ABSTRACT

The maximum mass of neutron stars (M_{TOV}) plays a crucial role in understanding their equation of state (EoS). Previous studies have used the measurements for the compactness of massive pulsars and the tidal deformability of neutron stars in binary neutron star (BNS) mergers to constrain the EoS and thus the M_{TOV} . The discovery of the most massive pulsar, PSR J0952-0607, with a mass ~ 2.35 M_{\odot} , has provided a valuable lower limit for M_{TOV} . Another efficient method to constrain M_{TOV} is by examining the type of central remnant formed after a BNS merger. Gravitational wave (GW) data can provide the total mass of the system, while accompanying electromagnetic signals can help infer the remnant type. In this study, we combine all the previous constraints and utilize the observational facts that about 24% of the short gamma-ray bursts are followed by an X-ray internal plateau, which indicate that roughly this fraction of BNS mergers yield supermassive neutron stars, to perform (Markov Chain) Monte Carlo simulations. These simulations allow us to explore the probability density distribution of M_{TOV} and other parameters related to BNS mergers. Our findings suggest that M_{TOV} is likely around 2.49 M_{\odot} – 2.52 M_{\odot} , with an uncertainty range of approximately [-0.16 M_{\odot} , 0.15 M_{\odot}] ([-0.28 M_{\odot} , 0.26 M_{\odot}]) at 1 σ (2 σ) confidence level. Furthermore, we examine the type of merger remnants in specific events like GW170817 and GW190425 to further constrain M_{TOV} and other relevant parameters, which can help to understand the physical processes involved in BNS mergers.

Key words: neutron stars – neutron star mergers – gamma-ray burst: general – gravitational waves

1 INTRODUCTION

The equation of state (EoS) for neutron stars (NSs) has long been an open question, although astronomical observations continues to tighten the allowed parameter space. Generally, constraints on the EoS for NSs come from two main perspectives: their compactness at a certain mass or radius, and their maximum mass under non-rotating conditions (M_{TOV}).

The compactness of a NS can be inferred through the jointly measuring its mass and radius. In the case of a known massive pulsar with precise mass measurement (usually done through Shapiro delay) (e.g. Antoniadis et al. 2013; Cromartie et al. 2020; Romani et al. 2022), its radius can be inferred from X-ray observations, such as those conducted by the X-ray observations by the Neutron star Interior Composition Explorer (NICER) (e.g. Miller et al. 2019; Riley et al. 2019; Miller et al. 2021; Riley et al. 2021). Once the radius of a NS at a specific mass is constrained, any EoS predicting a radius outside the allowed region at this mass could be ruled out. The tidal deformability of NSs which reflects their compactness, can also be inferred from the GW waveform in the late-inspiral phase of binary neutron star (BNS) mergers (Flanagan & Hinderer 2008; Favata 2014). Constraints on the parameters related to the NS EoS has been derived from GW170817 (Abbott et al. 2017a, 2018) and GW190425 (Abbott et al. 2020). Dietrich et al. (2020) made the first attempt to combine as many as multi-messenger observations, including the pulsar mass measurements of PSR J0740+6620, PSR J0348+4042, and PSR J1614-2230 (Demorest et al. 2010; Antoniadis et al. 2013; Arzoumanian et al. 2018; Cromartie et al. 2020), GW data from the NS mergers GW170817 and GW190425, information from the kilonova AT 2017gfo and the gamma-ray burst GRB 170817A and its afterglow (Abbott et al. 2017a,b,c), and the NICER observation of PSR J0030+0451 (Riley et al. 2019; Miller et al. 2019), to pose a joint constraint on the EoS of NSs. Under this framework, people continues to refine the constraints with updated observational data and models, e.g. adding the NICER and XMM-Newton measurements for PSR J0740+6620 (Rilev et al. 2021: Miller et al. 2021: Biswas 2021: Li et al. 2021a; Annala et al. 2022; Somasundaram & Margueron 2022; Raaijmakers et al. 2021; Legred et al. 2021; Pang et al. 2021). A comprehensive review on the previous related works is presented in Pang et al. (2021). Generally, the existing constraints on the charac-

[‡] E-mail: bing.zhang@unlv.edu

teristic radius $R_{1.4}$ of NSs are much more stringent than those on M_{TOV} , e.g. $R_{1.4} = 12.56^{+0.45}_{-0.40}$ km and $M_{\text{TOV}} = 2.27^{+0.34}_{-0.18} M_{\odot}$ with the uncertainties at 1σ confidence level in Miller et al. (2021).

A tight constraint on the maximum mass of NSs (M_{TOV}) is sorely needed now, because along with the already well-constrained compactness, it becomes much easier to differentiate NS EoSs proposed in the literature. A direct lower limit on M_{TOV} is the mass of the most massive pulsar observed. For example, as mentioned above, several pulsars with masses greater the $2M_{\odot}$ have been confirmed, such as PSR J0348+0432 ($M = 2.01^{+0.04}_{-0.06} M_{\odot}$) (Antoniadis et al. 2013), PSR J0740+6620 ($M = 2.072^{+0.067}_{-0.066} M_{\odot}$) (Cromartie et al. 2020; Riley et al. 2021) and PSR J0952-0607 ($M = 2.35^{+0.17}_{-0.17} M_{\odot}$) (Romani et al. 2022), with PSR J0952-0607 being the currently most massive one. Therefore, approximately $M_{\text{TOV}} > 2.35M_{\odot}$ is obtained.

