A series of $\text{Fe}_x \text{Rh}_{100-x}$ (30 $\leq x \leq$ 57) films were epitaxially grown using magnetron sputtering, and were systematically studied by magnetization-, electrical resistivity-, and Hall resistivity measurements. After optimizing the growth conditions, phase-pure Fe_xRh_{100-x} films were obtained, and their magnetic phase diagram was revisited. The ferromagnetic (FM) to antiferromagnetic (AFM) transition is limited at narrow Fe-contents with $48 \le x \le 54$ in the bulk $\mathrm{Fe_xRh_{100-x}}$ alloys. By contrast, the FM-AFM transition in the Fe_xRh_{100-x} films is extended to cover a much wider x range between 33% and 53%, whose critical temperature slightly decreases as increasing the Fe-content. The resistivity jump and magnetization drop at the FM-AFM transition are much more significant in the Fe_xRh_{100-x} films with \sim 50% Fe-content than in the Fe-deficient films, the latter have a large amount of paramagnetic phase. The magnetoresistivity (MR) is rather weak and positive in the AFM state, while it becomes negative when the FM phase shows up, and a giant MR appears in the mixed FM- and AFM states. The Hall resistivity is dominated by the ordinary Hall effect in the AFM state, while in the mixed state or high-temperature FM state, the anomalous Hall effect takes over. The absence of topological Hall resistivity in $Fe_x Rh_{100-x}$ films with various Fe-contents implies that the previously observed topological Hall effect is most likely extrinsic. We propose that the anomalous Hall effect caused by the FM iron moments at the interfaces nicely explains the hump-like anomaly in the Hall resistivity. Our systematic investigations may offer valuable insights into the spintronics based on iron-rhodium alloys.

I. INTRODUCTION

The CsCl-ordered equiatomic iron-rhodium (Fe-Rh) alloy undergoes a first-order magnetic phase transition from the high-temperature ferromagnetic (FM) state to the lowtemperature antiferromagentic (AFM) state near room temperature [1, 2]. Such a transition leads to a significant drop in the magnetization and a jump in the electrical resistivity, which can be applied to the spintronic devices. The FM-AFM transition in Fe-Rh alloys can be easily tuned by external control parameters, such as chemical substitution [3], epitaxial strain [4–6], and magnetic or electric fields [7–10]. Many exotic properties have been found in Fe-Rh alloys, which are closely related to their FM-AFM transition. The spin-orbit torque efficiency can be significantly tuned by varying the temperature across the FM-AFM transition in Fe-Rh-based heterostructures [11]. The large magnetocaloric effect can be controlled by ferroelectric domains in Fe-Rh film near the FM-AFM transition [12]. Since the FM-AFM transition presents near the room temperature, therefore, Fe-Rh alloys represent one of the ideal candidate materials for spintronic applications, such as memory resistor [13], heat-assisted magnetic recording [14], and magnetic refrigeration [12].

The bulk Fe-Rh alloys exhibit a rich phase diagram when varying the Fe- or Rh concentrations. We summarize the phase diagram of bulk Fe-Rh alloys in Fig. 1(a). On the Rhrich side, the γ -PM indicates the paramagnetic (PM) phase with a face-centered cubic (FCC) crystal structure, where both Rh- and Fe atoms occupy the same sites [see Fig. 1(b)]. For the intermediate Fe concentration (< 48%), the Fe-Rh alloys adopt the mixed α - and γ -phases. While the γ -phase remains PM, the α -phase becomes FM below certain temperatures [denoted as $(\alpha+\gamma)$ -(FM+PM) in Fig. 1(a)]. When

increasing the Fe-content above 48%, the Fe-Rh alloys show a pure α -phase with a body-centered cubic (BCC) crystal structure. In particular, the Fe-Rh alloys with 48-54% Fecontent undergo multiple magnetic transitions, from hightemperature PM state (marked as α -PM) to the FM state $(\alpha$ -FM), and then finally to the low-temperature AFM state $(\alpha$ -AFM). The FM-AFM transition temperature decreases as increasing the Fe-content. For these alloys, the Fe and Rh atoms occupy the corner- and center sites, respectively [see Fig. 1(c)]. It is noted that the α -FM and α -AFM are also known as ordered α '-phase and α "-phase. On the Ferich side, both Rh- and Fe atoms occupy the same sites [see Fig. 1(d), and the Fe-Rh alloys behave similarly to pure Fe metal, exhibiting a FM ground state below the Curie temperature (\sim 1000 K). In the α -AFM phase, the Fe-moments are aligned with a collinear G-type magnetic structure, exhibiting a typical magnetization value of $\sim 3.1 \,\mu_{\rm B}$ [15]. However, there is no net moment on the Rh site. While in the α -FM phase, both Fe-moments (\sim 3.2 $\mu_{\rm B}$) and Rh-moments (\sim 0.9 $\mu_{\rm B}$) are aligned ferromagnetically along the <001>direction [16].

In addition to the exotic properties related to the FM-AFM transition in the Fe-Rh alloys [17–19], the topological Hall effect (THE) has been observed recently in equiatomic Fe-Rh thin films [20]. In general, the THE is often considered as the hallmark of spin textures with a finite scalar spin chirality, e.g., magnetic skyrmions [21, 22]. The THE in Fe-Rh film is proposed to be attributed to the emergence of noncollinear spin texture arising from the competition among different exchange interactions in its AFM state. The interfacial inhomogeneity in the magnetic thin film could lead to an inhomogeneous anomalous Hall effect (AHE), whose signal resembles the THE [23–26]. Considering that a large amount of the remaining FM phase persists in the AFM state of Fe-Rh film in the previous work [20], the origin of THE requires further investigation. In addition, while most of the thin-film studies focus on equiatomic Fe-Rh films

^{*} tshang@phy.ecnu.edu.cn

[†] qfzhan@phy.ecnu.edu.cn

(i.e., \sim 50% Fe-content), less is known for Fe-Rh films with different Fe-contents.

