Abstract. We discuss the magnetic field influence on diffuse gamma-ray emission from extragalactic electromagnetic cascades initiated by ultra-high energy cosmic rays. Regions in space vary considerably in field strength: it is possibly of 10^{-12} G and lower in voids, of $\sim 10^{-6}$ G inside galaxies, galactic clusters and groups, of $\sim 10^{-7}$ G around them, and of $\sim 10^{-8}$ - 10^{-9} G in filaments. Structures having fields higher than in voids occupy comparatively small fraction of the Universe, so they affect weakly on cascade emission. Still knowledge of this influence may be relevant studying large-scale component of the extragalactic magnetic field and to the search for exotic particles, as in the latter case contribution of all components to extragalactic gamma-ray background should be known, one of which is cascade emission. To study magnetic field effect we simulate particle propagation in homogeneous magnetic field of $\sim 10^{-6}$, 10^{-9} , and 10^{-12} G and lower. It is found that in fields of $\sim 10^{-9}$ G and lower the spectra of diffuse cascade gamma-rays at energies $E \leq 10^{17}$ eV coincide. Thus no specific models of EGMF are required to study contribution of cascade emission in the extragalactic gamma-ray background at $E \leq 10^{17}$ eV. In the case of uniform field of 10^{-6} G (which seems to be unrealistic), this inference is valid in the energy range of $\sim 10^7$ - 10^9 eV. Results obtained can be also used studying large-scale component of the extragalactic magnetic field.

Keywords: cosmic rays; electromagnetic cascades; extragalactic magnetic field; extragalactic diffuse gamma-ray background

1. Introduction.

Soon after the cosmic microwave background (CMB) has been discovered it was shown that cosmic particles at ultra-high energies (UHE) $E > 4 \times 10^{19}$ eV interact with it losing energy (GZK-effect) [Greisen, 1966; Zatsepin and Kuz'min, 1966] and giving rise to electromagnetic cascades [Hayakawa, 1966; Prilutsky and Rozental 1970]. UHECRs interact also with radio background emission [Berezinsky et al. 1990], and particles produced in cascades interact with CMB, radio emission and extragalactic background light (EBL).

Extragalactic cascades arise in the following processes. UHECRs assuming to be

protons, interact in intergalactic space with CMB and radio emission mainly via reactions: $p+\gamma_r \rightarrow p+\pi^0$, $p+\gamma_r \rightarrow n+\pi^+$. Produced pions decay through the channel $\pi^0 \rightarrow \gamma+\gamma$, $\pi^+ \rightarrow \mu^++\nu_\mu$ giving rise to gamma-quanta, neutrinos and muons. Muons decay via $\mu^+ \rightarrow e^++\nu_e+\bar{\nu}_\mu$ and give rise to positrons and neutrinos. Neutrons decay producing p, e^- and $\bar{\nu}_e$. Gamma-quanta, electrons and positrons are the particles which generate electromagnetic cascades in the interaction with background emission (CMB, radio, and EBL): $e+\gamma_b \rightarrow e'+\gamma'$ (IC scattering) and $\gamma+\gamma_b \rightarrow e^++e^-$ (pair production). Other reactions give a minor contribution to electromagnetic cascades. The development of the electromagnetic cascades in the universe in presence of CMB and EBL is described e.g. in [Berezinsky and Kalashev, 2016].

In addition to interaction with background emission, cascade electrons generate synchrotron radiation in the extragalactic magnetic field (EGMF), which quanta take part in IC scattering. The value of EGMF that weakly affects cascade process is estimated e.g. in [Uryson, 1998]: $B < 10^{-9}$ G. Experimental indication of EGMF is analyzed intensively (see, e.g. [Kronberg, 1994, 2016; Beck 2009; Elyiv et al. 2009; Govoni et al. 2019; Abbasi et al. 2020; Dzhatdov et al. 2020], but at present its structure and value has not yet clarified in detail. Diffuse cascade emission produced in homogeneous EGMF of various values was studied previously e.g. in [Beresinsky et al. 2011; Wang et al. 2011].

EGMF is apparently inhomogeneous, and regions in space vary considerably in field strength. Simulation of large-scale structure along with EGMF evolution was performed in e.g. [Dolag et al. 2005; Ryu et al. 1998; Ryu et al. 2008]. Recently codes ENZO and IllustrisTNG (TNG) has been applied to predict the evolution and present-day distribution of extragalactic magnetic fields: by Hackstein et al. (2016), Vazza et al. (2017) using a large suite of cosmological simulations with ENZO-code, and by Arámburo-García et al. (2021a, b) with a suite of large-volume cosmological simulations TNG.