Another method to constrain M_{TOV} is based on the type of central remnant of the BNS mergers. In theory, the type of merger remnant depends on M_{TOV} and the remnant mass M_{rem} (Rosswog et al. 2000; Rezzolla et al. 2010, 2011; Howell et al. 2011; Lasky et al. 2014; Rosswog et al. 2014; Ravi & Lasky 2014; Gao et al. 2016; Radice et al. 2018; Ai et al. 2020), while the latter can be calculated from the total mass of the BNS-merger system extracted from the GW data. When

$$M_{\rm rem,0} > (1 + \chi_r) M_{\rm TOV},\tag{1}$$

a black hole (BH) or short-lived hyper-massive NS (HMNS) would be produced; When

$$M_{\rm rem,0} < (1 + \chi_r) M_{\rm TOV}, \ M_{\rm b,rem} > M_{\rm b,TOV},$$
 (2)

a long-lived super-massive NS (SMNS) with rigid rotation would be produced; When

$$M_{\rm b,rem} < M_{\rm b,TOV},$$
 (3)

a stable NS (SNS) would be produced. Here $\chi_r \leq 0.2$ stands for the critical enhancement factor for NS mass for different types of merger remnants (Cook et al. 1994; Lasota et al. 1996; Breu & Rezzolla 2016; Ai et al. 2020). The mass with subscript "0" represents the value at the initial spin period for a rigidly rotating NSs, while the mass with subscript "b" is the baryonic mass. The remnant mass can be calculated from the total mass of the BNS system. In short, if we know both the type and mass of the merger remnant, we can obtain constraints on M_{TOV} .

It has been long believed that BNS mergers are the source of short gamma-ray busrts (SGRBs) (Paczynski 1986; Eichler et al. 1989; Paczynski 1991; Narayan et al. 1992), before it was confirmed by the joint detection of GW and electromagnetic (EM) signals. Observationally, a good fraction (~ 24%, see Appendix A for details) of sGRBs are followed by an internal X-ray plateau (a plateau followed by an extremely steep decay) on the GRB afterglow's light curve. This feature cannot be explained within the framework of external shock, but can be naturally attributed to the collapse of the postmerger SMNS to a BH. Therefore, about 24% of the BNS mergers would produce a SMNS. Due to the lack of mass information on these BNS systems, no constraint on M_{TOV} can be made with individual sources. However, given the mass distribution of BNS merger systems, the fraction of SMNS as the merger remnants can be estimated for each M_{TOV} . By comparing the inferred fraction from the theory with the observed one, constraints on M_{TOV} can be made, e.g. $M_{\rm TOV} \sim 2.3 M_{\odot}$ (Gao et al. 2016).

So far, only two BNS merger events have been identified through GW observation: GW170817 (Abbott et al. 2017a) and GW190425 (Abbott et al. 2020). GW170817 was the first event to be detected

through both GW and EM observations, providing valuable insights into the physical processes involved in BNS mergers (Abbott et al. 2017b,c). However, the nature of the remnant formed after GW170817 is still a subject of debate. While the existence a shortlived hyper-massive NS after the merger can explain most of the EM signals, including the 1.7s time delay for the sGRB after the merger¹ and the required ejecta mass to power the two-component kilonova, some argue that a long-lived neutron has to be produced to serve as the central engine that powers the bright kilonova emission (Yu et al. 2018; Li et al. 2018). Based on the scenario in which a short-lived HMNS was produced in GW170817, lasting for ~ 1.7s, various studies have constrained the maximum mass of NSs (Margalit & Metzger 2017; Rezzolla et al. 2018; Ruiz et al. 2018), e.g. $M_{\text{TOV}} \le 2.16 M_{\odot}$ (Margalit & Metzger 2017). To provide a comprehensive analysis, Ai et al. (2020) proposed several universal relations for the masses and spin periods of rigidly rotating NSs, and summarized the constraints on M_{TOV} for different assumptions regarding the types of merger remnants. They claim that, if the merger remnant was a short-lived HMNS, one should have $M_{\text{TOV}} < 2.09^{+0.11}_{-0.09} M_{\odot}$; if it was a long-lived HINNS, one should have $M_{10V} < 2.0_{-0.09}^{-0.09} < 0.12_{-0.08}^{-0.09} M_{\odot}$; if it was a SNS, one should have $M_{TOV} > 2.43_{-0.08}^{+0.10} M_{\odot}$. The uncertainties are in the 2σ confidence level. The results from all of these works are under the assumption that $\chi_r \sim 0.2$. However, Shibata et al. (2019) claimed that the angular momentum of the remnant might be efficiently lost during the differential rotating phase, so that the initial spin of the SMNS (if it was formed) cannot be Keplerian, and χ_r could be significantly smaller than 0.2. Again, based on the scenario that the merger remnant of GW170817 was a short-lived HMNS, they relaxed the constraint on M_{TOV} to be approximately smaller than $2.3M_{\odot}$. Recently, Margalit et al. (2022) also suggested that, after the merger, a rigidly rotating core inside the HMNS may form and later collapses into a BH before the differential rotation vanishes, so that $\chi_r < 0.2$.

In the case of GW190425, the total mass of the BNS system was found to be approximately $3.4M_{\odot}$ (Abbott et al. 2020), which deviates significantly from the total mass of Galactic DNSs. Interestingly, a fast radio burst (FRB) FRB190425A was discovered at ~ 2.5 hours after the merger time of GW190425, and there is a possibility of association between the two events at a 2.8σ confidence level (Moroianu et al. 2023; Panther et al. 2023). If the association is indeed true, the blitzar FRB model could be applied. This model predicts that non-repeating FRBs could be emitted when a SMNS collapses into a BH (Zhang 2014; Falcke & Rezzolla 2014; Most et al. 2018). In this scenario, under the framework of NSs, roughly $M_{\rm TOV} > 2.6 M_{\odot}$ is required (Moroianu et al. 2023). According to the follow-up study by Panther et al. (2023), the most possible common host galaxy for GW190425 and FRB 20190425A is UGC10667, with a redshift z = 0.03136. Knowing the exact distance and the sky location of the source, the parameters of the BNS-merger system extracted from the GW data can be refined. Bhardwaj et al. (2023) found that, if the host galaxy of GW190425 was UGC10667, our viewing angle for this BNS merger should be greater than 30 degree, where the massive merger ejecta would cause a significant attenuation for the FRB signal at 400MHz. Therefore, the proposed association could not be

¹ The 1.7*s* time delay is not necessarily due to the delayed formation of the BH. This is because: 1) Recent numerical simulations show that a jet could be launched in the BNS merger with a magnetar as the central engine (Kiuchi et al. 2023); 2) The 1.7*s* delay could be decomposed in several components, with the dominant portion naturally explained by the travel time of the jet before the release of gamma-ray photons (Zhang 2019).

real. Note that there are still several other candidate host galaxies for FRB 20190425A that could allow the association, even though with smaller chance probabilities (Panther et al. 2023). In this work, we still treat the pair as a possible association and discuss its contribution to the constraints on M_{TOV} and other parameters.

