A new multiplex-type inelastic neutron scattering spectrometer, HOrizontally Defocusing Analyzer Concurrent data Acquisition spectrometer (HODACA), was recently developed and built at the C1-1 cold neutron beam port in JRR-3. The spectrometer is suitable for dynamics measurements in the energy range of $-1 \text{ meV} \leq \hbar \omega \leq 7 \text{ meV}$, catering to a broad array of research fields in physics and material science. HODACA combines 24 detectors and 132 pieces of analyzer crystals and has an estimated measurement efficiency that is 70 times greater than the existing conventional triple-axis spectrometer at the C1-1 beam port. The concept, design, specification, and results of commissioning experiments are described.

KEYWORDS: Inelastic neutron scattering spectrometer, HODACA

1. Introduction

Neutron scattering is an indispensable experimental technique in various fields, including physics, chemistry, materials science, and engineering. In 1949, Nobel laureate C. G. Shull demonstrated the utility of neutron scattering for magnetic structure analysis by observing magnetic Bragg peaks in the antiferromagnet MnO,¹⁾ using the spin of neutrons. Since then, in the field of liquids and soft matter, large cross section of hydrogen or deuterium, has greatly advanced structural analysis using the small angle neutron scattering technique.²⁾ In engineering, neutron diffraction and radiography are utilized for non-destructive testing of engines, concrete, and other materials.^{3,4)} In condensed matter physics, neutrons with wavelengths of the order of atomic spacing are employed to study collective excitations in crystals⁵⁾ and magnetic materials.⁶⁾ For example, in the presence of magnetic order, excitations are described as spin waves, which propagate as small fluctuations of spins. The dispersion relation, which relates the wavevector q and energy E of spin waves, can be measured by neutron inelastic scattering (INS) spectrometers,⁷⁾ revealing the dynamics of magnetic materials and determining the spin Hamiltonian. Since the proposal of spin liquids,⁸⁾ the dynamics of frustrated magnetic materials such as triangular,⁹⁾ Kagome,¹⁰⁾ and pyrochlore¹¹⁾ lattices have been actively investigated. When the ordering of spin dipoles is hindered, nontrivial physical quantities such as vector chirality, scalar chirality, and spin nematicity can be expected to order. In some cases, small perturbations such as DM interactions¹²⁾ and magnetic dipole interactions¹³⁾ play crucial roles in determining the ground state. In all these cases, the spin Hamiltonian of the system can be determined by dynamics measurements using INS spectrometers, and the investigation of nontrivial ground states is conducted.

The neutron triple-axis spectrometer (TAS) has been

widely used in both inelastic and elastic scattering experiments since its development in the 1950s, establishing its position as a versatile and important spectrometer.¹⁴⁾ In a traditional TAS, a neutron scattered by a sample crystal is analyzed by a single analyzer crystal and detected by a single detector. Accumulated knowledge and expertise over the years have enabled high signal-to-noise ratio measurements at specific points in wave vector - energy (q - E) space. This is different for time-of-flight (TOF) chopper spectrometer, a type of advanced inelastic scattering spectrometers, which is mainly installed at pulse neutron sources such as ISIS, SNS, and J-PARC. This spectrometer analyzes neutron energy by measuring the flight time, allowing simultaneous measurements over a wide range of energies. By placing multiple detectors around the sample, it enables simultaneous measurements over a wide range of q space, which allows for efficient measurements in a broad q - E space. The multiplextype TAS spectrometer is another type of the advanced spectrometers. This spectrometer increases the number of analyzers and detectors to enable efficient measurements and is often installed at constant neutron sources, such as FLATCONE¹⁵⁾ at ILL, MACS¹⁶) at NIST, and CAMEA¹⁷) at PSI. Currently, the design, construction, and operation of multiplex-type TAS spectrometers employing various concepts are being carried out globally, yielding significant achievements in the wide range of fields including frustrated magnetism,^{9–11)} lowdimensional quantum magnets,18-20) spin liquids,21,22) molecular magnets,²³⁾ superconductivity,^{24,25)} heavy fermions,²⁶⁾ Weyl semimetals,²⁷⁾ van der Waals materials,²⁸⁾ and relaxors.²⁹⁾ However, in Japan, progress in multiplex-type TAS spectrometers has stagnated because the research reactor JRR-3, a constant neutron source, had been shut down since the Great East Japan Earthquake in March 2011 until February 2021. This has changed recently with the design and construction of an advanced multiplex-type TAS spectrometer for the above mentioned research fields at the C1-1 beam port

of JRR-3. The Inverse Rowland Inelastic Spectrometer (IRIS) concept proposed by Harriger and Zaliznyak^{30,31)} has been selected. This concept was implemented in an instrument named HODACA, which stands for HOrizontally Defocusing Analyzer Concurrent data Acquisition. In this paper, design, simulation, and components of HODACA, as well as test measurements on standard samples are described.