Here, we revisit the phase diagram of Fe-Rh epitaxial thin films by varying the Fe- or Rh-contents, and report a comprehensive study of their magnetic and transport properties by means of magnetization-, electrical resistivity-, and Hall resistivity measurements. Different from the bulk alloys, the Fe-Rh films show a pure α -phase in a wide Fe-concentration range (i.e., 33 to 53%). The absence of topological Hall resistivity in our high-quality epitaxial Fe-Rh films with different Fe-contents excludes its possible nontrivial origin. We propose that the anomalous Hall resistivity caused by the remaining FM moments could give rise to a THE-like signal in the Hall resistivity.

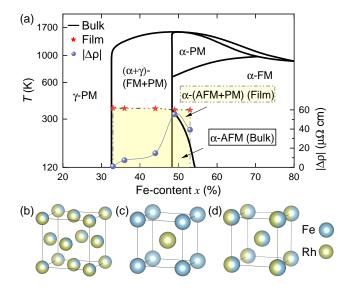

FIG. 1. (a) Phase diagram of bulk Fe-Rh alloys and epitaxial Fe-Rh films. Data of bulk alloys were taken from Refs. 16 and 27. The star symbols represent the FM-AFM magnetic transition temperatures (left axis) for Fe-Rh films, while the sphere symbols show the resistivity jump $|\Delta\rho|$ (right axis) for these films against the Fe-content. Crystal structures for (b) γ -phase (FCC, Fm-3m, No. 225) and (c) α -phase (BCC, Pm-3m, No. 221) Fe-Rh. The crystal structure of disordered α -phase is shown in panel (d). Different from the ordered α -phase in (c), the Fe or Rh atoms occupy the same site in the disordered α -phase and γ -phase.

II. EXPERIMENTAL DETAILS

A series of $Fe_x Rh_{100-x}$ ($30 \le x \le 57$) films with a thickness of ~ 50 nm were epitaxially grown on (001)-oriented MgO substrates by magnetron co-sputtering Fe and Rh targets in an ultrahigh vacuum chamber with a base pressure lower than 1×10^{-8} Torr. To remove surface contamination, MgO substrates were pre-annealed at $600\,^{\circ}\mathrm{C}$ for 1 h in the vacuum. Afterwards, the substrates were heated up to $700\,^{\circ}\mathrm{C}$, where both Fe and Rh atoms were deposited under a 3 mTorr-Ar pressure. During the deposition, MgO substrates were continuously rotated to improve homogeneity. After the deposition, $Fe_x Rh_{100-x}$ films were annealed in situ at $750\,^{\circ}\mathrm{C}$ for an extra hour to improve their crystallinity. Finally, a 3-nm-thick Ta cap layer was deposited at room temperature to avoid oxidation.

The crystal structure and the epitaxial nature of Fe_xRh_{100-x} films were characterized by Bruker D8 Discover

high-resolution x-ray diffractometer (HRXRD). The thickness of films were determined by x-ray reflectivity (XRR). The measurements of electrical resistivity (ρ) , Hall resistivity (ho_{xy}), and magnetization were performed on a Quantum Design physical property measurement system (PPMS) and a magnetic property measurement system (MPMS), respectively. For the transport measurements, the Fe_xRh_{100-x} films were patterned into a Hall-bar geometry (central area: $0.2 \,\mathrm{mm} \times 4 \,\mathrm{mm}$; electrodes: $0.4 \,\mathrm{mm} \times 0.65 \,\mathrm{mm}$) by using a shadow mask during the growth. To avoid spurious resistivity contributions due to misaligned Hall probes, the longitudinal contribution to the Hall resistivity ρ_{xy} , was removed by an anti-symmetrization procedure, i.e., $\rho_{xy}(H)$ = $[\rho_{xy}(H) - \rho_{xy}(-H)]/2$. Similarly, in the case of longitudinal electrical resistivity ρ measurements, the spurious transverse contribution was removed by a symmetrization procedure, i.e., $\rho(H) = [\rho(H) + \rho(-H)]/2$.

III. RESULTS AND DISCUSSIONS

A. x-ray diffraction and lattice parameters

We estimated the composition of Fe_xRh_{100-x} films using the following model:

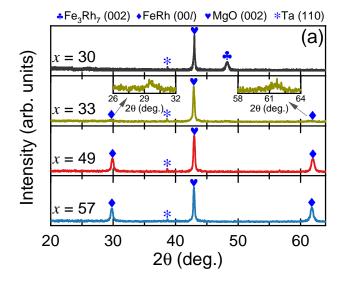

$$x = n \cdot N_A = (m/M_A) \cdot N_A = [(\beta \cdot \nu \cdot t \cdot S)/M_A] \cdot N_A. \quad (1)$$

Here, n, m, N_A , and M_A are molar number, mass, Avogadro constant, and molar mass; ν and t are deposition rate and time; β and S represent the density and surface area of the film, respectively. The deposition rate ν was controlled by adjusting the DC sputtering power of Fe and Rh targets, which was further calibrated by XRR measurements. Table I lists the sputtering power of Fe- and Rh targets for different Fe $_x$ Rh $_{100-x}$ films. For instance, to produce the Fe $_{30}$ Rh $_{70}$ film, the $P_{\rm Fe}$ and $P_{\rm Rh}$ were set to 20 and 15 W, respectively. We compared the magnetization- and electrical-resistivity results of the Fe $_{49}$ Rh $_{51}$ film prepared by co-sputtering method with the one grown from Fe $_{50}$ Rh $_{50}$ alloy target, both films show almost identical behaviors, suggesting that the above model gives correct Fe and Rh contents. Seven Fe $_x$ Rh $_{100-x}$ films with x ranging from 30 to 57 were deposited.