In this work, based on the previous constraints on NS EoS with multi-messenger method, we focus on the central remnants of BNS mergers to establish joint constraints on the maximum mass of NSs (M_{TOV}) . Section 2 introduces the fundamental formula for the masses associated with BNS mergers. In Section 3, we gather all the observations into a Bayesian framework and employ Markov chain Monte Carlo (MCMC) simulations to infer M_{TOV} and other essential parameters. Our conclusions and discussions are presented in Section 5.

2 FORMULA FOR THE MASSES RELATED TO BNS MERGERS

2.1 remnant mass of a BNS merger

The masses of NSs obtained from the GW data are gravitational masses, while what was conserved during the merger is the total baryonic mass of the system. In order to calculate the mass of merger remnant, universal relations that independent to NS EoSs, to convert between the gravitational mass and baryonic mass are needed. Gao et al. (2020) proposed several universal relations based on a collection of common EoSs with M_{TOV} ranging from $2.05M_{\odot}$ to $2.78M_{\odot}$, which cover the generally believed M_{TOV} range. A more detailed comparison between the microscopic and macroscopic parameter spaces for the EoSs used to construct the universal relations and the parameter spaces constrained by latest multi-messenger observations is shown in Appendix D.

Consider a BNS merger system with the masses of two pre-merger NSs as M_1 and M_2 ($M_1 \ge M_2$), respectively. Supposing the spins of the pre-merger NSs are relatively low, their baryonic masses can be calculated with the universal relation for non-rotating or slow-rotating NSs, which reads as (Gao et al. 2020)

$$M_{b,i} = M_i + A_0 M_i^2, (4)$$

where i = 1, 2 and $A_0 = 0.08$. The baryonic mass of the central remnant could be calculated as

$$M_{\rm b,rem} = M_{b,1} + M_{b,2} - M_{\rm ej},\tag{5}$$

where M_{ej} is the mass ejected during the merger Applying the relation of gravitational mass and baryonic mass for a post-merger rapidly rotating NS with an arbitrary rigid rotation period (Gao et al. 2020),

$$M_b = M + A_s M^2 \tag{6}$$

with $A_s = 0.073$, the gravitational mass for the remnant $M_{\text{rem},0}$ can be estimated (assume the remnant is a rigidly rotating NS first and test the hypothesis later). Hereafter, the initial gravitational mass of the merger remnant is simply denoted as M_{rem} instead of $M_{\text{rem},0}$. According to Gao et al. (2020), the conversion between the two types of masses introduce a non-negligible uncertainty, denoted as f_{err} , which is at most 6% and does not have a clear dependence on the mass of the neutron star. In this work, we add this percentage error directly to the baryonic mass of the central remnant to simplify the calculation, which reads as

$$M_{\rm b,rem} = M_{b,1} + M_{b,2} - M_{\rm ej} + f_{\rm err}(M_{b,1} + M_{b,2}).$$
(7)

In different converting directions, the uncertainties would partially

cancel each other out, so we do not introduce another uncertainty on the gravitational mass of the merger remnant. For GW170817, the ejecta mass inferred from the kilonova observation is $M_{\rm ei} \approx 0.06 M_{\odot}$ when only radioactive heating of the ejecta is considered (e.g. Villar et al. 2017). In principle, the required ejecta mass could be lower if a long-lived central engine existed. The existing numerical simulations predict that the ejecta mass might be in order of $10^{-4} M_{\odot} \sim \text{a few} \times 10^{-2} M_{\odot}$ (Rezzolla et al. 2011; Rezzolla & Zanotti 2013; Hotokezaka et al. 2013; Siegel & Metzger 2017; Fujibayashi et al. 2018). Generally, the gravitational mass of the central remnant can be expressed as $M_{\text{rem}} = \mathcal{G}(M_{\text{tot}}, q, f_{\text{err}}, M_{\text{ei}})$, where $M_{\rm tot} = M_1 + M_2$ represents the total mass and $q = M_2/M_1$ is the mass ratio, from which M_1 and M_2 can be easily calculated. For a certain total mass $M_{\rm tot}$, the influence of different mass ratios on the remnant mass is also tested. We find that, for q = 0.5 - 1, the influence is negligible. So, we always set q = 1 when q is unknown.

2.2 mass distribution of BNS-merger systems

Currently, the measurement of the total mass of BNS merger systems can only be achieved through the detection of GWs (Li et al. 2021b). Due to the limited number of detections (only two events), obtaining a meaningful mass distribution for BNS merger systems is challenging. The most similar system to the BNS merger is the Galactic double neutron star (DNS) systems. Even if we exclude DNS systems that will not merge within the *Hubble* timescale, the overall mass distribution remains largely unchanged (Farrow et al. 2019). This distribution can be described by a Gaussian distribution with { μ_G , σ_G } = {2.64 M_{\odot} , 0.13 M_{\odot} } (See Appendix B for details).

Before the detection of GW170817 and GW190425, it is generally believed that mass of BNS merger systems follows the mass distribution of the Galactic DNS systems. However, for GW190425, the total mass reaches ~ $3.3M_{\odot}$ with low-spin prior assumption for the premerger NSs, and ~ $3.4M_{\odot}$ with high-spin prior assumption. These values lie outside the 5σ confidence region of the distribution of the Galatic DNS systems (Abbott et al. 2020). Therefore, besides the contribution of Galactic-DNS-like systems, a high-mass component must exist in the mass distribution of BNS mergers.