2. Design of HODACA

In HODACA, efficient collection of neutrons at the scattering plane is achieved through "anti-focusing" using an array of analyzers based on the concept of the Rowland circle^{30,31}) implemented as shown in Fig. 1. Neutrons scattered from the sample are reflected at a fixed angle, corresponding to specific scattered neutron energy, by the array of analyzers located on the Rowland circle. According to the circumferential angle theorem, the neutron path after reflection is depicted as spreading out from the sample image on the circumference (anti-focusing). The reflected neutrons are then detected by a group of detectors arranged around the sample image. To suppress cross-talk between neutrons before and after passing through the analyzer array, a radial collimator is placed before and after the analyzer group, which is expected to efficiently reduce background noise. Previous work using wideangle analysis with position-sensitive detector has shown that usage of background-reducing radial collimator is absolutely essential for successful operation of such a setup.^{32,33} Based on this principle, HODACA enables high signal-to-noise ratio measurements in a wide q space at constant energy (E) surfaces. Monte Carlo simulation software McStas^{34,35)} was used for the design of the neutron scattering spectrometer, where various parameters were tuned to calculate the spectra and compare the intensities, energy resolution, and angular resolution. Optimization was performed based on these comparisons. As a result, HODACA became a spectrometer capable of measuring spectra from -1 meV to 7 meV by fixing the scattered neutron energy E_f at 3.635 meV. It consists of 24 analyzers and 24 detectors spaced at 2° intervals, covering a scattering angle A2 of 46°. Each analyzer is composed of 3 to 7 PG crystals mounted in a vertically focusing configuration. The vertical size of each analyzer (number of PG crystals) is determined to ensure that the solid angles spanned by the analyzer viewed from the sample position are the same. Ra-

dial collimators with divergence angle of 2° are installed between the sample-analyzer and analyzer-detector to minimize cross-talk of scattered neutrons from neighboring analyzers. The optimized parameters of the analyzers setup are summarized in Table I.

3. Simulation of HODACA and HER

The comparison of the performance between the optimized HODACA and HER is shown in Fig. 2. The simulation for HODACA was performed with a configuration covering

 10° < A2 < 56°. The collimator condition of HER was Ni guide - 200' - 80' - 80', and the analyzer mode was flat. First, let's compare the energy resolution as shown in Fig. 2(a). HO-DACA exhibits a location-dependent energy resolution ranging from 0.13 to 0.21 meV. This is due to the varying distances between the sample-analyzer and analyzer-detector, which are fixed at 0.8 m and 0.6 m, respectively. In contrast in HER, the energy resolution is constant at 0.15 meV, since the sampleanalyzer distance and analyzer-detector distance remain constant. The maximum energy resolution of 0.21 meV in HO-DACA is equivalent to the energy resolution achieved in HER when the analyzer-detector collimator is 200'. Therefore, it is shown that at least one channel of analyzer-detector in HO-DACA has a performance that is superior to or equal to the collimator condition of Ni Guide - 200' - 80' - 200' in HER, in terms of energy resolution.

Figures 2(b) and 2(c) represent the intensity of Bragg peaks and the angular resolution, respectively, for virtual powder sample. Here, the term "virtual sample" refers to a sample that produces the same magnitude of the structure factor for all Bragg reflections scattered at angles from 15° to 50° in 5° increments. The Bragg peak intensity simulated for HO-DACA is higher than that for HER. This is due to the wider angular resolution of HODACA, ranging from 0.8° to 1.6°, as shown in Figure 2(c), compared to the angular resolution of 0.8° in HER. The angle-dependent distances between the sample-analyzer and analyzer-detector result in an angledependent angular resolution. The IRIS-type spectrometer is designed primarily for inelastic scattering experiments, and it is empirically known that angular resolution within 2° allows for analyzable measurement data in inelastic scattering experiments using cold neutrons. Therefore, the detector dependence of the angular resolution (Fig. 2(c)) is not a concern when conducting inelastic scattering experiments. It is shown that at least one pair of analyzer-detector in HODACA has a performance that is superior to or equal to the collimator condition of Ni guide - 200' - 80' - 80', in terms of angular resolution. Simulation using McStas compared TAS and HODACA, indicating that a single pair of analyzer-detector in HODACA has similar intensity and resolution to a TAS, but with 24 analyzer-detector channels HODACA provides 24 times higher measurement efficiency.

