomenon (Linial & Quataert 2023).

Rebrightenings are a common phenomenon in TDEs when the sources are monitored for a long enough duration (Jiang et al. 2019; Yao et al. 2023). They can be caused by the circularization of debris and delayed accretion following the initiation disruption (Chen et al. 2022; Wang et al. 2023). Other potential explanations for rebrightenings include partial TDE (Wevers et al. 2023; Malvali et al. 2023; Liu et al. 2023b) and SMBHB systems (Liu et al. 2014; Shu et al. 2020). It is worth noting that, in addition to the rebrightening observed after the primary peak, an early bump during the rising stage has also been detected in AT2020wey (Charalampopoulos et al. 2023). Partial TDEs offer us a great opportunity to observe the entire process across multiple wavelengths due to its repeatability. Consequently, we have requested several target of opportunity (ToO) observations from Swift to conduct multiwavelength observations on ASASSN-14ko. In this paper, we present new observations of this source and newly discovered phenomena. In Section 2, we describe the data reduction and the multiwavelength light curves. In Section 3, we analyze the X-ray spectra and the multiwavelength light curves. Finally, we discuss the physical mechanism of early bumps and rebrightenings in Section 4. In this work we assume cosmological parameters of  $H_0 = 70 \,\mathrm{km s^{-1}}, \mathrm{Mpc^{-1}}, \,\Omega_\mathrm{M} = 0.3, \,\mathrm{and}\,\,\Omega_\Lambda = 0.7$  in this work.

### 2. DATA REDUCTION AND RESULTS

# 2.1. Swift X-Ray photometry

We use the X-Ray Telescope (XRT) on board the Neil Gehrels *Swift* Observatory to perform X-ray photometry of the object, with a sensitivity range of 0.3 - 10.0 keV (Burrows et al. 2005). To monitor its multiwavelength behavior, we have requested 10 ToO observations with high cadence starting from 2022 December 2. We also retrieve the public data (PI: Payne) from the High Energy Astrophysics Science Archive Research Center (HEASARC) website. The *Swift* data are processed with HEASoft 6.31.1. To obtain the products (e.g., light curves and spectra), we run the task xrtpipeline, and then xrtproducts. The source region is chosen as a circular region centered on the object with a radius of 47.1", and the background region is chosen as a nearby circular region with a radius of 120".

# 2.2. Swift UV/Optical photometry

The UV/Optical Telescope (UVOT) is another instrument in the *Swift* observatory, which is equipped with seven filters (V, B, U, UVW1, UVM2, UVW2 and white) (Roming et al. 2005). We run uvotimsum to sum up the images and then execute the task uvotsource to generate the light curves with the source and background regions defined by circles with radii of 10" and 40", respectively. Following Schlafly & Finkbeiner (2011), we derive the Galactic extinction value of E(B - V) = 0.043 using an online tool<sup>1</sup>, and then we corrected the magnitude for each band using the extinction law of Cardelli et al. (1989). In this work, we adopt the Galactic extinction values of 0.14, 0.18, 0.21, 0.27, 0.42, and 0.41 mag for the V, B, U, UVW1, UVM2, and UVW2bands, respectively.

### 2.3. Multiwavelength light curves

The UV/optical light curves of ASASSN-14ko show a "fast rise and slow decay" pattern, which has been reported in previous work (Payne et al. 2021, 2022, 2023). Long-term multiwavelength light curves are shown in Figure 1. For convenience, we have divided the period of MJD 58927–60110 into different epochs. As we can see, the UV/optical light curves in epochs 10 and 11 do not follow a trend similar to that in previous epochs. Interestingly, early bumps can be seen in the rising part of the UV/optical light curves in epochs 10 and 11. Additionally, the rebrightening feature is also detected in both epochs 10 and 11. We carefully examined the light curves of previous epochs and read the detailed reports

<sup>&</sup>lt;sup>1</sup> https://irsa.ipac.caltech.edu/applications/DUST/

Figure 1. Multiwavelength light curves of ASASSN-14ko. In panel (a), the historical X-ray light curve, hardness ratio, and UV/optical light curves are shown. In panel (b), we plot the details of the multiwavelength light curves of the new observations. For comparison, the light curves of epochs 2 and 3 are also plotted. The early bumps and rebrightenings are marked by a color shadow region. The magnitudes are host-subtracted. The triangles represent the  $3\sigma$  upper limit.

of Payne et al. (2021, 2022, 2023), and discovered that the bump during the rising phase and the rebrightening during the declining phase is an unprecedented occurrence. Moreover, the X-ray light curve in the interval covering epochs 10 and 11 shows signs of quasiperiodicity and we derive a probable period of 2 months using the Lomb-Scargle package (VanderPlas 2018). However, more high-cadence X-ray observations are needed to confirm the periodicity.