Recycled pulsars, which include all millisecond pulsars and accreting NSs with low-mass companions, form a population of NSs with masses higher than their birth masses. Their mass distribution can be described by a Gaussian distribution with $\{\mu_r, \sigma_r\}$ = $\{1.54M_{\odot}, 0.23M_{\odot}\}$, which significantly deviates from the mass distributions of slow pulsars and NSs in the Galactic DNS systems (Özel & Freire 2016). The masses of slow pulsars and NSs in the Galactic DNS systems also follow Gaussian distributions, expressed as $\{\mu_s, \sigma_s\} = \{1.49M_{\odot}, 0.19M_{\odot}\}$ and $\{\mu_{\text{DNS}}, \sigma_{\text{DNS}}\} =$ $\{1.33M_{\odot}, 0.09M_{\odot}\}$, respectively (Özel & Freire 2016). These mass distributions are shown in the upper panel of Figure 1. It is natural to expect that high-mass BNSs are supposed to contain at least one recycled neutron star. Given that the formation channels of merging BNS systems are still uncertain, we randomly select NSs from the three populations, each with an equal chance, following the mass distribution of each population, to form high-mass BNS systems together with the recycled NSs. The mass distribution of the secondary NSs is also shown in the upper panel of Figure 1. The overall distribution of the total masses of BNS merger systems can be written as

$$\mathcal{D}_{\text{BNS}}(M_{\text{tot}} \mid \mathcal{R}) = (1 - \mathcal{R})\mathcal{D}_G(M_{\text{tot}}) + \mathcal{R}\mathcal{D}_{\text{H}}(M_{\text{tot}}), \tag{8}$$

where \mathcal{D}_G and \mathcal{D}_H represent the mass distributions of Galactic DNSs

Figure 1. Upper panel: The solid lines represent the mass distributions of NSs in different populations. The black dashed line stands for the mass distribution of the secondary NSs in the high-mass BNS systems. Middle panel: The probability density distributions of the total masses (M_{tot}) for GW170817 and GW190425, under the high-spin (HS) and low-spin priors (LS), respectively. Lower panel: The solid lines represent the mass distribution of the Galactic DNS systems and the high-mass component. The dashed black line represents the resultant mass distribution of BNS mergers with $\mathcal{R} = 0.5$ as an example. The dotted vertical lines represents the 3 σ upper bounds for the mass distributions. The black and pink shades represent the range of the total mass for GW190425 under the low-spin and high-spin priors, respectively.

and the high-mass BNSs, respectively. \mathcal{R} is a fraction parameter that represents the contribution of the high-mass component.

3 CONSTRAINTS ON THE MAXIMUM MASS OF NEUTRON STARS

Multi-messenger observations can place constraints on the maximum mass of NSs (M_{TOV}). However, sometimes the observations are also related to other parameters, such as the maximum enhancement factor for the mass of the post-merger rigidly rotating NS (χ_r), and the fraction of high-mass components for the mass distribution of BNS merger systems (\mathcal{R}). Besides, we also include the ejecta mass of BNS merger (M_{ej}) and the uncertainty of the universal relations for the $M - M_b$ conversion (f_{err}) into the parameter set. These parameters are included in $\Theta = \{M_{\text{TOV}}, \chi_r, \mathcal{R}, f_{err}, M_{ej}\}$. The Bayesian infer-

Figure 2. The probability density distributions for the fraction parameter \mathcal{R} inferred from the total mass of GW170817 and GW190425. The measurements of M_{tot} for the two GW-BNS-merger events with both high-spin prior and low-spin prior assumptions are shown, respectively. We do not consider the case where one event has a high-spin prior while the other has a low-spin prior, as it could result in a curve located between the two shown modified priors.

ence method is applied in this section. Before constraining M_{TOV} , we first need to determine reasonable priors for these parameters. In the absence of convincing information on χ_r , it can only be assumed to be uniformly distributed in the range [0.02, 0.2] (Shibata et al. 2019). Similarly, the prior of $f_{\rm err}$ is set to be a uniform distribution in the range [-6%, 6%] while the prior of M_{ei} is set to be a uniform distribution in logarithmic space in the range $[10^{-4}, 6 \times 10^{-2}]$. The probability density function of \mathcal{R} can be inferred from the total mass of the two BNS merger systems detected via GWs (GW170817 and GW190425), independently from the other two parameters. Before the detection of BNS merger via GWs, it was assumed that the mass distribution of BNS mergers follows that for the Galatic DNSs ($\mathcal{R} = 0.0$), while it would be highly unlikely that most of the BNS-merger systems consist of two massive millisecond pulsars $(\mathcal{R} = 1.0)$. Therefore, we set \mathcal{R} to follow a Gaussian distribution with $\{\mu_{\mathcal{R}}, \sigma_{\mathcal{R}}\} = \{0.0, 0.33\}, \mathcal{R} > 0$, as the original prior $(p(\mathcal{R}))$. This distribution can be modified by the GW170817 and GW190425 systems as

$$p(\mathcal{R} \mid \mathbf{M}_{\text{tot}}) \propto \left[\prod_{i} \int \mathcal{D}_{\text{BNS}}(M_{\text{tot},i} \mid \mathcal{R}) p(M_{\text{tot},i}) dM_{\text{tot},i} \right] p(\mathcal{R}) \quad (9)$$

where $\mathbf{M}_{\text{tot}} = \{M_{\text{tot},i}\}\)$ and M_i represents the total mass of each BNS-merger system. The probability density distribution $(p(M_{\text{tot},i}))\)$ can be obtained by conducting kernel density estimation for the posteriors for the masses provided by LIGO-Virgo-Kagra science collaboration², which are shown in the middle panel of Figure 1. The joint distributions of M_{tot} and mass ratio q for GW170817 and GW190425 are shown in Figure C1 in Appendix C. The total mass distribution depends on the spin prior for the two pre-merger NSs, so that these cases will be discussed separately. The original prior and the modified priors of \mathcal{R} are shown in the lower panel of Figure 2, with the latter being used for future calculations.