Table I. Summary of the sputtering power of Fe ($P_{\rm Fe}$) and Rh ($P_{\rm Rh}$) targets for Fe_xRh_{100-x} thin-film growth and the estimated Fe-content for the obtained films. The deviation of Fe-content is about 2%. Except Fe₃₀Rh₇₀ film, all other Fe-Rh films adopt a pure α -phase.

P _{Fe} (W)	20	25	30	35	40	45	35
P_{Rh} (W)	15	15	15	15	15	15	10
x (Fe-content)	30	33	36	44	49	53	57

The HRXRD measurements were performed to check the crystal structure and the epitaxial nature of the deposited $\text{Fe}_x \text{Rh}_{100-x}$ films. Figure 2(a) shows representative XRD patterns for $\text{Fe}_x \text{Rh}_{100-x}$ films with x=30, 33, 49, and 57. For x=30, the (002)-reflection of $\text{Fe}_3 \text{Rh}_7$ -phase is clear, which adopts a γ -phase [28] and is consistent with the bulk phase diagram in Fig. 1. Since the γ -phase $\text{Fe}_{30} \text{Rh}_{70}$ is paramagnetic, its magnetic- and electrical transport properties will not be discussed here. No sign of the α -phase can be identified in this film. When increasing the Fe-content up

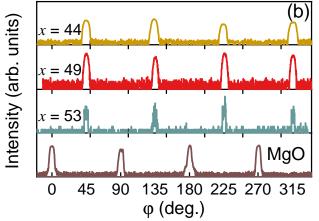

FIG. 2. (a) Representative XRD patterns of Fe_xRh_{100-x} films for x=30,33,49, and 57. The insets show enlarged plots of (001)-and (002)-reflections of $Fe_{33}Rh_{67}$ film. (b) φ -scan measurements for some selected Fe_xRh_{100-x} films. The intensity is plot on the logarithmic scale.

to 33%, the γ -phase disappears, in the meanwhile, α -phase starts to show up [see insets in Fig. 2(a)]. For $33 \le x \le 57$, all $Fe_x Rh_{100-x}$ films show a pure α -phase, exhibiting distinct (001)- and (002) reflections. This is obviously different from the bulk materials. In the bulk form, Fe-Rh alloys (with x < 48) show mixed γ - and α -phases. The absence of foreign phases or misorientation suggests the good quality of our deposited Fe_xRh_{100-x} films. It is noted that the α -phase Fe_xRh_{100-x} films were epitaxially grown on the MgO substrates with an in-plane 45° rotation, i.e., FeRh[110](001) | MgO[100](001) [5], which was further checked by φ -scan measurements [see Fig. 2(b)]. It is noted that, for x = 33, the intensities of the XRD reflections are rather low due to the increased mismatch between the film and the substrate, its epitaxial nature cannot be verified by the φ -scan measurements. For x=33, the epitaxy is less good than the rest of the films, and it might be polycrystalline in nature but with preferred (00*l*) orientation.

We estimated the out-of-plane lattice constant (i.e., c-axis) for the α -phase Fe_xRh_{100-x} (33 $\leq x \leq$ 57) films according to the XRD patterns. As shown in Fig. 3, for x=49, the lattice parameter (2.989 Å) is almost identical to the value of $Fe_{50}Rh_{50}$ film (2.988 Å) grown by using a $Fe_{50}Rh_{50}$ alloy target [31], which further proves that the above model [see

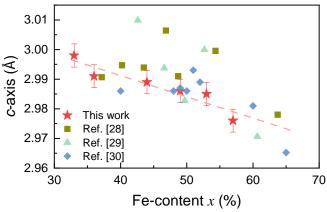

FIG. 3. Out-of-plane lattice parameters for the Fe_xRh_{100-x} films and bulk counterparts as a function of the Fe-content. The star symbols represent the current work, while the other symbols stand for the previous studies, which were taken from Refs. 28–30. The dashed line is a guide to the eyes.

Eq. (1)] estimates the proper Fe- or Rh concentration. The obtained lattice parameter linearly decreases as increases the Fe-content x (see star symbols). While in the previous studies, the lattice parameters are clearly more scattered (see square and triangle symbols). Such linear x-dependent lattice parameters again confirm that our $\text{Fe}_x \text{Rh}_{100-x}$ films are very homogeneous and have a better quality.