4. Components of HODACA

Based on the design shown in Fig. 1, each component of the HODACA spectrometer was designed. (002) reflection of PG crystal is used for the analyzer. A total of 132 pieces, each measuring 20 mm \times 20 mm \times 2 mm, with a mosaic spread of 0.4° to 0.5° , are used. The HER analyzer is equipped with 49 PG crystals, which have the same mosaic spread as those used in HODACA. The crystals are arranged in a 7 by 7 configuration. The PG crystals for HODACA are fixed to an aluminum shaft using aluminum foils (Figs. 3(a) and 3(b)). Additionally, to suppress scattering by the aluminum shaft, Gd sheets are inserted between the PG crystals and aluminum shaft. To drive the 24 analyzers consisting of PG crystals and aluminum shaft, Oriental Motor CRK525PMAP motors and CRD5103P drivers are employed, for each of the 24 channels. The drivers are installed in the lower rack of the HODACA spectrometer. Two units of Tsuji Electronics Co., Ltd.'s 16-channel pulse motor controller (PM16C-16) are used to control these com-

Fig. 3. (a) A photograph of the analyzer viewed from the side. (b) A photograph of the analyzer viewed from the front. (c) A photograph showing the opened door of the shielding.

Fig. 4. (a) The top view (to scale) of the HER installed at the C1-1 beam port for $E_i = 3.635$ meV and $E_i = 11$ meV. (a) The top view (to scale) of the HODACA installed at the C1-1 beam port for $E_i = 3.635$ meV and $E_i = 11$ meV.

ponents.

For the detector bank, we used the spare detectors of AGNES spectrometer³⁶⁾ in JRR-3. This detector is a ³He detector manufactured by Reuter Stokes, with a size of 1 inch diameter \times 300 mm length, and operates as a 0-dimensional detector with 10 atmospheres of ³He gas pressure.

The fabrication of the analyzer, detector, radial collimator, and shielding components was entrusted to Hitachi Denki Kogyo Co., Ltd. Figure 4 is a scaled top view of the HER and HODACA installed at the C1-1 beam port. It shows the configurations for $E_i = 3.635$ meV and $E_i = 11$ meV. It can be observed that the measurement range covered by HER is also covered by HODACA. The shielding components of HODACA are indicated by vermilion color. Boron-10wt% polyethylene is used for the shielding material. The darker vermilion areas indicate the possibility of direct neutron hits from the monochromator, for which boron-20wt% polyethylene is used. The ceiling plate of the shielding components is designed to be easily removable to facilitate adjustments of the analyzer and detector. Additionally, the shielding components feature a door mechanism that allows immediate access for adjusting the analyzer bank (Fig. 3(c)). The detector is covered with a 4 mm thick boron-50wt% B4C rubber and boron-10wt% polyethylene (Fig. 5(b)). The B4C rubber has a 16 mm \times 60 mm window, and a cadmium (Cd) plate is attached to the rear of the fourth radial collimator, also with a window size of $16 \text{ mm} \times 60 \text{ mm}$ (Fig. 5(a)). These measures ensure that only scattered neutrons within the designed flight path are detected. The detector is securely fixed to the same boron-containing polyethylene pedestal as the shielding components, and the holes for wiring are curved to prevent neutron infiltration (Fig. 5(d)). The blades of the radial collimator are made of 1 mm thick Cd plates. Cd plates are very soft and prone to bending under gravity, so mechanisms are installed to attach each Cd plate with upper and lower ceiling plates. A crane is used to switch between HER and HODACA. The total weight of HODACA is 732 kg. HODACA is mounted on an aluminum frame, which includes the integrated radial collimator, analyzer, detector, and shielding components. To facilitate optical axis adjustment, the entire integrated assembly can be horizontally shifted.

