Abstract

Some fraction of the diffuse photon background is supposed to be linked to high-energy neutrinos by astrophysical mechanisms of production and electromagnetic cascades. This article presents a simulation study of axion-like particles (ALPs) implications for that component, exploiting transport equations. Alternations of that spectrum due to ALP-photon conversion in the intergalactic magnetic field (IGMF) in the cases of various ALP parameters and mixing regimes at sources are studied. The results indicate considerable influence of IGMF-conversion on the ALP-photon flux even in the case of inverse ALP-photon coupling constant M equal to $10^{11.5}$ GeV and some residual effects in the case of $M = 10^{12}$ GeV. Furthermore, the scenario shows another aspect of a complex multimessenger interplay between IceCube and Fermi data, to a certain extent relieving the tension between them.

Keywords: ALPs, electromagnetic cascades, diffuse background, transport equations

1. Introduction, motivation of the paper

Axion-like particles (ALPs, sometimes for simplicity called axions in our paper) are hypothetical particles that are predicted by extensions of the Standard Model and can interconvert with photons in an external magnetic field. This became the basis for most observational ALP searches.[1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11]. At the same time, two main mechanisms have been discussed: the first involves conversion near the source, propagation through intergalactic space, and later reconversion in the Milky Way (MW) magnetic field; the second involves conversion of photons and axions on their way from the source in the intergalactic magnetic field (IGMF), despite scarce information and constraints on them (for the latter Ref. [12, 13, 14, 15], one of most recent Ref. [16], also discussed in the context of supernova dimming in Ref. [17, 18, 19]). Apart from Gaussian fields, other structures of magnetic fields are considered in the literature, for example, domain-like structures and their variations (Ref. [20, 21, 15]), various computational approaches and programs are described (for instance, Ref. [22, 23]). Though many of the listed works considered the joint influence of conversion and pair production process (PP), as far as we know none of them involved inverse Compton scattering (ICS). ALP-related effects outside of conversion have also been studied for relieving multimessenger tensions (for instance, in Ref [24]).

Electromagnetic cascade (later e-m cascade) is the process of sequential PP and ICS processes on background radiation, due to which the photons reach the observer at lower energies than emitted (for a review see Ref. [25]). Different approaches and programs (except for the one we are using in our studies) for the modeling of e-m cascades exist [26, 27].

The production of high energy gamma-rays in astrophysical environments is connected with the emission of neutrinos via so-called pp -mechanism (in other words, hadronic interactions, named that way because of the protons or nucleus colliding over nucleus at rest) and $p\gamma$ -mechanisms (or, alternatively, photohadronic interactions, in which the target is replaced by gamma-rays), so neutrinos are supposed to have their injected photon counterpart with energies and fluxes of the same order of magnitude [28]. In the context of this work it allows us to normalize the photon flux and compare that contribution with the diffuse background detected by Fermi-LAT, thus deepening our understanding of its nature and composition, which is a complex problem (see Ref. [29]). The synergy of photons and neutrinos in the ALP context has also been studied, though for sub-PeV energies, in Ref. [30].

We assume, for simplicity, that the full or at least most of IceCube flux has extragalactic origin (see discussions in Ref. [31] and references therein). However, it is important to notice the recent studies, providing indications about the fraction of neutrinos with galactic origin [32, 33, 34].

For our purposes we set out to use the approach of transport equations, adopt the code TransportCR [35] as a tool for simulations. At this point, we primarily aim to catch the key features and possibilities for the IGMF-mixing on the upper bound (~ 1 nG) to modify the spectra rather than draw robust constraints on the parameter space.

We organize the paper as follows. First, we derive modified transport equations (Eq. 7), describing cascade development influenced by ALP-photon (later sometimes abbreviated as ALPh in this paper) conversion in Subsec. 2.1 and 2.2. Next, we list the parameters that were included in the model and the motivation of their choice in Subsec. 2.3, 2.5, 2.6 and 2.4. Finally, we present the results of our modeling (propagation of the ALP-

Email address: kr548@cam.ac.uk (Kirill Riabtsev)

photon flux from the sources until it reaches the MW magnetic field) and discuss their features in Sec. 3.