### 2.3.1. UV/Optical light curves in epoch 10

For epoch 10, the UV/optical bands start to rise from MJD 59935 and reach the early bump at MJD 59943. At the bump, the host-subtracted magnitudes are 16.12 (upper limit), 16.81, 16.77, 16.89, 16.72, 16.65 for V, B, U, UVW1, UVM2, and UVW2, respectively. The bump lasts until MJD 59952 and then the UV/optical bands continue to rise and reach the peak at MJD 59962, with the magnitudes of 16.42, 16.02, 15.81, 15.87, 15.66, 15.59 for V, B, U, UVW1, UVM2, and UVW2, respectively. After the peak, the UV/optical light curves decline until MJD 59970, with magnitudes of 16.91 (upper limit), 16.65, 16.58, 16.78, 16.69, 16.63 in V, B, U, UVW1, UVM2, and UVW2, respectively. Subsequently, a rebrightening trend is observed and the brightness increases to magnitudes of 16.53, 16.19, 16.22, 16.23, 16.09, and 16.02 (V, B, U, UVW1, UVM2, and UVW2) at MJD 59975. Unfortunately, Swift missed the peak of the rebrightening phase.

### 2.3.2. UV/Optical light curves in epoch 11

In epoch 11, the UV/optical bands rise slowly from MJD 60034. Instead of a smooth evolution, fluctuations can be seen in the rising phase. We use the  $\chi^2$  test to assess the significance of the "fluctuations" in different bands during the rising phase. We find that the "fluctuations" are significant, although the data have relatively large errors. The same test is applied to the data set from epoch 10, and no significant fluctuations are found. Until MJD 60060, the UV/optical reach a short plateau with magnitudes of 16.86 (upper limit), 16.62, 16.72, 16.82, 16.63, and 16.59 in V, B, U, UVW1, UVM2, and UVW2, respectively. At MJD 60065, they start to rise and reach the UV peak at MJD 60070, with magnitudes of 16.15, 15.82, 15.70, 15.68, 15.49, and 15.39 for V, B, U, UVW1, UVM2, and UVW2, respectively. After the peak, the brightness declines and a rebrightening phenomenon is seen until MJD 60075. The peak of rebrightening is around MJD 60081, with magnitudes of 16.12, 15.90, 15.92, 15.89, 15.74, and 15.72 for V, B, U, UVW1, UVM2, and UVW2, respectively. As the light curves drop, a small bump is seen in the range of MJD 60089–60096. During the peak of this small bump, the

magnitudes of V, B, U, UVW1, UVM2, and UVW2 are 16.85 (upper limit), 16.51, 16.51, 16.84, 16.69, and 16.64, respectively.

### 3. ANALYSIS

### 3.1. UV/Optical Evolution in Epochs 10 and 11

We use the Python package lmfit (Newville et al. 2016) to fit the spectral energy distributions (SEDs) of the simultaneous UV/optical bands with a blackbody model, and obtain the evolution of the blackbody temperature (T<sub>bb</sub>) and radius (R<sub>bb</sub>). SED fittings are shown in Figure 2. During epochs 10 and 11, the blackbody temperature evolves with luminosity (L<sub>bb</sub>), but remains high (> 10<sup>4</sup> K) even when the source is quiescent (around log(L<sub>bb</sub>/erg s<sup>-1</sup>) = 43, within an amplitude of 0.2). The results are shown in Figure 3.

