Abstract

Shale, a material that is currently at the heart of energy resource development, plays a critical role in the management of civil infrastructures. Whether it concerns geothermal energy, carbon sequestration, hydraulic fracturing, or waste storage, one is likely to encounter shale as it accounts for approximately 75% of rocks in sedimentary basins. Despite the abundance of experimental data indicating the mechanical anisotropy of these formations, past research has often simplified the modeling process by assuming isotropy. In this study, the anisotropic elasticity model and the advanced anisotropic elastoplasticity model proposed by Semnani et al. (2016) and Zhao et al. (2018) were adopted in traditional gas production and strip footing problems, respectively. This was done to underscore the unique characteristics of unconventional shale. The first application example reveals the effects of bedding on apparent permeability and stress evolutions. In the second application example, we contrast the hydromechanical responses with a comparable case where gas is substituted by incompressible fluid. These novel findings enhance our comprehension of gas flow and solid deformation in shale.

KEYWORDS

Shale gas; flow and deformation; anisotropy; elastoplasticity

1 | INTRODUCTION

Shale, as an essential geomaterial with wide-ranging applications in both energy production and civil infrastructure, has garnered significant attention in recent years^[1,2,3,4,5]. Understanding the mechanical behavior of shale is crucial for optimizing extraction techniques in the energy sector and ensuring the stability of structures built on shale formations. Numerical simulation has proven to be a valuable tool in unraveling the intricate mechanics of shale, offering insights into its gas flow and solid deformation characteristics^[6,7,8,9]. This paper aims to delve into the complexities of gas flow and solid deformation in unconventional shale through comprehensive numerical investigations, shedding light on crucial factors that influence these phenomena.

Shale gas production simulation has been extensively studied especially focusing on post-hydraulic fracturing scenarios within shale gas reservoirs^[10,11,12,13,14,15,16]. These simulations often overlooked the directional dependence of elastic properties and the influence of bedding planes in the hydromechanical

coupling^[17,18,19] implementation, which are inherent characteristics of shale formations^[1,20,21]. Consequently, there is a notable gap in the literature regarding the investigation of field quantities predominantly influenced by these features. Addressing this research gap is of paramount importance to enhance our understanding of shale behavior and improve the accuracy of numerical simulations in shale gas production.

In addition to the study of shale gas production, this research also delves into the strip footing problem, which is a classic geotechnical inquiry^[22]. Traditionally, strip footing problems involve the assumption of porous material saturated with water beneath the footing. McNamee and Gibson^[23,24] provided an analytical solution for such a scenario under the framework of poroelasticity. Zhang et al.^[25] and Zhang et al.^[26] considered the double porosity nature of such porous material (shale) and investigated its preferential fluid flow patterns. Later, a multiple porosity generalization is derived in Zhang et al.^[27]. For non-linearity, Zhao and Borja^[28,29] extended this problem by considering plasticity effects and two effective stress measures^[30,31], a breakthrough in poromechanics theory. However, an intriguing question remains unexplored: What if the porous material beneath the strip footing is (nearly) saturated with a compressible gas instead? To date, no studies have investigated the implications of this scenario, and the differences between the behaviors induced by water and compressible gas remain unexplored. Thus, this study aims to address this question and discern the contrasting responses induced by these two significantly different fluids in the context of strip loading.

By examining these two prominent aspects of shale mechanics, this research seeks to advance our understanding of gas flow and solid deformation in unconventional shale. The outcomes of this study will provide valuable insights into the influence of directional dependence, bedding planes, and fluid characteristics on the behavior of shale formations. Moreover, the findings will contribute to the refinement of numerical models and improve the accuracy of simulations for shale gas production and geotechnical applications involving strip loading.

In summary, this paper will explore the intricate mechanics of gas flow and solid deformation in unconventional shale. By addressing the limitations of existing numerical simulations and investigating the influence of directional dependence, bedding planes, and fluid characteristics, our research aims to fill critical gaps in the understanding of shale behavior. The insights gained from this study will facilitate more accurate modeling and simulation approaches for shale gas production and geotechnical engineering, ultimately advancing the knowledge and practical applications in the field of unconventional shale mechanics.

2 | VERIFICATION ON STRESS DISTRIBUTION

Before the field application, model verification is necessary. As shown by Fig. 1, a single fracture model is used to verify the stress distribution over the whole domain^[32]. The computational grid is also given in Fig. 1.