2. Mathematical formalization of the problem, parameters of the model

2.1. Basics of ALP-photon (ALPh) conversion

ALPs are coupled to the electromagnetic field via the interaction term of the Lagrangian, see Ref. [36]:

$$\mathcal{L}_{int} = -\frac{1}{4} \frac{a}{M} F_{\mu\nu} \widetilde{F}^{\mu\nu}, \quad (1)$$

where $F_{\mu\nu}$ is the electromagnetic stress tensor and $\widetilde{F}^{\mu\nu}$ is its dual, a is the pseudo-scalar ALP field, $g = \frac{1}{M}$ denotes photon-axion coupling constant and M is its inverse, m further denotes the ALP mass.

As presented in Ref. [36] for constant magnetic fields and as holds true in the case of non-uniform magnetic fields for order-of-magnitude estimates, there are two main conditions for ALPh mixing to be significant (which is called the strong, or maximal, mixing). The first one is given as (see the definitions of $\Delta_{\alpha\gamma x,y}$ and Δ_a below)

$$2\Delta_{\alpha\gamma x,y} \gtrsim \Delta_a \quad (2)$$

The second one is given by the relation between the characteristic length (that is, the size of the region in which mixing should be effectively carried out, it is for instance either the physical size of the source or attenuation length, that effectively may prohibit conversion of photons into axions due to attenuation on background light) and the oscillation length:

$$L_{osc} \cong \frac{\pi}{\Delta_{osc}} \lesssim L \quad (3)$$

In these expressions $\Delta_{\alpha\gamma x,y}$, Δ_a and Δ_{osc} are given by

$$\Delta_{osc} = \sqrt{4\Delta_{\alpha\gamma x,y}^2 + \Delta_a^2}, \quad (4)$$

$$\Delta_{\alpha\gamma x,y} = \frac{B_{x,y}}{2M} = 153 \times 10^{-9} \left(\frac{B_{x,y}}{1 \text{ nG}} \right) \left(\frac{10^{10} \text{ GeV}}{M} \right) \text{ pc}^{-1}, \quad (5)$$

$$\Delta_a = \frac{m^2}{2E} = 7,8 \times 10^{-4} \left(\frac{m}{10^{-7} \text{ eV}} \right)^2 \left(\frac{10^{12} \text{ eV}}{E} \right) \text{ pc}^{-1}, \quad (6)$$

where $B_{x,y}$ is the magnetic field strength in one of the directions traverse to the direction of propagation. E is the photon (axion) energy.

2.2. Modified transport equations

We will treat ALP-photon mixing within the formalism of the density matrix, the evolution of which follows Liouville equation, for a review see Ref.[37, 38].

Using the same mathematical technique, as suggested in Ref. [39] for the study of neutrino oscillations. and denoting $\rho_0, \rho_1, \rho_2, \rho_3, \rho_4, \rho_5, \rho_6, \rho_7, \rho_8$ as coefficient of expansion of the density matrix in the basis of the Gell-Mann matrices together with the identity matrix (for a review on their properties, including (anti)commutation relations, see [40]), we obtain:

$$\begin{cases} \frac{dN_{ph1}}{dt} = 2\Delta_{\alpha\gamma x}\rho_5 + \dots, \\ \frac{dN_{ph2}}{dt} = 2\Delta_{\alpha\gamma y}\rho_7 + \dots, \\ \frac{dN_a}{dt} = -2(\Delta_{\alpha\gamma x}\rho_5 + \Delta_{\alpha\gamma y}\rho_7), \\ \frac{d\rho_1}{dt} = \Delta_{\alpha\gamma x}\rho_7 + \Delta_{\alpha\gamma y}\rho_5 - \Gamma\rho_1, \\ \frac{d\rho_2}{dt} = \Delta_{\alpha\gamma x}\rho_6 - \Delta_{\alpha\gamma y}\rho_4 - \Gamma\rho_2, \\ \frac{d\rho_4}{dt} = \Delta_{\alpha\gamma y}\rho_2 - \Delta_a\rho_5 - \frac{1}{2}\Gamma\rho_4, \\ \frac{d\rho_6}{dt} = -\Delta_{\alpha\gamma x}\rho_2 - \Delta_a\rho_7 - \frac{1}{2}\Gamma\rho_6, \\ \frac{d\rho_5}{dt} = -\Delta_{\alpha\gamma y}\rho_1 + \Delta_a\rho_4 + \Delta_{\alpha\gamma x}(N_a - N_{ph1}) - \frac{1}{2}\Gamma\rho_5, \\ \frac{d\rho_7}{dt} = -\Delta_{\alpha\gamma x}\rho_1 + \Delta_a\rho_6 + \Delta_{\alpha\gamma y}(N_a - N_{ph2}) - \frac{1}{2}\Gamma\rho_7, \\ \frac{dN_e}{dt} = \dots \end{cases} \quad (7)$$