In the first peak during epoch 10 (MJD 59962), we derive a peak luminosity of log ( $L_{bb}/erg s^{-1}$ ) = 44.24 ± 0.22, with log ( $T_{bb}/K$ ) = 4.37 ± 0.05 and log ( $R_{bb}/cm$ ) = 14.95 ± 0.06. For the early bump, we derive a maximum luminosity of log ( $L_{bb}/erg s^{-1}$ ) = 43.78 ± 0.27 in MJD 59943, with log ( $T_{bb}/K$ ) = 4.32 ± 0.05 and log ( $R_{bb}/cm$ ) = 14.81 ± 0.08. During the rebrightening phase, we derive a maximum luminosity of log ( $L_{bb}/erg s^{-1}$ ) = 44.04 ± 0.25 in MJD 59975, with log ( $T_{bb}/K$ ) = 4.34 ± 0.05 and log ( $R_{bb}/cm$ ) = 14.92 ± 0.08.

During epoch 11, we obtain a peak luminosity of  $\log (L_{bb}/\text{erg s}^{-1}) = 44.33 \pm 0.23$  in MJD 60070, and the temperature and radius are  $\log (T_{bb}/\text{K}) = 4.39 \pm 0.05$  and  $\log (R_{bb}/\text{cm}) = 14.97 \pm 0.06$ , respectively. On the short plateau, we derive  $\log (L_{bb}/\text{erg s}^{-1}) = 43.81 \pm 0.27$ ,  $\log (T_{bb}/\text{K}) = 4.31 \pm 0.05$  and  $\log (R_{bb}/\text{cm}) = 14.85 \pm 0.09$  in MJD 60060. In the rebrightening phase of epoch 11, we derive a maximum luminosity of  $\log (L_{bb}/\text{erg s}^{-1}) = 44.17 \pm 0.20$  in MJD 60081, with  $\log (T_{bb}/\text{K}) = 4.33 \pm 0.04$  and  $\log (R_{bb}/\text{cm}) = 14.99 \pm 0.06$ .

#### 3.2. X-Ray behavior in Epochs 10 and 11

During epochs 10 and 11, *Swift* observes a relatively low brightness with a mean count rate of 0.01, compared to the previous epochs, which have an average count rate of 0.03. The average hardness ratio  $(HR)^2$  in epochs 10– 11 is -0.08, while for previous epochs, the value is -0.24.

To analyze the X-ray spectra in epochs 10 and 11, we stack the spectra in the three epochs separately and

<sup>&</sup>lt;sup>2</sup> The hardness ratio is defined by  $\frac{H-S}{H+S}$ , where H and S denote the count rate of the hard X-ray (2.0–10.0 keV) and the soft X-ray (0.3–2.0 keV), respectively.

Figure 2. SED fitting results of epochs 10 and 11. The time in the legend is relative to the UV peak. The X-ray data points at 2 keV are plotted, but are not included in the fitting.

Figure 3. Evolution of UV/optical bands. Here, to reduce the impact of the large data error in the v band, we excluded this band and fitted the remaining data to derive the results. The top panel plots the evolution of host-subtracted UV/optical bolometric luminosity. The evolution of the blackbody temperature and radius are shown on the middle and bottom panels.

group them with a minimum of 10 photons. The effective exposure times are 363, 82.5, 90.58 ks for the spectrum of previous epochs, epoch 10 and epoch 11, respectively. Through xspec v12.13.0c, three spectra including previous epochs, epochs 10 and 11 are fitted by an absorb power-law model (tbabs\*zashift\*powerlw). The XRT spectra exhibit the Fe K $\alpha$  line; however, Payne et al. (2023) find that the feature originates from the nearby source. Therefore, we only used the 0.3–2.0 keV range in our spectral fitting to exclude the contribution of the nearby source. Fixing a Galactic hydrogen density

of  $3.49 \times 10^{20} \,\mathrm{cm}^{-2}$  (HI4PI Collaboration et al. 2016), we derive the photon index of  $2.17 \pm 0.07$  ( $\chi^2/\mathrm{dof}=1.42$ ),  $2.27^{+0.20}_{-0.21}$  ( $\chi^2/\mathrm{dof}=0.92$ ), and  $2.33^{+0.15}_{-0.16}$  ( $\chi^2/\mathrm{dof}=1.20$ ) for the results of 0.3-2.0 keV in previous epochs, epoch 10 and epoch 11, respectively. The spectra in epochs 10 and 11 are slightly softer than those in the previous epochs, but no significant difference in profile is found in these X-ray spectra. Due to the inability of *Swfit*/XRT to distinguish the source adjacent to ASASSN-14ko in the image, we limit ourselves to a qualitative comparison here. The fitted results are shown in Figure 4.