We divide the observations related to M_{TOV} into two Categories,

² The public data for GW170817 and GW190425 can be access through https://dcc.ligo.org/LIGO-P1800370/public and https://dcc.ligo.org/LIGO-P2000026/public, respectively.

Figure 3. Constraints on M_{TOV} with the facts in Catalog I. The blue and orange solid lines are extracted from Miller et al. (2021) and Li et al. (2021a), respectively.

based on whether it can be constrained independently from the other four parameters in Θ (Category I) or not (Category II).

3.1 Observations: Category I

The observations included in Category I are denoted as $\mathbf{d}_{I} = \{d_{I,i}\}$, which are listed as:

• $d_{I,1}$: The constraints on M_{TOV} presented in previous works, based on the GW data from BNS merger events GW170817 and GW190425, as well as the joint measurements for the radii and masses of some massive pulsars (i.e. PSR J0030+0451 and PSR J0740+6620), assuming the NSs are composed of predominately neutrons without a quark core (i.e. Miller et al. 2021) or with a quark core (i.e. Li et al. 2021a).

• $d_{I,2}$: The heaviest pulsar so far, PSR J0952-0607, with gravitational mass $M = 2.35 \pm 0.17 M_{\odot}$ (Romani et al. 2022). $M_{\text{TOV}} > 2.35 \pm 0.17 M_{\odot}$ can be obtained.

The observation $d_{I,1}$ summarizes the constraints on M_{TOV} from previous works and can directly give the probability density distribution of M_{TOV} , which is shown in Figure 3. When $d_{I,2}$ is included, the posterior of M_{TOV} can be expressed as

$$p(M_{\text{TOV}} \mid \mathbf{d}_{\text{I}}) \propto \mathcal{L}(d_{\text{I},2} \mid M_{\text{TOV}}) p(M_{\text{TOV}} \mid d_{\text{I},1}), \tag{10}$$

where

1

$$P(d_{\rm I,2} \mid M_{\rm TOV}) = \int_{-\infty}^{M_{\rm TOV}} \frac{1}{\sqrt{2\pi}\sigma_{\rm NS}} \exp\left[-\frac{(m-M_{\rm NS})^2}{2\sigma_{\rm NS}^2}\right] dm, \ (11)$$

with $M_{\rm NS} = 2.35 M_{\odot}$ and $\sigma_M = 0.17 M_{\odot}$ adopted. The new PDF of $M_{\rm TOV}$ is also shown in Figure 3. The observations in this category can be used to constrain $M_{\rm TOV}$ independently to the other two parameters. We have $M_{\rm TOV} \sim 2.43 - 2.50 M_{\odot}$ with an uncertainty $[-0.19 M_{\odot}, 0.23 M_{\odot}]$ ($[-0.34 M_{\odot}, 0.42 M_{\odot}]$) at 1σ (2σ) confidence level (see Table 1).

3.2 Observations: Category II

The observations included in Category II, denoted as \mathbf{d}_{II} , are related to the type of remnant of BNS mergers. They are further divided into two sub categories, IIA ($\mathbf{d}_{\mathrm{IIA}}$) and IIB ($\mathbf{d}_{\mathrm{IIB}}$), based on whether they come from population properties or from one specific BNS merger. The observations in Category IIA are listed as, • $d_{\text{IIA},1}$: According to the observation of X-ray internal plateaus in the sGRB afterglows, ~ 24% of the BNS mergers would produce a SMNS.

The observations in Category IIB are listed as,

• $d_{\text{IIB},1}$: The possible association of GW190425 and FRB 20190425A indicates that the merger remnant of GW190425 might be a SMNS.

• $d_{\text{IIB},2}$: The type of merger remnant of GW170817 is under debate. In different cases, $d_{\text{IIB},2}$ can be written as $d_{\text{IIB},2,\text{BH}}$, $d_{\text{IIB},2,\text{SMNS}}$ and $d_{\text{IIB},2,\text{SNS}}$, respectively.

Generally, the posterior of Θ can be expressed as

$$p(\boldsymbol{\Theta} \mid \mathbf{d}_{\mathrm{II}}) \propto \left[\prod_{i} \mathcal{L}(d_{\mathrm{IIA},i} \mid \boldsymbol{\Theta}) \right] \left[\prod_{i} \mathcal{L}(d_{\mathrm{IIB},i} \mid \boldsymbol{\Theta}) \right] \\ \times p(M_{\mathrm{TOV}} \mid \mathbf{d}_{\mathrm{I}}) p(\chi_{r}) p(\mathcal{R} \mid \mathbf{M}).$$
(12)

where the priors of M_{TOV} and \mathcal{R} in this step come from Equations 9 and 10, respectively.

In details, for the observation $d_{\text{IIA},1}$, the likelihood can be expressed as

$$\mathcal{L}(d_{\text{IIA},1} \mid \boldsymbol{\Theta}) \propto p(f_{\text{SMNS}} \mid M_{\text{TOV}}, \chi_r, \mathcal{R}, f_{\text{err}}, M_{\text{ej}}, f_X), \quad (13)$$

where $f_X = 0.243$ (see Appendix A) represents the observational fraction of X-ray internal plateau in sGRBs. According to the De Moivre-Laplace Central Limit Theorem, we know that the probability of the observed fraction deviates from the real fraction within a small positive value ϵ is

$$P(|f_X - f_{\rm SMNS}| < \epsilon) \approx 2\Phi\left(\epsilon\sqrt{\frac{n}{f_{\rm SMNS}(1 - f_{\rm SMNS})}}\right) - 1, \quad (14)$$

where $\Phi(x)$ is the cumulative distribution function for the standard normal distribution and n = 144 is the total number of sGRBs in our sample (see Appendix A). The approximation in Equation 14 is valid when $n f_{\text{SMNS}} > 5$. Therefore, the likelihood can be further written as