Following results [Dolag et al. 2005; Ryu et al. 1998; Ryu et al. 2008; Vazza et al. 2017], magnetic field in voids is $B \leq 10^{-12}$ G (and has no effect on cascade process), it is of $\sim 10^{-6}$ G inside galaxies, galactic clusters and groups, of $\sim 10^{-7}$ G around them, and of $\sim 10^{-8} - 10^{-9}$ G in filaments. The limit of EGMF in voids approximately less than 10^{-11} G is derived analyzing CMB radiation in [Ade et al. 2016; Jedamzik and Saveliev, 2019]. Results by [Hackstein et al. 2016; Arámburo-García et al 2021a, b] demonstrate that space magnetization is influenced by processes of galaxy evolution, that might considerably enhance the fraction of space volume with $B > 10^{-12}$ G, which might influence the propagation of UHE CRs.

In our paper we find out the EGMF influence on cascade emission, analyzing cases of homogeneous EGMF along particle way: a field of 10^{-12} G and lower, a field of $\sim 10^{-9}$ G, and of

$\sim 10^{-6}$ G. This allowed us to avoid modelling of EGMF structure which is not reconstructed in detail.

Previously UHE CR cascade emission produced in homogeneous EGMF of values less than 1 nG was studied in [Berezinsky et al. 2011; Wang et al. 2011] (in order to obtain constraint on UHE CR emissivity satisfying data both on extragalactic gamma-ray background and cosmogenic neutrinos).

One of the first papers claiming that UHE CRs along with cascade emission can probe the large-scale component of the EGMF is [Lee et al. 1995] in which cascade gamma-ray spectra in EGMF of different values is analyzed. Lee et al. (1995) discuss gamma-ray energies above 10^{18} eV (at these energies cascade particle interaction with EBL are ignored). In our paper we also discuss the EGMF influence on the intensity of diffuse cascade gamma-quanta, but we analyze cascade emission in the energy range of $10^6 - 10^{20}$ eV. This range includes energies of gamma-rays available for Fermi-LAT covering the range of (20 MeV – 820 GeV) [Ackermann et al. 2015] along with planned gamma-ray telescope GAMMA-400 with the range of (1-500) GeV [Egorov et al. 2020], and future gamma-ray observatories CTA and SWGO with ranges (20 GeV-300 TeV) and (100s of GeV to PeV) respectively [Acharya et al. 2018; López-Coto et al. 2021]. Therefore our results can be used analyzing data of these gamma-ray telescopes and observatories.

In addition we choose the recent UHECR source model [Giacinti et al. 2015] which describes the bulk of CR data.

Our results could be of interest using both UHE CRs with their cascade emission as a probe for the EGMF, and when contribution of various components to the gamma-ray background should be known.

An example of the latter is hunting for dark matter particles, as it is expected that their annihilation or decay produce gamma-quanta in various objects (see e.g. [Roszkowski et al. 2018]). Then in order to filter a relatively weak hypothetical dark matter signal from the gamma-ray background the contribution of all components to the background should be known, including cascade gamma-rays.

The information about UHECR sources is needed to study electromagnetic cascades. This is CR sources, injection spectra, source distribution and evolution as sources can be located at distances according to red shifts up to 4-5.

UHECR sources have not been fully clarified. The general result was obtained by Hillas (1984): possible sites of particle acceleration should satisfy the condition between the size and magnetic field strength described by Eq.1 in [Hillas, 1984], as a result of which only objects above diagonal line in the plot “magnetic field strength-size” could accelerate protons to 10^{20} eV.

Source candidates satisfying this condition are active galactic nuclei (AGN) [Berezinsky et al. 1990], radio galaxy lobes ([Norman et al. 1995; Biermann, 1997] and ref. therein), and sites in SMBH vicinity. The latter case is analyzed in e.g. [Kardashev, 1995; Neronov et al. 2009].

UHECR injection spectra depend on processes of particle acceleration. CR accelerating by electric fields in the vicinity of SMBH or in jets, injection spectra are close to a monoenergetic one [Kardashev 1995; Neronov et al 2009; Istomin and Gunya 2020], while acceleration on shock fronts (existing e.g in AGN jets) results in exponential CR spectra: $\propto E^{-\alpha}$ with the spectral index $\alpha \approx 2.2-2.5$ [Krymskii 1977; Bell 1978; Cesarsky 1992]. The unified model of CR acceleration and subsequent UHE proton propagation was suggested in [Giacinti et al. 2015] to describe data on fluxes of both CRs and diffuse gamma-rays and neutrinos. In this model sources have following parameters. First, a spectral slope of CR protons is $\alpha=2.2$. Second, the source red shift evolution is as that of Blue Lacertae objects (BL Lac), which are one of the AGN types. These source characteristics are used in our paper. For illustration we also consider another case of evolution that is history of cosmic star formation [Yüksel et al. 2008] in the form given by Wang et al. (2011). (Cosmic star formation rate possibly describes the evolution of UHE CR source density.)