Figure 4. 0.3–2.0 keV X-ray spectra in different epochs of ASASSN-14ko. All three spectra are fitted with the absorb power-law model tbabs\*zashift\*powerlw.

It should be noted that the variability of the X-rays is not consistent with the UV/optical bands. The Xray and UV/optical fluxes show anticorrelated behavior in epochs 10 and 11, as they did in previous epochs. When the UV/optical fluxes increase, the X-ray fluxes decrease, and vice versa. This phenomenon has been

Figure 5. (a), the correlation between  $\alpha_{ox}$  and the luminosity of 2500 Å in different epochs. (b), the distribution of  $\alpha_{ox}$  at different epochs

observed by Payne et al. (2021, 2022, 2023) Therefore, we suggest that the X-ray flare near the UV/optical bumps and rebrightenings is not a new feature, but a continuation of the previous epoch. To measure the X-ray to UV/optical flux ratio, we use the parameter  $\alpha_{ox} = 0.3838 \log \left[ \frac{F(2 \text{ keV})}{F(2500 \text{ Å})} \right]$ , where F(2 keV) and  $F(2500\text{\AA})$  are the flux at 2 keV and 2500Å, respectively (Tananbaum et al. 1979; Strotjohann et al. 2016). The values of  $\alpha_{ox}$  range from -1.3 to -2. In Figure 5,  $\alpha_{\rm ox}$  in epochs 10 and 11 lie mainly on different sides from previous epochs. For previous epochs,  $\alpha_{ox}$  mostly ranges from -1.8 to -1.4, while for epochs 10 and 11, it is lower. Especially for epoch 11, we find a dominant distribution of  $\alpha_{ox}$  values between -2.0 and -1.6. For  $\log(L_{2500\text{\AA}}/\text{erg}\,\text{s}^{-1}\,\text{Hz}^{-1}) > 28.3, \,\alpha_{ox}$  in epochs 10 and 11 tends to be lower, where  $L_{2500\text{\AA}}$  is the luminosity in 2500 Å. The result suggests a distinct correlation between the X-ray and UV/optical bands in epochs 10 and 11.

# 3.3. Energy release in UV/Optical bands

Since the light curves in the previous epochs showed a smooth "fast-rise and slow-decay" pattern, we assume that they resulted from the same mechanism and that the folded light curves in the previous epochs can serve as a baseline for the analysis. Therefore, we can derive the extra energy in epochs 10 and 11 by subtracting the energy in the previous epochs.

The total energy released in epoch 10 is  $4.74 \times 10^{50}$  erg, and in epoch 11, the value of  $4.66 \times 10^{50}$  erg is reached, while the average energy release in the previous epochs is  $2.64 \times 10^{50}$  erg. Compared to previous epochs, the extra energy released in the early bumps of epochs 10 and 11 is  $1.15 \times 10^{50}$  erg and  $9.15 \times 10^{49}$  erg, respectively. For the rebrightening phases, the extra energy released in epochs 10 and 11 is  $7.63 \times 10^{49}$  erg and  $7.57 \times 10^{49}$  erg, respectively. The energy released in epoch 10 slightly exceeds that in epoch 11, but both are significantly higher than the average values of previous epochs.

## 4. THEORETICAL INTERPRETATION

The UV/optical light curves of the newly observed epochs 10 and 11 appear to deviate from the pattern observed in previous epochs, <sup>3</sup> indicating anomalies in the behavior of ASASSN-14ko. Unlike the previous epochs, which exhibited a consistent "fast rise and slow decay" pattern in their UV/optical light curves during each outburst (Payne et al. 2021, 2022, 2023), epochs 10 and 11 show a much slower rise, taking more than 1 month to reach their peaks. This longer rise can be attributed to the presence of a bump structure, which was not observed in the earlier epochs. A similar bump structure was also observed in the rising phase of AT2020wey, although it was fainter compared to ASASSN-14ko (Charalampopoulos et al. 2023). Another noteworthy phenomenon is the rebrightenings in the declining UV/optical light curves of epochs 10 and 11. While rebrightenings in TDEs are common, these recent rebrightenings in ASASSN-14ko are particularly intriguing as they occur in a periodic source that previously exhibited a rather smooth decline in its outbursts. Therefore, the rebrightening phenomenon observed in ASASSN-14ko might have a different origin compared to rebrightenings reported in other TDEs.