where Γ is the photon absorption rate and N_{ph1}, N_{ph2} denote the number of photons of different polarizations and N_a denotes the number of axions, after "...” terms of usual transport equations, that account only for ICS, PP and source density, are followed, N_e denotes the number of electrons/positrons (as in "usual" transport equations describing e-m cascades (for a detailed description see Ref. [41]). Note that ρ_0, ρ_3, ρ_8 are not included, since, as suggested in [39], we keep the diagonal terms in the natural basis N_{ph1}, N_{ph2}, N_a .

2.3. ALP parameter space, the region selected for the simulations

We consider ALP inverse coupling up to 10^{12} GeV, which (almost) prohibits conversion due to the oscillation length exceeding attenuation and coherence (see Subsec. 2.4) lengths, and focus mostly on the region not constrained by CAST (see Ref. [42] for a review on the current limits and their nature). Axion mass m is taken according to the condition (Eq. 2) in order to "turn off" the effect of ALP-photon conversion below Fermi or IceCube ranges (see Subsec. 3.3 and the legend of Figures 1 to 6 therein , where the ALP parameters are specified).

2.4. IGMF model

We consider a divergence-free Gaussian turbulent magnetic field with a Kolmogorov spectrum, zero mean, and root mean square (RMS) B_0 equal to 1 nG, generating it following the procedure described in Ref. [43]. Minimal and maximal spatial scales are picked to be equal to 10^2 Mpc and 10^{-1} Mpc, which corresponds to the coherence length of 20 Mpc, according to Ref. [44]. Note that Ref. [45, 46] give values that are close to our model, while Ref. [47] predicts more stringent limits. In the latter case the presented results of simulations would remain valid, but for stronger coupling, that is, to M approximately half an order of magnitude lower than in Subsec. 3.3.

The evolution of the magnetic field as $B \propto B_0 (1+z)^2$ was considered. [5, 48]

2.5. Other parameters

We use a single power law from Ref. [49] for the neutrino injection spectrum, not extrapolating it beyond the fit. We choose the redshift distribution from Ref. [50].

Figure 1: To subsection 3.1 Multimessenger connection; two pairs of ALP parameters are specified in the legend; IceCube spectrum from analysis [49]; Fermi spectrum from [54]; “ $g = 0 \text{ GeV}^{-1}, \gamma$ ” corresponds to the standard scenario, “ γ/a ” labels photons (the sum of both polarizations)/axions; solid/dotted lines are used for photons/axions here and further in Figures 2 to 6).

We take the relationship between photons and neutrinos injected as in $p\gamma$ -mechanism (see Ref. [51]), which does not affect the order of magnitude of the results and the spectral shapes.

For the model of the extragalactic background light (EBL) we choose the “Best-fit” model from Ref. [52].

2.6. Potential mixing at sources: axion injection spectrum

If strong mixing is present, the ratio of photons to axions is 2:1 (or equipartition among two photon polarizations and axions is established, see Ref. [53], though it can be directly seen from Eq. 7).

For our simulations we consider two opposite cases: when strong mixing with that relation is present and when mixing is completely absent, in other words, when only photons are injected.

At the same time, realistic mixing at the sources is quite complex (see Ref. [53], discussed also in Ref. [55]), but in our work we focus on the response of the IGMF-mixing to the two mentioned above different scenarios of ALP-photon injection.