B. Magnetic properties of Fe_xRh_{100-x} films

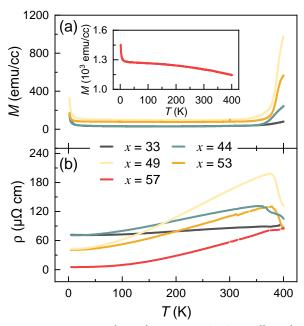

FIG. 4. Temperature-dependent magnetization collected in a field of $\mu_0 H = 0.1\,\mathrm{T}$ (a) and zero-field electrical resistivity (b) for $\mathrm{Fe}_x\mathrm{Rh}_{100-x}$ (33 $\leq x \leq$ 57) films. The inset shows the magnetization data for x= 57 film.

The $\operatorname{Fe}_x \operatorname{Rh}_{100-x}$ (33 $\leq x \leq$ 57) films were first characterized by temperature-dependent magnetization M(T) and electrical resistivity $\rho(T)$. For the α -phase $\operatorname{Fe}_x \operatorname{Rh}_{100-x}$ (33 $\leq x \leq$ 53) films, there is a clear anomaly around 380 K, which is attributed to the FM-AFM transition. Since the onset of this transition is above 400 K in zero-field condition in

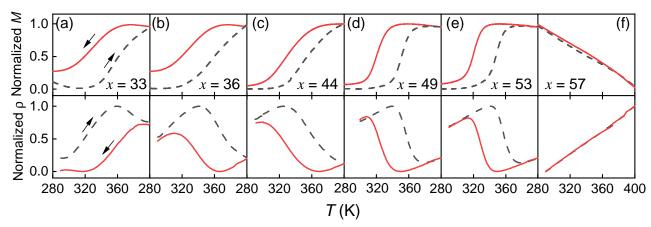

FIG. 5. Temperature dependence of the magnetization (up-panels) and the electrical resistivity (bottom-panels) for $\text{Fe}_x \text{Rh}_{100-x}$ (33 \leq x \leq 57) films. All the data were collected in a magnetic field of $\mu_0 H = 5 \, \text{T}$ during the cooling (solid lines) and heating processes (dashed lines). To better compare the results of different films, both the magnetization and electrical resistivity data are normalized to the values between 0 and 1.

Fe_xRh_{100-x} films, the entire transition can not be detected up to 400 K. However, the magnetic field can efficiently tune such a FM-AFM transition, and thus, the full transition can be clearly seen in a field of 5 T. For x=57, the bulk sample undergoes a FM transition at very high temperature (~1000 K) (see Fig. 1). As shown in the inset of Fig. 4(a), the magnetization of Fe₅₇Rh₄₃ film resembles the pure Fe film [32], and there is no magnetic transition below 400 K. The magnetization of Fe₅₇Rh₄₃ film (~1200 emu/cc) is almost 10 times larger than the Fe_xRh_{100-x} (33 \leq x \leq 53) films in their AFM state (~100 emu/cc). It is noted that in all the Fe_xRh_{100-x} films, the upturn feature below 10 K is most likely attributed to the PM contribution of MgO substrate [33].

Figure 4(b) presents the zero-field temperature-dependent electrical resistivity $\rho(T)$ for $\text{Fe}_x\text{Rh}_{100-x}$ (33 $\leq x \leq$ 57) films. All the films show a typical metallic behavior below 350 K, the electrical resistivity decreases as lowering the temperature. Similar to the magnetization results, the resistivity jump at FM-AFM transition is not completed up to 400 K for x = 44, 49, 53. For x = 33, though the resistivity anomaly is very weak, it is still can be observed (see Fig.5). While for x = 57, there is no clear anomaly in the studied temperature range, consisting with its magnetization data [see inset in Fig. 4(a)].

To better track the FM-AFM transition of Fe_xRh_{100-x} films, the M(T) and $\rho(T)$ were also collected upon heating and cooling the temperature in a field of $\mu_0 H = 5$ T. For $33 \le x \le 53$, the M(T) exhibits a significant drop below 400 K upon cooling (see solid lines in the up panels in Fig. 5), indicating that these Fe_xRh_{100-x} films undergo a magnetic phase transition from high-T FM state to low-T AFM state. Such a FM-AFM transition is clearly reflected also in $\rho(T)$ data. As shown by solid lines in the bottom panels of Fig. 5, in contrast to the M(T) data, the $\rho(T)$ undergoes a significant jump near the FM-AFM transition. In the FM state, both the Fe- and Rh moments are aligned along the c-axis [16], resulting in a low-resistivity state. While in the AFM state, the enhanced magnetic scattering leads to a high-resistivity state. When increasing the magnetic field, the Fe moments are forced to ferromagnetically align again, accompanied by a resistivity drop at the metamagnetic transition [34]. Upon heating, all the Fe_xRh_{100-x} films undergo an AFM-FM transition, reflected by a jump in the magnetization or a drop in the electrical resistivity (see dashed lines in Fig. 5).

While for x = 57 [see Fig. 5(f)], similar to the results in Fig. 4, no trace of magnetic transition can be identified in a field of 5 T, consistent with its FM nature in the studied temperature range.

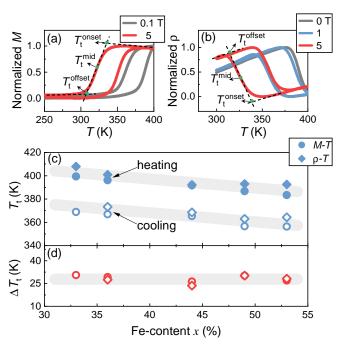

FIG. 6. Temperature-dependent magnetization (a) and electrical resistivity (b) collected under various magnetic fields up to 5 T for Fe₄₉Rh₅₁ film. Both the magnetization and electrical resistivity data are normalized to the values between 0 and 1. (c) The magnetic transition temperatures $T_{\rm t}$ (i.e., $T_{\rm t}^{\rm mid}$) determined from magnetization- and electrical-resistivity measurements vs. Fe-content. Open- and solid symbols represent the $T_{\rm t}$ determined from the measurements upon cooling- and heating processes, respectively. (d) The transition width $\Delta T_{\rm t}$ (= $T_{\rm t}^{\rm conset}$ - $T_{\rm t}^{\rm offset}$) of the FM-AFM (or AFM-FM) transition vs. the Fe-content.