$$\mathcal{L}(d_{\mathrm{IIA},1} \mid \boldsymbol{\Theta}) \propto \frac{1}{\sqrt{2\pi}} \exp\left\{-\frac{\left[\epsilon' \sqrt{\frac{n}{f_{\mathrm{SMNS}}(1-f_{\mathrm{SMNS}})}}\right]^2}{2}\right\}$$
(15)

where

$$\epsilon' = |f_X - f_{\text{SMNS}}(\Theta)|. \tag{16}$$

For a certain parameter set Θ , the predicted fraction of SMNS as the merger remnant can be written as

$$f_{\text{SMNS}} = \frac{\int_{M_{\text{th},1}}^{M_{\text{th},2}} p(M_{\text{rem}} \mid \mathcal{R}, q, f_{\text{err}}, M_{\text{ej}}) dM_{\text{rem}}}{\int_{0}^{\infty} p(M_{\text{rem}} \mid \mathcal{R}, q, f_{\text{err}}, M_{\text{ej}}) dM_{\text{rem}}},$$
(17)

where

$$M_{\text{th},1} = (1 + \chi_r) M_{\text{TOV}} \tag{18}$$

and

$$M_{\rm th,2} = \frac{-1 + \sqrt{1 + 4A_s M_{\rm b,TOV}}}{2A_s}.$$
 (19)

The probability density distribution of M_{rem} under a certain parameter set can be expressed as

$$p(M_{\text{rem}}(M_{\text{tot}}, q, f_{\text{err}}, M_{\text{ej}}) | \mathcal{R}, q, f_{\text{err}}, M_{\text{ej}}) dM_{\text{rem}}$$
(20)
$$\propto \mathcal{D}(M_{\text{tot}} | \mathcal{R}) dM_{\text{tot}},$$

where

$$dM_{\rm rem} = \frac{\partial \mathcal{G}(M_{\rm tot}, q, f_{\rm err}, M_{\rm ej})}{\partial M_{\rm tot}} dM_{\rm tot}.$$
 (21)

For the observations $d_{\mathrm{IIB},1},$ the likelihood function can be expressed as

$$\mathcal{L}(d_{\mathrm{IIB},1} \mid \mathbf{\Theta}) = \int dM_{\mathrm{tot}} \int dq \mathcal{L}(d_{\mathrm{IIB},1} \mid \mathbf{\Theta}, M_{\mathrm{tot}}, q) p(M_{\mathrm{tot}}, q), \quad (22)$$

where

$$\mathcal{L}(d_{\text{IIB},1} \mid \boldsymbol{\Theta}, M_{\text{tot}}, q) = \begin{cases} 1 & \text{if GW190425} - \text{SMNS,} \\ 0 & \text{ELSE,} \end{cases}$$
(23)

and $p(M_{\text{tot}}, q)$ can be numerically obtained by conducting 2D kernel density estimation from the posteriors of M_{tot} and q from GW public data (See detailed in Appendix C). $\mathcal{L}(d_{\text{IIB},2} | \Theta)$ for GW170817 can be expressed in a similar way but different types of merger remnant are considered. For each parameter set, the merger remnant can be determined following the criteria listed in the introduction.

3.3 Results

We employ the python module *emcee* (Foreman-Mackey et al. 2013) to conduct the Bayesian MCMC parameter estimation. The constraints on M_{TOV} solely with **d**_I has been presented in Section 3.1. Here, we first combine the observations in Category I and IIA to constrain Θ . Figure 4 shows an example with M_{tot} inferred using lowspin prior for both GW170817 and GW190425, assuming the NSs are made of pure neutrons. It is worth noting that, instead of close to 0.2, the probability density distribution of χ_r is supposed to peak at about 0.1, although with a relatively large uncertainty. The detailed results with different assumptions are listed in Table 1. In general, when considering both \mathbf{d}_{I} and \mathbf{d}_{IIA} , we find $M_{\text{TOV}} \approx 2.49 M_{\odot} - 2.52 M_{\odot}$ with an uncertainty range of $[-0.16M_{\odot}, 0.15M_{\odot}]$ ($[-0.28M_{\odot}, 0.26M_{\odot}]$); $\chi_r \approx 0.10$ with an uncertainty range of [-0.04, 0.06] ([-0.06, 0.08]); and $\mathcal{R} \approx 0.41 - 0.44$ with an uncertainty range of [-0.20, 0.22] ([-0.31, 0.36]). All the uncertainties presented here are at 1σ (2σ) confidence level.

The observations in Category IIB are not confirmed, so that we have to discuss them case by case. Generally, the posterior of Θ is expressed as

$$p(\mathbf{\Theta} \mid d_{\mathrm{IIB},i}, \mathbf{d}_{\mathrm{IIA}}, \mathbf{d}_{\mathrm{I}}) \propto \mathcal{L}(d_{\mathrm{IIB},i} \mid \mathbf{\Theta}) p(\mathbf{\Theta} \mid \mathbf{d}_{\mathrm{IIA}}, \mathbf{d}_{\mathrm{I}})$$
$$\propto \mathcal{L}(d_{\mathrm{IIB},i} \mid \mathbf{\Theta}) \mathcal{L}(\mathbf{d}_{\mathrm{IIA}} \mid \mathbf{\Theta}) p(\mathbf{\Theta} \mid \mathbf{d}_{\mathrm{IIA}}^{\prime})$$

The posteriors of Θ with observations in Category I and IIA, along with one certain case in Category IIB are shown in Figure 5 and 6. These figures display the inferences made using the remnant type of GW190425 and GW170817, respectively. The central values and 1σ (2σ) uncertainties with different assumptions are listed in Table 2. The results can be summarized as follows:

• If one assumes that the remnant of GW170817 collapses directly into a BH after the differential rotating phase, a preferred value of M_{TOV} around $2.30M_{\odot} - 2.35M_{\odot}$ is obtained, with an uncertainty range of $[-0.13M_{\odot}, 0.12M_{\odot}]$ ($[-0.20M_{\odot}, 0.19M_{\odot}]$) at the 1σ (2σ) confidence level. The maximum enhancement factor for the mass of a rigidly rotating NS produced after a BNS merger would be more likely to be $\chi_r \sim 0.07$ with an uncertainty range of [-0.03, 0.05]([-0.03, 0.08]) at the 1σ (2σ) confidence level.