Cascade gamma-ray intensity depends on UHE CR composition what has been studied in [Berezinsky et al. 2016] where pure proton composition or having admixture of Helium was analyzed. UHECR mass composition being a subject of active discussion, Hanlon et al. (2018) compare TA and PAO data and demonstrate that there is no contradiction between the data, thus UHECRs have mixed composition. Recently both TA and PAO [Abbasi et al. 2018; Aab et al. 2020] report on mixed composition including Helium and heavier nuclei up to Ferrum. Yet in our paper we study the EGMF influence on cascades from CR protons without analyses of cascade emission initiated by various nuclei.

UHECR propagation has been computed with the publically available code TransportCR [Kalashev and Kido, 2015], which is 1D code. It is valid because we calculate diffuse cascade emission initiated by randomly directed UHECRs. 3D simulation is applied when analyzing cascades which are originated by particles from a single source or in a blazar jet (see e.g. [Neronov and Aharonian 2007; Khalikov and Dzhatdov, 2021]) or analyzing CR angle anisotropy (e.g. [Hackstein et al. 2018]).

In our paper we find out the EGMF influence on cascade emission, analyzing cases of homogeneous EGMF along particle way: a field of 10^{-12} G and lower which is typical in the extragalactic space beyond clusters, sheets, and filaments, a field of $\sim 10^{-9}$ G which possibly fills sheets, and filaments, and of $\sim 10^{-6}$ G, which is common inside galaxies and galactic clusters. This allowed us to avoid modelling of EGMF structure which is not reconstructed in detail.

We obtain that in the EGMF with $B=10^{-9}$ G and $B\leq 10^{-12}$ G diffuse cascade emission is similar at energies $E\leq 10^{17}$ eV. Thus no specific models of EGMF are required to study contribution of cascade emission in the extragalactic gamma-ray background at these energies.

Considering EGMF of 10^{-6} G the result obtained is valid in the energy range of $\sim 10^7$ - 10^9 eV.

In the paper we use “photons” for particles of background emission, “quanta” for those produced in interaction with cosmic background and synchrotron process, and “electrons” for both electrons and positrons.

2. Method.

In this section we list assumptions underlying the model.

CRs are accelerated in processes in the vicinity of SMBH in galactic centers. As particle acceleration is connected with SMBH, AGNs can be UHECR sources regardless of their type and distance [Istomin and Gunya, 2020; Uryson, 2001].

We suppose that CRs are accelerated on shock fronts in vicinity of SMBH (e.g. in jets) which mechanism produces exponential injection spectra $\propto E^{-\alpha}$. In the model $\alpha=2.2$ following [Giacinti et al. 2015].

Distances from sources correspond to red shifts $z\approx 0.0$ - 5 . The SMBH evolution is unclear. We use the evolution of Blue Lacertae objects (BL Lac), which are one of the AGN types, because the bulk of CR data is described with it [Giacinti et al. 2015]. Also we consider for illustration one more case of evolution when source density is proportional to the cosmic star formation rate [Yüksel et al. 2008]. It was used in the form given in [Wang et al. 2011].

UHECR mass composition evidently is mixed, which is discussed in Introduction. Yet in the model we assume for simplicity that UHECRs consist of protons.

Extragalactic background emissions are considered in the following way. The CMB has Planck energy distribution with the mean value $\varepsilon_r=6.7\times 10^{-4}$ eV. The mean photon density is $n_r=400$ cm⁻³. The background radio emission has parameters from the model of the luminosity evolution for radio galaxies [Protheroe and Biermann, 1996; 1997]. The EBL parameters are taken from [Inoue et al. 2013].

We assume the EGMF to be uniform and consider the field values $B=10^{-6}$, 10^{-9} , and $B\leq 10^{-12}$ G.

3. Results and discussion.

Calculated gamma-ray spectra near the Earth in the fields of 10^{-6} , 10^{-9} , 10^{-12} G with two CR source evolution scenarios are shown in Fig. 1, 2. The spectra when $B<10^{-12}$ G coincide with that for $B=10^{-12}$ G, and are not shown in the figures.

In figures curves corresponding to same values of magnetic field are similar in shape, so evolution models under consideration have no effect on curve behavior.

At the energies $E \geq 10^{19}$ eV the calculated curves almost coincide as the bulk of the emission in this range is produced via π^0 -decay, which is not affected by magnetic field. At lower energies quanta are produced both in cascades and in electron synchrotron emission. Synchrotron quanta being scattered by cascade particles, the energy of the latter transfers to a lower range, and a dip is formed on the curves in the range of $\sim 10^{14}$ - 10^{18} eV. Larger is the field strength, the more is synchrotron emission and the more pronounced is the dip.