Figures 6(a) and 6(b) plot the normalized temperature-dependent magnetization and electrical resistivity collected under various magnetic fields up to 5 T between 250 and 400 K for $Fe_{49}Rh_{51}$ film. When increasing the magnetic field, the FM-AFM (or AFM-FM) transition is suppressed to lower temperatures. As indicated by the arrows, the $T_{\rm t}^{\rm onset}$, $T_{\rm t}^{\rm mid}$, and $T_{\rm t}^{\rm offset}$ are defined as the onset, middle, and offset of the

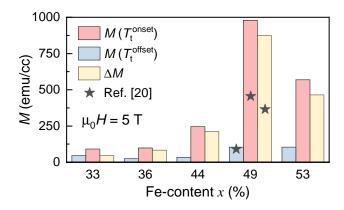

FIG. 7. The magnetization at $T_{\rm t}^{\rm onset}$ and $T_{\rm t}^{\rm offset}$, and their difference ΔM [= $M(T_{\rm t}^{\rm onset})$ - $M(T_{\rm t}^{\rm offset})$] for various ${\rm Fe}_x {\rm Rh}_{100-x}$ films (33 $\leq x \leq$ 53). The data were obtained from the magnetization collected during the cooling process (see details in Fig. 4). For the magnetization at $T_{\rm t}^{\rm onset}$ and $T_{\rm t}^{\rm offset}$, the background signal from the MgO substrates was subtracted according to $M_{\rm FeRh}(T_{\rm t}^{\rm onset}) = M_{\rm raw}(T_{\rm t}^{\rm onset}) - M_{\rm MgO}(T_{\rm t}^{\rm onset})$. The data extracted from Ref. 20 were also presented.

magnetic transition temperatures, respectively. We found that T_t is suppressed at a rate of -7 K/T by the external magnetic field for $Fe_{49}Rh_{51}$ film. The $T_t(H)$ exhibits a linear field dependence up to 10 T [34]. To obtain zero-field magnetic transition temperatures, T_t values determined from 5 T-data (see Fig. 5) were extrapolated to zero field using the above rate. The estimated zero-field T_t values (here we choose T_{\star}^{mid}) are summarized in Fig. 6(c) as a function of Fe-content. The T_t determined from magnetizationand electrical-resistivity measurements are highly consistent. When increasing the Fe-content, T_t determined during the heating process slightly decreases from 400 K for x = 33to 385 K for x = 53. The T_t determined during the cooling process exhibits an almost identical trend, yielding a x-independent transition width ΔT_t [see Fig. 6(d)]. Such $\Delta T_t(x)$ indicates that the first-order FM-AFM transition exists in the Fe_xRh_{100-x} (33 $\leq x \leq$ 53) films with a much wider Fe-content than the bulk alloys. For the latter case, it is limited only at $48 \le x \le 54$ (see details in Fig. 1).

To quantitatively describe the FM-AFM transition in $\text{Fe}_x \text{Rh}_{100-x}$ (33 $\leq x \leq$ 53) films, their magnetization at different magnetic states are summarized in Fig. 7. The $M(T_t^{\text{onset}})$ represents the magnetization at T_t^{onset} (i.e., FM state), while $M(T_{t}^{\text{offset}})$ is the magnetization at T_{t}^{offset} (i.e., AFM state). Both $M(T_t^{\text{onset}})$ and $M(T_t^{\text{offset}})$ reach a maximum value as the Fe-content increases up to 49%. According to the XRD results [see Fig. 2(a)], all the $Fe_x Rh_{100-x}$ (33 $\leq x \leq$ 53) films show a pure α -phase at room temperature, which is completely different from the bulk alloys (see Fig. 1). Therefore, in the Fe_xRh_{100-x} films, the larger magnetization value indicates a larger FM phase concentration at $T \ge T_{t}^{\text{onset}}$, and vice versa. As can be clearly seen in Fig. 7, the magnetization of x = 49 and 53 films is significantly larger than that of x < 49, implying that most of the Fe moments stay PM in the latter cases. In the AFM state (i.e., $T \leq T_r^{\text{offset}}$), the magnetization is mainly attributed to the pinned Fe moments at the Ta/Fe_xRh_{100-x} or Fe_xRh_{100-x}/MgO interfaces [35, 36]. As a consequence, the smaller magnetization value indicates a larger AFM phase concentration at $T \leq T_{t}^{\text{offset}}$, and vice versa. We also summarized the magnetization drop ΔM , a

measure of the FM-AFM transition, versus the Fe-content in Fig. 6. Similar to the $M(T_{\rm t}^{\rm onset})$, the ΔM also reaches a maximum value at x=49, which is significantly larger than the rest of Fe_xRh_{100-x} films.