The driving software used in HODACA is based on the SPectrometer and Instrument Control Environment, known as SPICE,³⁷⁾ which was modified for this purpose by CUSEY Co., Ltd. SPICE is commonly used for TAS control and allows intuitive and user-friendly control through simple commands. The main differences between HODACA and TAS are that in HODACA, control of C3 and A3 and control of vertical focusing are not required, and the output data includes counts for all 24 C3 and A3 channels. Here, C3 and A3 mean the rotation angle of an analyzer and the scattering angle of the analyzer, respectively. Data display and analysis are currently being performed by handcrafted Python and Matlab codes. The development of dedicated software is underway.

For noise reduction and signal amplification of the detector, two units of Clear Pulse 3341 16-channel counters and three units of 596 8-channel charge amplifiers are used. Currently, most of the aluminum components inside HODACA are exposed. However, plans are underway to add B4C rubber and Gd shielding to cover these components in 2023. Therefore, at present, it is expected that the background due to scattering from the aluminum components is significant. However, measurements using standard samples were conducted at this stage to establish the alignment direction, estimate the basic performance, and consider data display and analysis software.

5. Measurements of Standard Samples

In this section, measurements of standard samples are described. The definitions of the motor angles and the details of the optical alignment in prior to the measurements are explained in Appendixes A and B.

Fig. 5. (a) This is the detector cover made of B4C rubber. It has a window measuring 16 mm horizontally and 30 mm vertically. Additionally, at the rear of the fourth radial collimator, a Cd plate is attached, which also has a window measuring 16 mm horizontally and 30 mm vertically. (b) A photograph of the surroundings of the detector. (c) and (d) Photographs showing the detector configuration. In (c), the detector is assembled, while in (d), it is shown disassembled.

5.1 Vanadium

We performed measurements using a cylindrical vanadium sample with a radius of 1 cm and a height of 4 cm. This measurement was carried out to determine the energy resolution and correct for the detection efficiency of the detectors.

We conducted an energy scan in increments of 0.05 meV from -0.2 meV to 0.2 meV. The errors of the energy center were within 0.03 meV for all analyzers, which is within the motor tolerance range of A1. Here, A1 is the scattering angle of the monochromator as shown in Fig. A \cdot 1 in appendix. We fit the data using Gaussian functions and estimated the intensity as shown in Fig. 6(a). The intensity is normalized with the maximum intensity set to 1. The detectors are numbered, starting with the one installed at the lowest scattering angle, which is number 1, and the numbers increase with the scattering angle. It can be observed that the scattering intensity of vanadium decreases as the detector number increases. There are two main reasons for this. First, the distance between the sample and the analyzer varies depending on the position of the analyzer, but the width of the analyzer crystals is fixed at 2 cm. As a result, the apparent angle of the analyzer width from the sample's perspective is not constant. Second, as the analyzer and detector numbers increase, both the sample-analyzer distance and the analyzer-detector distance become longer, leading to reduced scattering intensity

Fig. 6. (a) Intensity of vanadium measured by HODACA. The maximum intensity is normalized to 1. (b) Energy resolution estimated from Gaussian fitting of the full width at half maximum (FWHM). The black symbols represent the experimental results, while the red and blue symbols represent the simulation results for the monochromator and analyzer mosaic of 50' and 75', respectively.

due to air scattering.

Vanadium exhibits isotropic scattering, and, ideally, the same intensity is detected by all detectors if the flight distance of neutrons from the vanadium to the detector are the same. The measured scattering intensities obtained from each detector are calibrated by using the data in Fig. 6(a). The data point at detector number 23 was found to be incorrect during the measurements of Al_2O_3 in the forthcoming subsection. It was corrected to the gray circle using the scaling factor of Bragg profile of Al_2O_3 .

In Fig. 6(b), the energy resolutions estimated from the full width at half maximum (FWHM) intensity in the experiment (black symbols) and simulation 1 (red symbols) are shown. For the simulation 1, the monochromator and analyzer mosaicities of 50', which was indicated by the specification of the commercial PG crystals, were used. Consistency is found in the detectors with smaller numbers. However, discrepancy grows with the increase in detector numbers. For the simulation 2, those of 75' were used. The consistency is better. The effective mosaicity of the monochromator and analyzer could be as large as 75' because of the secondary extinction of PG crystals.