3. Results of the simulations, interpretation

We proceed to the discussions of the effects and their combinations caused by ALP mixing in the IGMF.

3.1. Multimessenger connection

Here in Fig. 1 we illustrate fluxes of neutrinos (the single power law taken as in Ref. [49], shown per flavor on the graph),

Figure 2: To subsection 3.2 Contributions to the full flux from lower redshifts; the same ALP parameters everywhere (specified in the legend); the width of the lines is adjusted according to the maximal redshifts.

and its photon/axion counterpart. Presented are the cases of the “strong mixing” at the sources and “no mixing” at the sources (mixing in the IGMF happens both at IceCube and Fermi energies in both cases). For comparison and demonstrative purposes the isotropic gamma-ray background (IGRB) Model A from Fermi-LAT, Ref. [54] with error bars is also given (see Sec. 4 for the discussions). For comparison the “standard scenario”, not involving axions at all, is presented.

As far as we can see, photon to axion ratio at Fermi energies is canonical 2:1. As we also can see, the mixing in the IGMF combined with ICS and PP effectively pumps out injected axion component from most part of IceCube energies (the corresponding effect for the Fermi spectra will be discussed below in Subsec. 3.3.2, though leaving almost unchanged the highest energetic part of axion spectrum (an interesting consequence of a higher attenuation at these energies).

3.2. Contributions to the full flux from lower redshifts

Here we consider axion-photon spectra from sources distributed up to certain maximal redshifts and compare them to the full flux. $z_{max} = 0.1$, $z_{max} = 1.0$, besides the full spectra, are taken, equivalent to a sharp cutoff in the source redshift evolution (Sec. 2.5). The mass of axion is adjusted so that it results in the cutoff of axion spectra.

As can be seen in Fig. 2, “axion cutoff” region migrates leftwards to lower energies. That may be connected, first, to the evolution of the magnetic field taken (see Subsec. 2.4) and, secondly, to the redshifting of the incoming photons.

Figure 3: To subsection 3.3.1 ALP mixing in the IGMF at IceCube energies (no mixing at the sources).

Furthermore, as could be predicted, the fluxes of axions and photons reach canonical 2:1 for its parts coming from higher redshift, as propagation through distances that are large enough enables them to mix effectively.

3.3. Various cases and scenarios

We proceed to the classification of the scenarios. Specific areas of Figures 3 to 6 are zoomed in and placed as insets, for a better comparison of photon spectra in the cases of different couplings.

3.3.1. ALP mixing in the IGMF at IceCube energies (no mixing at the sources)

Since higher energies have lower attenuation lengths of photons, neither effective oscillation length of different M considered is sufficient to "capture" more ALP/photons at higher energies. Though at Fermi energies it leads to photon flux being consistently below the one in the non-axion (standard) scenario, the alternation does not exceed one percent, see Fig. 3.

3.3.2. ALP mixing in the IGMF at IceCube energies (strong mixing at the sources)

If the mixing in the IGMF was not present, the mixing at the sources would simply lead to the whole spectra being reduced by a factor of 3/2, however mixing at those energies frees up some axions, converting them into photons and thus letting them reach Fermi range energies, see Fig. 4. The effect gets more noticeable with lower M , however, even with $M = 10^{11.5}$ GeV it remains quite sufficient and is visible even with $M = 10^{12}$ GeV, which is additionally shown here (and it ceases to appear with $M = 10^{12.5}$ GeV).

Figure 4: To subsection 3.3.2 ALP mixing in the IGMF at IceCube energies (strong mixing at the sources); " $g = 0 \text{ GeV}^{-1}, \gamma$ " corresponds to the standard scenario, " $g = 0 \text{ GeV}^{-1}, 2/3, \gamma$ " corresponds to two thirds of that flux.

3.3.3. ALP mixing in the IGMF both at Fermi and IceCube energies (no mixing at the sources)

As we can see in Fig. 5, the full flux is distributed as expected 2:1 for sufficiently high values of the coupling constant and deviates from that ratio only for $M = 10^{11}$ GeV. The flux of axions is an order of magnitude lower for the value $M = 10^{11.5}$ GeV, when some influence on the photon spectrum is still present.