For the Fe-Rh-based spintronic applications, the ${\rm Fe}_x{\rm Rh}_{100-x}$ films with a large ΔM value are preferred [12–14], since it could also give rise to a pronounced jump in the electrical resistivity. The estimated resistivity jumps $\Delta \rho$ [= $\rho(T_{\rm t}^{\rm offset})$ - $\rho(T_{\rm t}^{\rm onset})$] [see details in Fig. 6(b)] of ${\rm Fe}_x{\rm Rh}_{100-x}$ (33 $\leq x \leq$ 53) films are summarized in the phase diagram (see Fig. 1). Indeed, for x=49 and 53, the $\Delta \rho$ values are significantly larger than that of x<49. For instance, the $\Delta \rho=55~{\rm \mu}\Omega{\rm cm}$ for x=49, while it is less than 10 ${\rm \mu}\Omega{\rm cm}$ for x=33. Our results demonstrate that the ${\rm Fe}_x{\rm Rh}_{100-x}$ films with Fe-content up to 53% exhibit magnetic and transport properties that are comparable to the ideal 49%-case. While for $x\leq44$, the FM-AFM transition is less pronounced, leading to small ΔM and $\Delta \rho$ values.

C. Magnetoresistivity and Hall resistivity

The field-dependent longitudinal- and transverse resistivity were measured in a wide temperature range for Fe_xRh_{100-x} films. Since the films with x = 44, 49, and 53 exhibit a more pronounced magnetic phase transition, here, the field-dependent measurements were focused on these films. Figure 8(a)-(c) plot the magnetoresistivity (MR) collected at various temperatures with the magnetic field up to 9 T. The MR values of $Fe_x Rh_{100-x}$ films at $\mu_0 H = 9$ T are summarized in Fig. 8(d). All three films exhibit similar temperature-dependent MR in the studied temperature range. In the AFM state ($T \le 250$ K), the MR is positive, which is mainly attributed to the enhanced magnetic scattering by applying external magnetic field. Once the magnetic field destroys the AFM phase and fully polarizes the Fe moments, the MR exhibits a significant drop near the metamagnetic transition [34, 37]. As the temperature increases close to room temperature, where the FM phase shows up, the MR becomes negative, a typical feature for the ferromagnets. While in the mixed AFM- and FM states, a giant MR was observed, whose value reaching almost 50% at $T = 350 \,\mathrm{K}$ for x = 53. Such a giant MR is related to the field-induced metamagnetic transition in Fe_xRh_{100-x} films, as observed in their AFM state [37].

The Fe₅₀Rh₅₀ film has been found to exhibit a topological Hall effect in a wide temperature range [20], which is often attributed to the topological spin textures in magnetic materials [38, 39]. Since the Fe-Rh alloys have a simple G-type AFM structure, the appearance of THE is rather puzzling. To further investigate the possible THE in Fe_xRh_{100-x} films, we also performed systematic Hall-resistivity measurements. As shown in Fig. 8, the $\rho_{xy}(H)$ were collected at various temperatures covering both the AFM- and FM states for Fe_xRh_{100-x} (x = 44, 49, and 53) films. In the FM state, the $\rho_{xy}(H)$ is dominated by the anomalous Hall effect (see 380-K curves in Fig. 9). While in the AFM state (i.e., $T < 300 \,\mathrm{K}$), in contrast to the previous work [20], all the $\rho_{xy}(H)$ curves exhibit almost a linear field dependence at $\mu_0 \dot{H} \leq 6$ T, definitely excluding the possible THE in our Fe_xRh_{100-x} films. While for $\mu_0 H >$ 6 T, the ρ_{xy} becomes nonlinear, which is clearly reflected by the 300- K curves in Fig. 9. Such nonlinear $\rho_{xy}(H)$ is attributed to the field-induced metamagnetic transition in

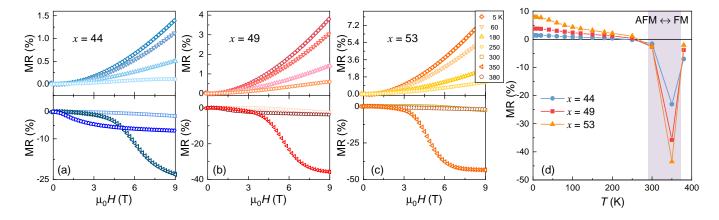

FIG. 8. Magnetoresistivity up to 9 T for (a) x = 44, (b) x = 49, and (c) x = 53 collected at various temperatures covering both the FM- and AFM states. (d) Temperature-dependent 9-T MR values for the above three films. The magnetic field was applied along the out-of-plane direction. The MR was calculated following MR = $[\rho(H) - \rho(0)]/\rho(0)$, where $\rho(0)$ is the zero-field electrical resistivity. The shaded region highlights the coexistence of AFM- and FM phases, where a giant MR appears.

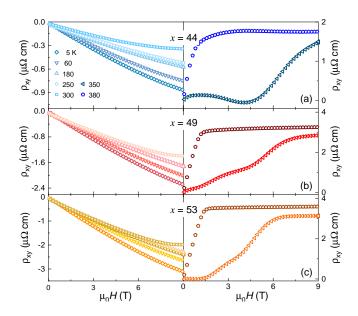

FIG. 9. Field-dependent Hall resistivity $\rho_{xy}(H)$ collected at various temperature below 400 K up to 9 T for $\text{Fe}_x \text{Rh}_{100-x}$ films with (a) x = 44, (b) x = 49, and (c) x = 53.