• If one assumes that the remnant of GW170817 is a SMNS, a preferred value of M_{TOV} around $2.47M_{\odot} - 2.51M_{\odot}$ is obtained, with an uncertainty range of $[-0.09M_{\odot}, 0.10M_{\odot}]$ ($[-0.14M_{\odot}, 0.15M_{\odot}]$) at the 1σ (2σ) confidence level. The maximum enhancement factor

for the mass of a rigidly rotating NS produced after a BNS merger would be more likely to be $\chi_r \sim 0.08 - 0.10$ with an uncertainty range of [-0.03, 0.06] ([-0.04, 0.08]) at the 1σ (2σ) confidence level.

• If one assumes that the remnant of GW170817 is a SNS, a preferred value of M_{TOV} around $2.58M_{\odot} - 2.63M_{\odot}$ is obtained, with an uncertainty range of $[-0.10M_{\odot}, 0.12M_{\odot}]$ ($[-0.17M_{\odot}, 0.21M_{\odot}]$) at the 1σ (2σ) confidence level. The maximum enhancement factor for the mass of a rigidly rotating NS produced after a BNS merger would be more likely to be $\chi_r \sim 0.14$ with an uncertainty range of [-0.04, 0.04] ([-0.06, 0.05]) at the 1σ (2σ) confidence level.

• If the association of GW190425 and FRB 20190425A is real, a preferred value of M_{TOV} around 2.66 M_{\odot} – 2.69 M_{\odot} is obtained, with an uncertainty range of $[-0.11M_{\odot}, 0.11M_{\odot}]([-0.17M_{\odot}, 0.19M_{\odot}])$ at the 1σ (2σ) confidence level. In this case, it is highly likely that the merger remnant of GW170817 is a SNS. The value of χ_r should be very close to 0.2.

In all cases, the fraction of high-mass component in the BNS mass distribution, denoted as \mathcal{R} , cannot be well constrained, while the central value is around $\mathcal{R} \sim 0.37 - 0.51$.

4 CONCLUSION AND DISCUSSION

We attempted to constrain the maximum mass of NSs (M_{TOV}), the maximum enhancement factor for the mass of rigidly rotating NSs produced after BNS mergers (χ_r), and the fraction of high-mass components in the BNS merger mass distribution (\mathcal{R}) by combining as many astronomical observations as possible.

Starting from the previous constraints on M_{TOV} in the literature based on the compactness (tidal deformability) measurements for NSs, we added constraints on M_{TOV} from the most massive pulsars observed so far (PSR J0952-0607), and the facts that approximately 24% sGRBs are followed by an X-ray internal plateau, which indicates that about 24% of BNS mergers would produce a SMNS. This led to a preferred value of M_{TOV} to be approximately $2.49M_{\odot} - 2.52M_{\odot}$, with an uncertainty of $[-0.16M_{\odot}, 0.15M_{\odot}]([-0.28M_{\odot}, 0.26M_{\odot}])$ at the 1σ (2σ) confidence level.

Furthermore, we can impose additional constraints based on the type of merger remnants in GW170817 and GW190425. The remnant type could be inferred from the electromagnetic signals during and after the merger, but is still under debate. If the remnant collapsed into a BH immediately after the differential rotating phase, a value of $M_{\rm TOV}$ around $2.3M_{\odot} - 2.4M_{\odot}$ would be preferred. In this case, the maximum mass of rigidly rotating NSs produced by BNS mergers can only be $\chi_r \sim 0.07$ greater than M_{TOV} ; If the remnant was a SMNS, a higher value of M_{TOV} around 2.5 M_{\odot} would be preferred. The central value of χ_r would be around 0.08 - 0.10; If the merger remnant was a SNS, a larger value of M_{TOV} around 2.6 M_{\odot} would be preferred. The central value of χ_r would be approximately 0.14. The constraints on \mathcal{R} , the fraction of high-mass components in the BNS merger mass distribution, are relatively loose. However, in any case, a high mass component for the mass distribution of BNS merger system is expected to exist.

The possible association of GW190425 and FRB 20190425A indicates that the merger remnant of GW190425 might be a SMNS. If that was true, $M_{\text{TOV}} \sim 2.7 M_{\odot}$ would be preferred while χ_r should be very close to 0.2. Again, the constraints on \mathcal{R} is loose.

If a SNS was produced in GW170817, constraints from the observations of its electromagnetic counterparts suggest that the surface magnetic field of the remnant should be relatively low, with a poloidal magnetic field B_p less than approximately 10^{11} G (Ai et al. **Table 1.** Constraints on Θ with observations in Category I (\mathbf{d}_{I} , including the measurements for compactness, tidal deformabilities and the mass of the most massive pulsar) and IIA (\mathbf{d}_{IIA} , the fraction of X-ray internal plateaus in sGRBs). "HS" and "LS" represent the high-spin prior and low-spin prior for the pre-merger NSs in GW170817 and GW190425, which influence the modified prior of \mathcal{R} .