5.2 Al₂O₃

We conducted a diffraction experiment using Al_2O_3 as a standard sample with a radius of 10 mm and a height of 25 mm. This measurement allowed us to determine the value of $A2_n$ and to ascertain the presence or absence of cross-talk. Here $A2_n$ is the scattering angle for *n*th analyzer and detector.

Fig. 7. The measured diffraction pattern of Al_2O_3 . The intensity is corrected using Fig. 6(a), and the offset of each analyzer (A2) is also corrected. The diffraction pattern is presented with a logarithmic scale on the vertical axis for the entire measured range in (a). The patterns are further magnified in the ranges of 30° to 60° in (b), 60° to 90° in (c), and 90° to 120° in (d).

The definitions of $A2_n$ as well as C1, A1, C2, C3n, and A3n are described in Appendix A.

At $E_i = 3.635$ meV, a fewer number of Bragg peaks were detected. Therefore, we performed the measurement using the second-order harmonics of neutrons, which are neutrons with $E_i = 15.54$ meV. This was made by removing the Be/PG filter between the monochromator and the sample. We measured neutron counts at $A2_n$ with 0.1-degree intervals with a duration of 5 seconds per point. The results are shown in Fig. 7, where the intensity has been corrected by vanadium data shown in Fig. 6(a). Additionally, we have also corrected offsets of $A2_n$, where the offsets are presumed to be the same for all $A2_n$. As shown in Fig. 7, the intensities and peak positions from all $A2_n$ match, meaning that the design of the spectrometer is sound. If the detector had detected reflections from adjacent analyzers, false peaks would have appeared at angles shifted by 2 degrees from the true angles. No such false peaks were observed in Fig. 7, confirming the absence of cross-talk.

5.3 Frustrated Magnet CsFeCl₃

We have selected a frustrated magnet CsFeCl₃ as the standard sample for the measurement of an INS spectrum. The compound is an easy-plane-type antiferromagnet with onedimensional chains of effective S = 1 spins forming a triangular lattice. It belongs to the P63/mmc space group with lattice parameters of a = b = 7.2355 Å, c = 6.0508 Å, $\alpha =$ $\beta = 90^{\circ}$, and $\gamma = 120^{\circ}$. Orbital moment of Fe²⁺ ion is not quenched, and the ground state of the compound is known to be a quantum disordered state. Even though the magnitude of the magnetic moment has not been reported for CsFeCl₃ at ambient pressure, the reported magnitude of 3.15 $\mu_{\rm B}$ in the pressure-induced 120° structure at 2.2 GPa³⁸⁾ would be a good reference value. The observed dispersion relations by INS at ambient pressure was adequately explained by the Extended Spin Wave Theory (ESWT).^{39,40)} The spin Hamiltonian is as follows:

$$\mathcal{H} = J_1 \sum_{n.n.}^{\text{chain}} S_i \cdot S_j + J_2 \sum_{n.n.n.}^{\text{chain}} S_i \cdot S_j + J_3 \sum_{n.n.}^{\text{plane}} S_i \cdot S_j + D \sum_{i}^{\text{site}} (S^z)^2, \qquad (1)$$

where J_1 is the nearest-neighbor interaction along the caxis, J_2 is the next-nearest-neighbor interaction, J_3 is the the nearest-neighbor interaction within the ab plane, and D is the easy-plane anisotropy. The estimated parameters are $J_1 =$ $-0.271(1) \text{ meV}, J_2 = 0.045(2) \text{ meV}, J_3 = 0.016(1) \text{ meV}, \text{ and}$ $D = 2.144(4) \text{ meV.}^{40)}$

The single crystal sample of CsFeCl₃ was grown using the vertical Bridgman method.⁴¹⁾ The samples, weighing 1.64 g and 0.84 g, were prepared. The crystals were coaligned using the transmission Laue method with a high-energy X-ray camera, ensuring that the [001] and [110] axes were in the horizontal plane. The coaligned crystals were fixed in the standard aluminum cell of Institute for Solid State Physics, the university of Tokyo. Cd shield for bulk aluminum or stainless steel screws of the cell was not installed.