3.3.4. ALP mixing in the IGMF both at Fermi and IceCube energies (strong mixing at the sources)

As we can see in Fig. 6, the effect combines features described in Subsec. 3.3.2 and 3.3.3, namely, the mixing at Fermi energies leads to certain ratios between photons and axions at Fermi energies, and injection of both photons and axions at IceCube energies leads to a "displacement", lowering of these spectra as we described. Thus, these two mechanisms lead to similar effects, and different spectra "whirl around" two thirds of the standard scenario spectrum.

3.4. Potential effects of later conversion in the Milky Way magnetic field

The solutions for the flux after propagation through the MW magnetic field can be found in the formalism of the same transport equations, this time not taking into account ICS and PP, passing the components $\rho_0, \rho_1, \rho_2, \rho_3, \rho_4, \rho_5, \rho_6, \rho_7, \rho_8, N_a, N_{ph1}, N_{ph2}$ from the output of the IGMF-solver to the input of the "MW-solver".

However, the geometry of magnetic fields in the MW is quite vague, and different models of its regular component exist (see Ref. [56], comparing conversion probabilities isocountours for

Figure 5: To subsection 3.3.3 ALPh mixing in the IGMF both at Fermi and IceCube energies (no mixing at the sources); solid/dotted colored lines are used for photons/axions.

different MW field models, thus showcasing model-dependence of that problem).

The effect of mixing itself will at best reduce the photon flux up to 2/3 of it. Due to the MW magnetic field anisotropy, from the most general considerations, the photon flux may acquire some anisotropy, which is a separate problem for discussion.

Taking for an estimate $L \sim 10$ kpc, $B \sim 1$ mG, referring to the condition (3), $10^{10.5}$ GeV (close parameter see in the map of isocontours of probabilities in Ref. [56]) corresponds to a kind of a critical, transitional case between the strong mixing with $M = 10^{9.5}$ GeV and almost no mixing with $M = 10^{11.5}$ GeV. From simplified logic, in the cases when the mixing in the IGMF is strong or leans towards the strong one, for $M = 10^{10}$ GeV or $M = 10^{10.5}$ GeV and likely for $M = 10^{11}$ GeV the mixing in the IGMF is supposed to outweigh the MW and shield its effects (note that if it was not for the IGMF-mixing, there would be a possibility for the photon flux to be reduced up to two thirds of it at energies from 10^{11} eV to 10^{12} eV (see Fig. 1).

In order not to obscure the physical interpretation presented in the classification of the scenarios in Sec. 3, here we conclude our analysis. Note that the results of the simulations are readjustable: if the magnitude of the IGMF is weaker, the considered parameters shift towards stronger coupling, and in that case the results of the paper (Sec. 3) remain valid (but, if the MW conversion was included, numerous combinations of the MW models and the IGMF magnitudes would bring intertwined results).

Figure 6: To subsection 3.3.4 ALPh mixing in the IGMF both at Fermi and IceCube energies (strong mixing at the sources); Same as in Fig. 5, but for strong mixing at the sources.

4. Discussions and conclusion

Unlike in most research papers on the subject of ALPh conversion effect, in our configuration the conversion goes in parallel with the interaction of the flux with background radiation and the energies of injection and detection of the effect do not overlap. The features and possible resulting regimes are briefly described and demonstrated.

The effect discussed in the paper may alleviate the tension between neutrino and photon spectra (discussed in Ref. [31] or in Ref. [57, 50]), see Fig. 1, at energies from 10^{10} eV to 10^{11} eV, however it leaves the flux of photons unchanged at energies from 10^{11} eV to 10^{12} eV.

Acknowledgements

The author is indebted to S. Troitsky for the original idea of the manuscript and valuable remarks throughout the entire work and much obliged to O. Kalashev, the creator of the tool TransportCR, for the helpful directions regarding its use and discussions devoted to the modification of its code.

This work is supported by the RSF grant 22-12-00253. Numerical calculations were performed on the Computational Cluster of the Theoretical division of INR RAS. The author thanks the Theoretical Physics and Mathematics Advancement Foundation “BASIS” for the fellowship under the contract 22-1-122-1.