# 4.1. Stripped Stream-Disk Collision in the Partial TDE Scenario

The partial TDE model is thus far the primary model adopted to explain the periodic outbursts of ASASSN-14ko (Payne et al. 2021; Liu et al. 2023a). According to this model, a star in an eccentric orbit around the

 $<sup>^3</sup>$  Because the X-ray luminosity is lower than UV/optical by one order of magnitude, here we mainly focus on the latter.

black hole undergoes tidal stripping each time at the pericenter  $R_{\rm p}$ . The stripped material then undergoes circularization and subsequent accretion, resulting in the observed flare.

Tidal stripping requires  $R_{\rm p}$  to be on the same order as the tidal radius, i.e.,  $R_{\rm p} = \chi R_* (M_h/M_*)^{1/3}$ , where  $\chi \geq 1$  is a numerical coefficient; this is the distance to the SMBH at which a tiny amount of mass could be removed from the star. At this point, the star just fills its Roche lobe (though instantaneously due to the eccentric nature of the orbit). Thus,  $\chi \simeq 2$  according to early work (Paczyński 1971; Eggleton 1983; Sepinsky et al. 2007). Recent numerical simulation and analytical studies of TDE suggest similar values:  $\chi$  = 1.7  $\sim$  2 (Guillochon & Ramirez-Ruiz 2013; Coughlin & Nixon 2022). Note that a complete disruption would actually correspond to  $\chi \leq 1$ ). Here, we adopt  $\chi_s = 2$ . Thus,  $R_{\rm p} = 2.2 M_8^{-2/3} r_* m_*^{-1/3} R_{\rm S}$ , where  $M_8$  is the mass of the SMBH in unit of  $10^8 M_{\odot}$ ,  $r_*$  is the stellar radius in unit of solar radius,  $m_*$  is the stellar mass in unit of solar mass and  $R_{\rm S}$  is the Schwarzschild radius of the SMBH. Note that Payne et al. (2021) derived the SMBH mass of  $10^{7.85} M_{\odot}$  for ASSASN-14ko. The semi-major axis of the stellar orbit is related to the orbital period as in  $a = 110 \left( P/114 \,\mathrm{d} \right)^{2/3} M_8^{-2/3} R_{\mathrm{S}}.$ 

The unexpected profile change of the light curves during the most recent outbursts poses a challenge to the partial TDE explanation. Why were the bump in the rising phase and the rebrightening in the declining phase absent in the past? We propose the hypothesis that an accumulation effect is responsible for the two repeated bumps and rebrightenings. In this hypothesis, not all debris fragments from the partial TDE are immediately accreted, but instead some remain and gradually accumulate over time. As these materials accumulate from multiple partial TDEs, the accretion disk grows larger. Consequently, a collision occurs between the stripped stream and the disk, resulting in the early bumps and rebrightenings both before and after the flare peak. The schematic representation of the model can be seen in Figure 6. We will quantitatively examine and evaluate this model in the subsequent analysis.

At the collision radius  $R_{\rm p}$ , for a disk thickness  $H \gg R_*$ , the length of the penetration of the stream through the disk would be  $l \sim R_{\rm p}$ . The stream-disk velocity difference is  $v_{\rm rel} \sim \sqrt{2GM_h/R_{\rm p}}$ . The disk material to be shocked is in a volume of  $\pi R_*^2 R_{\rm p}$ , whose mass is  $\Delta M_{\rm s} = \pi R_*^2 R_{\rm p} \rho$  where  $\rho$  is the vertically averaged density of the disk, which is related to the disk accretion rate as  $\dot{M}_{\rm acc} = 3\pi\nu\rho H$ . Adopting the Shakura – Sunyaev viscosity model  $\nu = 2\alpha P/(3\Omega_{\rm K}\rho)$  and utilizing  $H = (P/\rho)^{1/2}/\Omega_{\rm K}$ , it can be rewritten as

$$\dot{M}_{\rm acc} = 2\pi R^2 \rho H \alpha \Omega_{\rm K} \left(\frac{H}{R}\right)^2,$$
 (1)

where  $\Omega_{\rm K}(R)$  is the disk Keplerian angular speed. With the density from Eq. (1), we get the mass of the shocked material  $\Delta M_{\rm s}$ . An optimistic estimate of the energy dissipated would be  $\Delta E_{\rm s} \approx \Delta M_{\rm s} v_{\rm rel}^2/2$ . Then we get