Neutron scattering measurements on CsFeCl₃ were performed at 2.4 K using GM refrigerator. The beam limiting aperture was installed in front of sample, and it was fully open. Firstly, diffraction profile was measured using the second order harmonics of the neutron with $E_i = 3.635$ meV, corresponding to 14.54 meV. The coverage of the A2 angle ranged from 14° to 56° and from 58° to 104°, while that of the C2 angle was within the range of 135°. Figure 8(a) shows the results of the measurement. Bragg peaks were observed at six points: (-1 - 1 2), (0 0 2), (1 1 2), (2 2 2), and (0 2)0 4). According to the extinction rule, Bragg peaks were not observed for odd values of l. These results confirmed that the data reduction was accurate and there were no issues with the spectrometer setup or sample alignment.

Next, we measured the INS spectra. The measurements were conducted with a 0.05 meV interval in the range of -0.4to 2.9 meV, and with a 0.1 meV interval in the range of 3.0 to 3.4 meV. The coverage of the A2 angle ranged from 14° to 60°, while that of the C2 angle was within a range of 138° with a 2° interval. A total of 70 points (corresponding to the C2 steps) were measured per energy slice. Each point was measured for 1 minute, resulting in approximately 70 min-

-1 0 1 -1 0 1 -1 0 1 -1 0 1 -1 0 1 -1 0 1 (h, h, 0) (r. l. u.) (h, h, 0) (r. l. u.)

Fig. 8. (a) False color plot of the elastic scattering in CsFeCl₃ measured using the second-order harmonics of the neutrons with $E_i = 3.635$ meV. (b) INS spectra in the range from -0.3 meV to 3.3 meV with increments of 0.2 meV.

Fig. 9. (a) INS spectrum at $\hbar \omega = 0.7$ meV. (b),(c) 1D cut along (b) (1/3, 1/3, l) and (c) (h, h, 0) direction at $\hbar \omega = 0.7$ meV. The ranges $(1/3 \pm 1)$ $0.05, 1/3 \pm 0.05, l$) and $(h, h, 0 \pm 0.05)$ highlighted in yellow rectangles in (a) are integrated. The blue circles represent experimental data, and the black curves represent Gaussian fitting.

Fig. 10. (a) False color plots for the (1/3, 1/3, l) direction and (b) (h, h, 0) direction. The integration ranges are $(1/3 \pm 0.05, 1/3 \pm 0.05, l)$ and $(h, h, 0 \pm 0.05)$, respectively. The white dashed curves represent the dispersion curves obtained from ESWT.(c) and (d) show Gaussian fits of the constant-energy scans in the range of 0.5 to 3.4 meV for the (1/3, 1/3, l) and (h, h, 0) directions, respectively. The blue circles indicate the peak center positions, and the error bars in the momentum direction represent FWHM/2. The black curves represent the dispersion curves obtained from ESWT.

utes to acquire the intensity map per energy slice. The total measurement time was approximately 84 hours. The data in the range from -0.3 meV to 3.3 meV with increments of 0.2 meV are shown in Fig 8(b). The binning size was set to 0.044 (r.l.u.) for both (0, 0, l) and (h, h, 0).

Figures 9(b) and 9(c) represent one-dimensional (1D) cut along q = (1/3, 1/3, l) and (h, h, 0) directions for the obtained energy slice at $\hbar \omega = 0.7$ meV. The integration ranges are $(1/3 \pm 0.05, 1/3 \pm 0.05, l)$ for the former and $(h, h, 0 \pm 0.05)$ for the latter as indicated by yellow rectangles in Fig. 9(a). The data indicated by blue open circles in Figs. 9(b) and 9(c) are reasonably well fitted by multiple Gaussians indicated by the black solid curves.

Figures 10(a) and 10(b) illustrate the false color plots for the INS spectra sliced by $\hbar\omega - q$ plane, where q = (1/3, 1/3, l)for the former and (h, h, 0) for the latter. The integration ranges are $(1/3 \pm 0.05, 1/3 \pm 0.05, l)$ and $(h, h, 0 \pm 0.05)$, respectively. The white curves in the figures represent the dispersion relation calculated using ESWT with the reported parameters.[?] Blue open circles in Figs. 10(c) and 10(d) display the dispersion relations obtained by fitting the 1D-cuts along q = (1/3, 1/3, l) and (h, h, 0), respectively. The error bars in the q directions indicate FWHM/2 from the fitting. The black curves represent the calculation obtained from ESWT. The experimental results are well reproduced by the calculations using the previously reported parameters.