	dI	$\mathbf{d}_{\mathrm{I}} + \mathbf{d}_{\mathrm{IIA}}$
NS without a quark core (HS)	$M_{\rm TOV} = 2.43^{+0.20(+0.41)}_{-0.18(-0.32)} M_{\odot}$	$M_{\text{TOV}} = 2.49^{+0.14(+0.23)}_{-0.16(-0.28)} M_{\odot}$ $\chi_r = 0.10^{+0.06(+0.08)}_{-0.05(-0.05)}$ $\mathcal{R} = 0.42^{+0.22(+0.36)}_{-0.20(-0.30)}$
NS without a quark core (LS)		$M_{\text{TOV}} = 2.49^{+0.14(+0.23)}_{-0.16(-0.28)} M_{\odot}$ $\chi_r = 0.10^{+0.06(+0.09)}_{-0.04(-0.05)}$ $\mathcal{R} = 0.41^{+0.21(+0.36)}_{-0.19(-0.29)}$
NS with a quark core (HS)	$M_{\rm TOV} = 2.50^{+0.23(+0.42)}_{-0.19(-0.34)} M_{\odot}$	$M_{\text{TOV}} = 2.52^{+0.15(+0.26)}_{-0.16(-0.28)} M_{\odot}$ $\chi_r = 0.11^{+0.06(+0.08)}_{-0.04(-0.06)}$ $\mathcal{R} = 0.44^{+0.21(+0.36)}_{-0.20(-0.31)}$
NS with a quark core (LS)		$M_{\text{TOV}} = 2.52^{+0.15(+0.25)}_{-0.16(-0.28)} M_{\odot}$ $\chi_r = 0.11^{+0.06(+0.08)}_{-0.04(-0.06)}$ $\mathcal{R} = 0.42^{+0.21(+0.36)}_{-0.20(-0.30)}$

2018). However, numerical simulations indicate that the magnetic field on the surface of neutron stars can be highly amplified during the merger (e.g. Kiuchi et al. 2023). Although most simulations only cover a short time-scale of less than 1s, a plausible mechanism is needed to dampen the enhanced magnetic field.

It is worth noting that, the prior of M_{TOV} in this work is directly extracted from Miller et al. (2021) and Li et al. (2021a). Raaijmakers et al. (2021) independently analized the NICER data and found a quite different probability density distribution for M_{TOV} on compared with Miller et al. (2021). They claimed that M_{TOV} is smaller that $2.4M_{\odot}$ at 95% confidence level. Combined with the mass measurement of J0952-0670 (~ $2.35M_{\odot}$), M_{TOV} should be well constrained near $2.3M_{\odot} - 2.4M_{\odot}$. A long-lived remnant is unlikely to be produced after GW170817 and the GW-FRB association is not real.

APPENDIX A: INTERNAL X-RAY PLATEAUS

We analyzed 144 sGRBs observed with Swift from 2005 January to 2023 January. In principle, we geometrically extrapolated the BATband (15–150 keV) data to the XRT-band (0.3–10 keV) by assuming a single power-law spectrum, and then performed a temporal fit to the combined light curve with a smooth broken power-law function to search for a possible plateau feature (shallow decay slope smaller than 0.5). In particular, we focused on collecting those sGRBs that exhibit a plateau followed by a decay index steeper than 3 as our internal plateau sample. The steeply decay slope would suggest a sudden cessation of central engine activity, which is very likely due to the collapse of a supra-massive NS into a BH. We finally found 35 sGRBs with internal plateau characteristic, which comprises 24% in the entire short GRBs' sample. An example of the internal Xray plateau light-curve fitting is shown in Figure A1. Remarkably, this fraction should be considered as a lower limit for supra-massive

Figure A1. An example of internal X-ray plateau light-curve fitting for GRB 160821B. The red solid line shows the broken power-law function fits, and the black circles and gray triangles represent XRT and BAT observation data, respectively.

NSs formation fraction from binary neutron star mergers, since some sGRBs may come from NS + BH mergers or some supermassive NSs collapsed so late that the relevant data were missed.

Table B1. List of confirmed and candidate Galactic DNS systems.

APPENDIX B: MASS DISTRIBUTION OF GALACTIC DNS SYSTEMS

We collected the confirmed and candidate Galactic DNS (containing at least one pulsar) systems with total mass measured in Table B1. Then we use a Gaussian function with mean value μ_G and standard deviation σ_G to characterize the distribution of their total masses. Using the Bayesian inference MCMC simulation, the probability density distribution of μ_G and σ_G can be obtained, which are shown in Figure B1.

APPENDIX C: TOTAL MASSES AND MASS RATIOS OF GW170817 AND GW190425

The posteriors of the parameter estimations for GW170817 and GW190425. For GW170817, the posteriors of $M_{d,1}$ and $M_{d,2}$ in the detector's frame. Considering that the redshift of GW170817 is known (z = 0.008) (Abbott et al. 2017b), the masses in the source frame are be calculated as $M_i = M_{d,i}/(1 + z)$. For GW190425, the masses in the source frame are directly given. The values shown in Figure C1 are all defined in the source frame.

APPENDIX D: PARAMETER SPACES OF EQUATION OF STATES USED TO CONSTRUCT UNIVERSAL RELATIONS

Gao et al. (2020) used a collection of common NS EoSs in the literature to build the universal relations of the gravitational and baryonic masses of non-rotating and rapidly rotating NSs. Their *P*-*n* and *M*-*R* relations are shown in Figure D1, together with the allowed parameter spaces for NS EoS constrained in Miller et al. (2021). Please find the list the EoS names, M_{TOV} and $R_{1.4}$ values in Gao et al. (2020) and the references therein. Generally, the EoSs used in Gao et al. (2020) can well cover the allowed parameter space in Miller

Figure B1. The probability density distribution of parameters to describe the mass distribution of Galactic DNSs. The titles show the central value and uncertainties at 1σ confidence level.

et al. (2021), so that the use of their proposed universal relations is conservative.

This paper has been typeset from a T_EX/LAT_EX file prepared by the author.

Figure C1. The joint probability density distributions of the total masses and mass ratios of the BNS-merger systems GW170817 and GW190425 in the source frame.

Figure D1. The microcosmic and macroscopic parameter space for NS EoSs. The black solid and dashed lines are extracted from Miller et al. (2021), which show the allowed parameter spaces at 68% and 95% confidence levels, respectively. The colored dotted lines show the *P*-*n* and *M*-*R* relations for the EoSs used to build the universal relation for *M*-*M*_b conversion in Gao et al. (2020).