 Fe_xRh_{100-x} films. The metamagnetic transition field is about 8.3 T at 300 K, which increases when decreasing temperature, reaching 9.8 T at $T=291\,\mathrm{K}$ [34]. Therefore, the ρ_{xv} is always dominated by the ordinary Hall effect (OHE) at $\mu_0 H \le 9 \text{ T}$ for T < 250 K. However, once the magnetic field is larger than the metamagnetic transition field, the $\rho_{xy}(H)$ resembles the typical features of AHE in ferromagnets. Interestingly, in the mixed AFM- and FM states, our Fe_xRh_{100-x} films exhibit a clear hump-like anomaly in the $\rho_{xy}(H)$. As shown in Fig. 9, a clear hump can be observed at $\mu_0 H \sim$ 3 T at 350 K. Such a hump-like anomaly resembles the topological Hall resistivity reported in the previous work [20]. However, such an anomaly is absent in the AFM state, implying that its origin is very unlikely the noncollinear spin textures. On the contrary, this anomaly can be reproduced, assuming anomalous Hall resistivity with different origins existing in the Fe_xRh_{100-x} films (see details in the discussion section).

D. Discussion

First, we discuss the magnetic phase diagram of Fe_xRh_{100-x} films. After optimizing the growth conditions, we could produce phase-pure Fe_xRh_{100-x} films with a wide x range (i.e., Fe-content). For the bulk case, the Fe_xRh_{100-x} alloys adopt the mixed α - and γ -phases for $33 \le x \le 48$ [see details in Fig. 1(a)]. While the γ -phase remains PM, the α phase becomes FM below certain temperatures. For x > 48, the Fe_xRh_{100-x} alloys show a pure α -phase with the Curie temperatures between 600 and 1000 K. For some particular Fe concentrations, i.e., $48 \le x \le 54$, the Fe_xRh_{100-x} alloys undergo multiple magnetic transitions, from PM state to the FM state, and then finally to the AFM state. Different from the bulk alloys, Fe_xRh_{100-x} films show significantly different structural and magnetic properties. For the Fe-deficient case, $Fe_{30}Rh_{70}$ film adopts a γ -phase, and there is no magnetic transition below 400 K, implying its PM nature. For $33 \le x \le 57$, all $\text{Fe}_x \text{Rh}_{100-x}$ films show a pure α -phase. For the bulk alloys, no additional magnetic transition has been found below the Curie temperature for $33 \le x \le 48$. While in the case of films, there is a distinct FM-AFM transition for $33 \le x \le 53$, whose critical temperature T_t determined during the heating process slightly decreases from 400 K for x = 33 to 385 K for x = 53 [marked as α -(AFM+PM) in Fig. 1(a)]. In the case of Fe-rich films (i.e., $x \ge 57$), though they show pure α -phase, the FM-AFM transition is absent, and all the films host a FM ground state. It is noted that the FM-AFM transition exists in the Fe_xRh_{100-x} films with a wide Fe-content, however, there is a large portion of remaining PM phase for $x \le 44$, which is reflected by a reduced resistivity jump $\Delta \rho$ and a magnetization drop ΔM (see details in Fig. 1 and Fig. 7). In addition, in all the Fe_xRh_{100-x} films, the Fe moments pinned at the interfaces also contribute to the magnetization in the AFM state and could lead to a hump-like anomaly in the Hall resistivity. The absence of AHE in the AFM state proves that our Fe_xRh_{100-x} films have negligible remaining FM contribution (see Fig. 9).

Now we discuss the possible THE in Fe_xRh_{100-x} films. Based on the experimental observations in Fig. 9, we show the schematic plots in Fig. 10 to discuss the Hall resistivity in Fe_xRh_{100-x} films. The linear $\rho_{xy}(H)$ is caused by the OHE (marked as ρ_{xy}^{0}), whose negative slope suggests that the

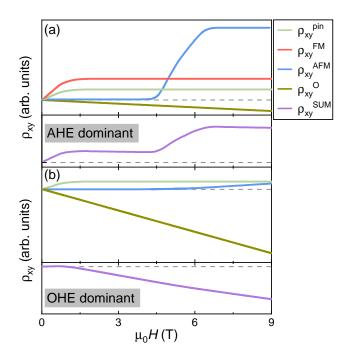

FIG. 10. Schematic plots of different contributions to the Hall resistivity for the Fe_xRh_{100-x} films in the mixed AFM- and FM states (a) or in the AFM state (b). In the mixed FM- and AFM states, $\rho_{xy}^{\text{SUM}} = \rho_{xy}^{\text{O}} + \rho_{xy}^{\text{pin}} + \rho_{xy}^{\text{FM}} + \rho_{xy}^{\text{AFM}}$, while in the AFM state, $\rho_{xy}^{\text{SUM}} = \rho_{xy}^{\text{O}} + \rho_{xy}^{\text{pin}} + \rho_{xy}^{\text{AFM}}$. Here, ρ_{xy}^{pin} , ρ_{xy}^{AFM} , and ρ_{xy}^{FM} all denote the anomalous-Hall resistivity.