Strong background was observed in the low energy range of $\hbar\omega = -0.3$ meV and 0.3 meV. Even though the origin was not clear at the time, the installation of Cd shield to the sample cell and adequate adjustment of the beam aperture reduced the background significantly in a recent experiment.

The obtained results were sufficiently analyzable even without scanning in the A2 direction. The measurement ef-

Fig. 11. (a)-(c) The spectrum (a) and 1D cuts (b),(c) were produced under the same analysis conditions as those in Fig. 9(a)-(c), assuming a counting time of 30 seconds for each point. (d),(e) The spectra were produced under the same analysis conditions as those in Fig. 10(a) and (b), assuming the energy step sizes were modified to be 0.1 meV increments from -0.4 meV to 1.2 meV, and 0.2 meV increments from 1.2 meV to 3.4 meV.

ficiency of HODACA on the energy slice surpasses the conventional TAS, such as HER, by a large margin. Here we will simulate how much we could reduce the measurement time. Let us reduce the measurement time per point to 30 seconds, half of the original experiment, and the results are shown in Figs. 11(a)-11(c). The error bars increase by a factor of $\sqrt{2}$. The fittings to the data in Figs 11(b) and 11(c) are still good. Figures 11(d) and 11(e) show the results obtained when the energy step size was changed to increments of 0.1 meV from -0.4 to 1.2 meV, and increments of 0.2 meV from 1.2 to 3.4 meV, respectively. Although the resolution is slightly coarse, sufficient data for determining the spin Hamiltonian can still be obtained. The data shown in Fig. 11 can be obtained in approximately 16 hours and 30 minutes by halving the measurement time and widening the energy step size. Even if all measurements were performed with the step size of 0.1 meV, the measurements would be completed in approximately 23 hours and 40 minutes, which means that the data of sufficient quality can be obtained within a day. Typical beam time assigned to one proposal for an INS experiment in JRR-3 ranges from 5 to 7 days, and using HODACA enables efficient measurements.

5.4 Recent measurement on Al_2O_3

Recently, we reduced the background by adjusting the electronics. We then measured the Bragg peak profile of Al_2O_3 to compare the intensities of HODACA and HER. As demon-

Fig. 12. Bragg peak profiles measured by HER (black symbols) and HO-DACA (red symbols). Collimator condition for HER was Ni guide - open - 80' - open.

strated in Fig. 12, the intensity measured by the No. 12 detector in HODACA, represented by red symbols, is three times larger than that measured by HER, denoted by black symbols. The measurement of detailed data for the intensity comparison is currently under way, but early indications suggest that the efficiency of the HODACA detector might be approximately three times that of HER. Given that the intensity of the No. 12 detector is close to the average of the other detectors, as illustrated in Fig. 6, and that HODACA can be considered an assembly of 24 HER spectrometers, as discussed in section 3, we estimate that the measurement efficiency of HODACA could be up to 70 times higher than that of HER.

The background shown in Fig. 12 is still large, though it has improved compared to that shown in Fig. 7. A supplementary radial collimator is currently being installed, with further improvements to the background expected.

6. Summary

In summary, we have designed and built a multiplex-type inelastic neutron scattering spectrometer HODACA at C1-1 beam port in JRR-3. The estimated measurement efficiency of HODACA is 70 times greater than that of an existing conventional triple-axis spectrometer at the beam port. An ideal spectrometer for measuring dynamics in the energy of cold neutrons is now ready for users.

Acknowledgements

We greatly appreciate Osamu Yamamuro for providing the spare ³He tube detectors of the AGNES spectrometer. Our heartfelt thanks also go out to Kenji Nakajima, Taka-hisa Arima, Tsuyoshi Kimura, and Yusuke Tokunaga for their valuable comments. We are also grateful to Makoto Ozeki for providing single crystals of CsFeCl₃. Special thanks to Ryosuke Sugiura, Toshio Asami and Daichi Kawana for their technical support in JRR-3. Hodaka Kikuchi was supported by the Japan Society for the Promotion of Science through the Leading Graduate Schools (SpringGX). This project was supported by US-Japan cooperative program on neutron scattering. This project was additionally supported by JSPS KAK-ENHI Grant Numbers 19KK0069, 20K20896 and 21H04441. Appendix A: Definition of Angles in HODACA

The definition of angles in the HODACA spectrometer is depicted in Fig. A·1. Unlike a conventional TAS, HODACA has 24 rows of analyzer, resulting in the existence of 24 channels for sample scattering angle A2, analyzer rotation angle C3, and analyzer scattering angle A3. Therefore, the analyzers are numbered consecutively starting from the lower angle of the sample scattering, such as 1, 2, ..., 24, and the corresponding angles for the nth analyzers are defined as $A2_n$, $C3_n$, and $A3_n$, respectively. Similarly, the detectors corresponding to each analyzers are also numbered accordingly.