$$\Delta E_{\rm s} = 8 \times 10^{49} r_*^{1/2} \left(\frac{\dot{m}_{\rm acc}}{0.1}\right) \left(\frac{\alpha}{0.1}\right)^{-1} \\ \times \left(\frac{H/R}{0.01}\right)^{-3} M_8 m_*^{1/2} \,\mathrm{erg},$$
(2)

where the accretion rate has been normalized by the Eddington rate as in  $\dot{m}_{\rm acc} \equiv 10 \, \dot{M}_{\rm acc} c^2 / L_{\rm Edd}$ . To match the observed energies for the early bumps (see 3.3), we chose a low (but not extreme) value for the disk height-to-radius ratio.

We note that the separation between the bump and the rebrightening in epoch 11 ( $\Delta t_{11}$ ) is shorter than that in epoch 10 ( $\Delta t_{10}$ ). The orbital precession of the stripped stream may cause the inequality between  $\Delta t_{10}$ and  $\Delta t_{11}$ . The stream impacts the accretion disk twice in each period but at different positions due to the precession. This leads to unequal intervals between the two impacts in each period. This explains why we observe  $\Delta t_{10} \neq \Delta t_{11}$ . A similar situation occurs in OJ287, except that in that source it is the secondary black hole that collides with the accretion disk (Valtonen et al. 2008, 2016; Dey et al. 2018; Laine et al. 2020).

For partial TDE, the outer radius of the disk is  $R_{\rm out} \simeq 2R_{\rm p}$ , and in the case of ASASSN-14ko,  $R_{\rm out} = 5.5R_{\rm S}$ . Such a short distance to the SMBH makes it difficult to accumulate the stream debris for a long time, and the expansion of the disk is improbable. However, for an evolved star whose envelope is extended  $R_* \sim 10R_{\odot}$ , as advocated by Liu et al. (2023a) for ASASSN-14ko, the disk size is much larger  $R_{\rm out} = 55 R_{\rm S}$ . At this distance, the accretion disk has the possibility of expanding. Furthermore, a larger  $R_*$  also helps increase the energy release for the collision.

#### 4.2. Other Scenarios

We explore alternative explanations that could account for the distinct periodic transient ASASSN-14ko, as well as the newly observed features. An abnormal behavior for the TDE scenario is the significant temperature evolution during the outburst (see Figure 3), in contrast to the relatively stable temperature observed in normal optical TDEs. This temperature fluctuation bears resemblance to the disk instability scenario. Particularly, we noticed that the disk instability model has

Figure 6. The star is tidally stripped by the black hole, creating a debris stream that orbits around it. The stream crashes into the accretion disk twice in every cycle. These collisions produce flares in the UV/optical bands. The first flare occurs when the front stream hits the disk, creating an early bump in the light curves. The second flare occurs when the trailing stream collides with the disk, causing a rebrightening of the emission. The main outburst is powered by the accretion of the stripped material onto the black hole.

been proposed to explain QPEs in previous studies (Pan et al. 2023; Śniegowska et al. 2023) and the X-ray flares observed in ASASSN-14ko are rather similar to QPEs. Another popular model involved in explaining QPE is the star-disk collision model (Xian et al. 2021; Linial & Metzger 2023), which is yet disfavored by a lower energy released by 1 order of magnitude than that observed in individual flares of ASASSN-14ko (~  $10^{50}$  erg). One potential explanation is that the star periodically intersects with the disk, triggering disk instability and giving rise to the prominent flares observed. In this case, the star has just been disrupted; the stripped material, along with the star itself, falls back onto the disk in two streams. These streams then collide with the accretion disk, resulting in the observed bumps before and after the main flare peaks.

#### 5. CONCLUSION

ASASSN-14ko is a rare event that displays periodic outbursts in UV/optical bands, which are likely caused by repeated partial TDEs. The two most recent observational epochs, reported in this paper, reveal that the last two flares show much extended temporal profiles, characterized by early bumps and postpeak rebrightenings. This new feature could potentially be explained by the additional energy dissipation from the plunging of the tidally stripped stream through an expanded accretion disk. The periodic nature of ASASSN-14ko provides us a unique and valuable opportunity to study the physical processes underlying TDEs by conducting well-designed multiwavelength observations, both in the most recent epochs and in the near future.