At energies $E \leq 10^{17}$ eV curves with $B=10^{-9}$ and $B=10^{-12}$ G coincide. This is in agreement with the result obtained for the range $E = 10^8$ - 10^{14} eV in [Berezinsky et al. 2011].

Fig.1. The spectra near the Earth of diffuse cascade gamma-rays produced by UHE protons. The evolution of UHECR sources is that of BL Lacs from [Giacinti et al. 2015]. The extragalactic magnetic field B is of 10^{-6} , 10^{-9} and 10^{-12} G. The spectra when EGMF is $B < 10^{-12}$ G and $B = 10^{-12}$ G coincide and are not shown in the figure. The maximal proton energy is of 4×10^{20} eV.

Fig.2. The same as in Fig.1, but UHE protons are from sources with evolution described by the star formation history [Yüksel et al. 2008] in the form [Wang et al. 2011].

Figures 1, 2 show that source evolution scenarios have no perceptible effect on the curve behavior. In contrast to this the calculated intensity of diffuse cascade gamma-ray emission depends on source evolution. This effect has been studied previously in e.g. [Kalashev et al. 2009; Wang et al. 2011; Berezhinsky et al. 2016; Gavish and Eichler, 2016] (in which papers it was shown that source evolution affects on diffuse gamma-ray flux to UHECR flux ratio).

In both figures the curve for $B=10^{-6}$ G is different from the others both in shape and intensity. However in the energy range of $\sim 10^7$ - 10^9 eV the intensity when $B=10^{-6}$ is close to the others. This is illustrated in Fig. 3 where the ratio R of cascade gamma-ray intensities in the range of 10^6 - 10^{11} eV in EGMF of 10^{-12} and 10^{-6} G is shown.

Equal intensities giving $R=1$, the relative deviation from unity is $\delta R \approx 0.25$ - 0.3 in the range of $\sim 10^7$ - 10^9 eV. At higher energies (to $\sim 10^{19}$ eV) the deviation is of ~ 10 - 100 .

Based on the coincidence of curves for $B=10^{-9}$ and $B=10^{-12}$ G we conclude that no specific models of EGMF are required to study contribution of cascade emission in the extragalactic gamma-ray background at $E \leq 10^{17}$ eV. In the seemingly unrealistic case of EGMF

of 10^{-6} G this inference is valid in the energy range of $\sim 10^7$ - 10^9 eV. (It is unrealistic because such field possibly fills only galaxies and their vicinity).

This result is obtained in the model where UHE CRs are protons. However CR nuclei possibly constitute a significant part of the UHE CR flux having a noticeable effect on the diffuse cascade emission (see e.g. [Berezinsky et al. 2016]). Study of UHE nuclei propagation and the resultant cascade gamma-ray emission will be performed in subsequent papers.

Fig. 3. The ratio R of diffuse cascade gamma-ray intensities produced by UHE protons in the EGMF of 10^{-6} and 10^{-12} G in the energy range of 10^6 - 10^{11} eV. The horizontal dashed line shows $R=1$.

4. Conclusion.

Diffuse cascade gamma-ray emission depends on EGMF due to electron synchrotron radiation and IC scattering of its quanta.

We analyze the EGMF influence on the diffuse cascade gamma-ray spectra in the model with the uniform extragalactic magnetic field considering the extreme case of 10^{-6} G and more realistic cases of 10^{-9} and 10^{-12} G. The former is seemingly common inside galaxies and galactic clusters, and the two others are typical in the extragalactic space beyond clusters in sheets and filaments, and in voids. It is shown that cascade gamma-ray intensity in EGMF with $B=10^{-9}$ and $B\leq 10^{-12}$ G are similar in the energy range $E\leq 10^{17}$ eV. Thus in this range specific models of extragalactic magnetic field are not required to study contribution of diffuse cascade emission in the extragalactic gamma-ray background. The result is obtained considering two possible scenarios of UHE CR source evolution. In the case of uniform EGMF of 10^{-6} G, which seems to be unrealistic, this inference is valid in the energy range of $\sim 10^7$ - 10^9 eV.

This result is seemingly valid also for purely electromagnetic cascades, as was discussed in [Dzhatdov et al. 2019].

Structures where $B>10^{-12}$ G fill the insignificant part of the space and their influence on the cascade emission is minor. Still our result could be of interest discussing UHE CRs and their cascade emission as a probe for the EGMF. The result obtained can be also relevant to the search for exotic particles, which are expected to annihilate or decay producing gamma-rays. Then in order to separate hypothetical dark matter signal from the gamma-ray background the contribution of all components to the background emission should be known, including cascade gamma-quanta.

We have considered the model where UHE CRs are protons. Study of UHE nuclei propagation and the resultant cascade gamma-ray emission will be performed in subsequent papers.