Appendix B: Optical alignment of HODACA

Before performing measurements on the standard sample, the optical alignment of the HODACA spectrometer was carried out. Firstly, the height of the HODACA analyzer was adjusted to align its center position with the beam center. The HODACA spectrometer has an air pad with a screw-type height adjustment mechanism. The laser level tool was used to ensure that the tips of the two center pins (sharp-pointed rods) installed on the sample stage and the HODACA spectrometer are aligned in a straight line.

Next, the optical alignment of the third radial collimator was performed. This involved tying thread crosses on both the upstream and downstream apertures of the collimator and adjusting the height to ensure that they align in a straight line with the laser beam from the previous setup. Additionally, the distance between the center pin on the sample stage and the intersection of the collimator aperture was adjusted to be 35 cm by adjusting the distance between the sample stage and the HODACA spectrometer.

Table C-1. Summary of the offset of $A2_n$ estimated from the measurement of $A1_2O_3$ and deviations from the ideal straight line.

No	$A2_n$ (°)	Deviation (°)	No	$A2_n$ (°)	Deviation (°)
1	-15.35	-0.088	13	8.79	0.057
2	-13.22	0.038	14	10.70	-0.030
3	-11.32	-0.061	15	12.74	0.013
4	-9.30	-0.038	16	14.79	0.066
5	-7.22	0.046	17	16.79	0.065
6	-5.21	0.058	18	18.80	0.077
7	-3.26	0.005	19	20.76	0.036
8	-1.39	-0.129	20	22.74	0.020
9	0.73	-0.009	21	24.73	0.010
10	2.84	0.109	22	26.65	-0.072
11	4.69	-0.046	23	28.58	-0.142
12	6.78	0.044	24	30.69	-0.032

The fourth radial collimator was fixed to the HODACA spectrometer during fabrication, making optical alignment impossible. However, the height was verified using the same procedure as the third radial collimator. Finally, the optical alignment of C3 was performed to ensure that the arrangement of the sample-analyzer-detector satisfies the scattering conditions for PG crystals. This was accomplished using a cylindrical acrylic with a radius of 10 mm and a height of 40 mm. By rotating C3, the intensity of the acrylic was observed at angles that satisfy the scattering conditions. The observed peaks were described by Gaussian functions. This process was performed for all 24 analyzers. The results were fitted by Gaussian functions, and the analyzers were fixed at the fitted center position for C3. Consequently, all analyzers were aligned to $E_f = 3.635$ meV.

Appendix C: Detailed profiles of Al₂O₃

Figures C·1 and C·2 show the results of the Rietveld analyses performed on the obtained 24 diffraction patterns using the Fullprof software.⁴²⁾ Most of the peaks were identified as reflections from Al₂O₃ with the neutron of $E_i = 14.54$ meV, which is the second-order harmonics of the primary neutron beam of $E_i = 3.635$ meV. Three peaks that did not match the experimental results were identified as reflections from Al(111) at 61 degrees with $E_i = 14.54$ meV, Al(200) at 71 degrees with $E_i = 14.54$ meV, and Al₂O₃(012) at 86 degrees with $E_i = 3.635$ meV. An aluminum holder was employed for the Al₂O₃ sample, leading to the origin of the observed Bragg peaks of Al.

An assembly of analyzers and detectors is moved by a motor, A2₀, which is originally used for controlling the scattering angle of a sample in HER. The value of A2_n when A2₀ = 0, which is defined as the offset for A2_n, was determined by the Rietveld analysis as shown in Fig. C·2. The offset of a2_n is linear with a slope of 2, which means that all analyzers were aligned as designed. Table C·1 summarizes the offset values and the deviations from their ideal positions. All the analyzers are positioned within 0.142 degree of the ideal locations. The reasons for this deviation is supposed to be the tilt caused by the Gd sheet and aluminum foil behind the PG crystal. This level of deviation does not cause cross-talk, and there are no issues with the arrangement of the analyzers.