electron carriers are dominant in the ${\rm Fe_xRh_{100-x}}$ films. The ${
ho_{{
m xy}}^{{
m pin}}}$, ${
ho_{{
m xy}}^{{
m AFM}}}$, and ${
ho_{{
m xy}}^{{
m FM}}}$ all denote the anomalous Hall resistivity, which are attributed to the ferromagnetically pinned Fe moments at the interfaces, AFM magnetization, and FM magnetization, respectively. In general, both ρ_{xy}^{pin} and ρ_{xy}^{FM} are proportional to the magnetization (i.e., $\rho_{xy}^{pin} \propto M^{pin}$, $\rho_{xy}^{FM} \propto M^{FM}$), typical for ferromagnets [40]. Here, M^{pin} and M^{FM} are the magnetization attributed to the pinned Fe moments at the interfaces and the FM regions of the film, both of which saturate when increasing the magnetic field up to 1 T. While the ρ_{xy}^{AFM} is proportional to $\rho^2 M$, ρM , or their combinations, depending on the intrinsic or extrinsic mechanism [41]. Here we use ρM to produce ρ_{xy}^{AFM} , while the $ho^2 M$ leads to similar behaviors. We assume that the AFM magnetization $M^{\rm AFM}$ is linear in the low-field region but undergoes a metamagnetic transition at higher magnetic field, whose critical field increases as lowering the temperature. For example, the metamagnetic transition field is close to 5 T near room temperature but increases to 7.5 T at 290 K [34]. As shown in Fig. 10(a), in the mixed AFM- and FM states, the AHE due to FM and AFM magnetization (i.e., $\rho_{\rm xy}^{\rm FM}$ and $\rho_{\rm xy}^{\rm AFM})$ is dominant, and as a consequence, the total Hall resistivity ho_{xy}^{SUM} shows a step-like feature, typical for the magnets that undergo a metamagentic transition. The $ho_{\mathrm{xy}}^{\mathrm{SUM}}$ qualitatively agrees very well with $ho_{\mathrm{xy}}\!(H)$ collected at 350 K. In the AFM state, as shown in Fig. 10(b), since the OHE is dominant, the observed $ho_{xy}(H)$ is almost linear in field. While the $ho_{\mathrm{xy}}^{\mathrm{pin}}$ could cause a hump-like anomaly in the ho_{xy}^{SUM} , resembling the observed topological Hall resistivity in Ref. [20]. However, such an anomaly is clearly absent in our Fe_xRh_{100-x} films with different Fe-contents

(see Fig. 9). Since the ho_{xy}^{pin} is attributed to the FM iron moments pinned at the interfaces, such a hump-like anomaly in the $\rho_{xy}(H)$ should strongly depend on the thin-film quality. We summarized the magnetization values from Ref. [20] in Fig. 7 to compare with our films. Though the remaining magnetization $M(T_t^{\text{offset}})$ is comparable to our Fe₄₉Rh₅₁ film, the FM-state magnetization $M(T_{\rm t}^{\rm onset})$ is two times smaller than our film. As a consequence, the $\rho_{xy}(H)$ is significantly affected by the $ho_{\mathrm{xy}}^{\mathrm{pin}}$ in the previous work. In addition, since the $ho_{
m xy}^{
m pin}$ has opposite sign against the $ho_{
m xy}^{
m O}$, the large contribution of ρ_{xy}^{pin} might cause the sign change in the $\rho_{xy}(H)$ when cooling the film down to lower temperatures. Indeed, such a sign change was observed in the previous work, the slope of $\rho_{xy}(H)$ becomes positive below 80 K [20]. While in our Fe_xRh_{100-x} (x = 44, 49, and 53) films, the $\rho_{xy}(H)$ is always negative in the AFM state, which again proves that the remaining FM magnetization at the interfaces has little effect in our Fe_xRh_{100-x} films. To conclude, the observed THE in Fe_xRh_{100-x} films is most likely an extrinsic effect. The other techniques, such as resonant x-ray scattering or Lorentz transmission electron microscopy, are highly desirable to search for possible topological magnetic phases in $Fe_x Rh_{100-x}$ family.

IV. CONCLUSION

To summarize, we grew a series of epitaxial Fe_xRh_{100-x} $(30 \le x \le 57)$ films on MgO substrates. By systematic x-ray diffraction-, magnetization-, and electrical resistivity measurements, we established the structural and magnetic phase diagram of Fe_xRh_{100-x} films. For $x \le 30$, Fe_xRh_{100-x} films are PM and adopt a γ -phase. For $x \ge 33$, all films show a pure α -phase. In the bulk $\operatorname{Fe}_x\operatorname{Rh}_{100-x}$ alloys, the FM-AFM transition is limited only at $48 \le x \le 54$. While the FM-AFM transition persists in the Fe_xRh_{100-x} films with $33 \le x \le$ 53, and the transition temperature slightly decreases from 400 K for x = 33 to 385 K for x = 53. As further increases the Fe-content (i.e., x > 53), the FM-AFM transition no longer exists, and Fe_xRh_{100-x} films are FM in the studied temperature range. The resistivity jump and magnetization drop at the FM-AFM transition are much more pronounced in the Fe_xRh_{100-x} films with ~50% Fe-content than in the Fe-deficient films, the latter have a large amount of PM phase. The magnetoresistivity is positive and weak in the AFM state, while it becomes negative when the FM phase shows up, and a giant MR appears in the mixed AFM- and FM states. The Hall resistivity measurements reveal trivial behaviors in the Fe_xRh_{100-x} films, which is dominated by the OHE in the AFM state and by the AHE in the mixedor FM state, respectively. Our results demonstrate that the previously observed topological Hall resistivity is absent in our Fe_xRh_{100-x} (x = 44, 49, and 53) films. We proposed that the AHE caused by the FM iron moments at the interfaces could explain the hump-like anomaly in the Hall resistivity. To conclude, the observed THE in Fe_xRh_{100-x} films can be explained by extrinsic mechanisms rather than the presence of noncollinear spin textures.