For simplicity, the fracture deformation is assumed to be elastic, and the reservoir and fracture properties are listed in Table 1. All the four external boundaries are impermeable, and at the center of the fracture, there is a line segment whose length is 0.2 m, and it represents a well with radius $r_w = 0.1$ m. The bottom-hole pressure (BHP) is applied on this line segment (acting as a Dirichlet boundary for fluid flow). A uniform constant compressive load of 30 MPa is applied on the right and top boundaries and maintained throughout the simulation. The left and bottom boundaries are supported by rollers. As for the initial conditions, we assume a zero displacement field and a uniform pressure field of 20 MPa, but what is more noteworthy is that for this problem, we have a non-zero effective stress field. By using the information given in Table 1, the initial effective stress is given as $\sigma'_{xx} = \sigma'_{yy} = -30 + 0.7 \times 20 = -16$ MPa where 0.7 is the Biot coefficient. Fig. 2 shows the comparison results for σ_{xx} and σ_{yy} at 100 days of production, which

FIGURE 1 Schematics of (a) the reservoir model and (b) the finite element mesh with local grid refinement in COMSOL. The mechanical boundary conditions are already included in the sketch.

suggests good agreement and the feasibility of our modeling method to explore stress distribution in more complex scenarios.

TABLE 1 Parameters used in the first verification example. Note the single fracture is modeled by the material with a much lower Young's modulus. Furthermore, we use nearly incompressible fluid instead of gas in this example.

Parameter	Value	Unit
Matrix initial porosity	0.1	1
Matrix permeability	0.001	mD
Matrix Young's modulus	10	GPa
Matrix Poisson's ratio	0.2	1
Fracture initial porosity	0.5	1
Fracture permeability	10^4	mD
Fracture Young's modulus	200	MPa
Fracture Poisson's ratio	0.2	1
Fracture initial aperture	0.005	m
Biot coefficient	0.7	1
Fluid compressibility	4×10^{-10}	1/Pa
Fluid viscosity	0.001	Pa · s
Fluid reference density	1000	kg/m ³
Initial pressure	20	MPa
Well radius	0.1	m
BHP	10	MPa

3 | GAS PRODUCTION ANALYSIS OF ANISOTROPIC FORMATION WITH DISCRETE FRACTURE

3.1 | Model setup

We first set up a horizontal two-dimensional (plane strain) anisotropic model as shown in Fig. 3. For this model, we focus on the effects of bedding plane orientation and initial matrix intrinsic permeability k_0 on the geomechanical responses (evolutions of pressure and effective stress, gas production, etc.) of the shale gas reservoir. For the discrete fracture, the fracture flow model is adopted to describe the gas migration behavior in fracture^[33,34,35,36,37], while we ignore the impact on the solid deformation response, in other words, those green line segments in Fig. 3 are not considered in the solution of solid mechanics problem.

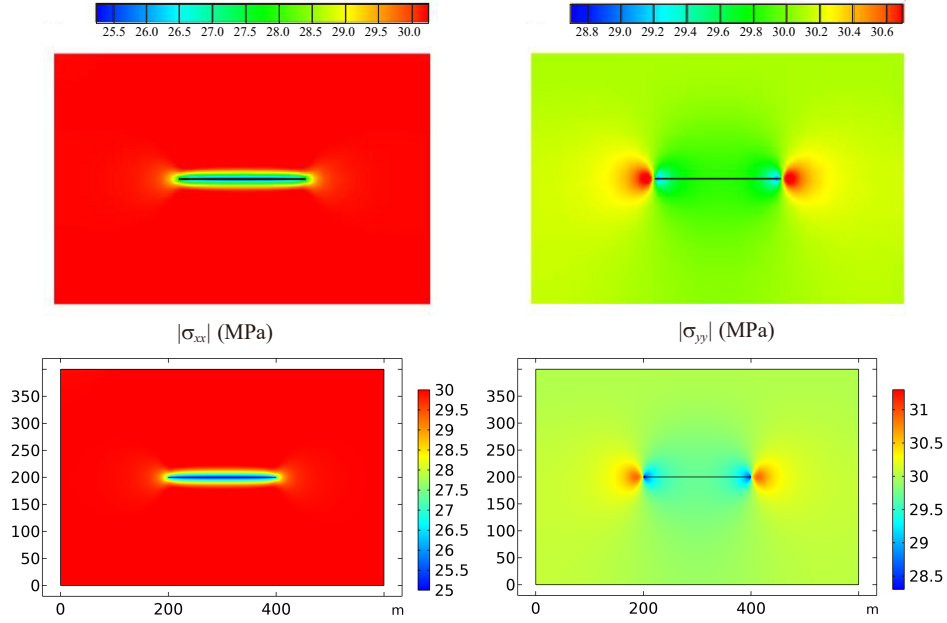

FIGURE 2 Comparison of σ_{xx} and σ_{yy} distributions calculated by the hybrid model^[32] (first row) and FEM in COMSOL (second row) after 100 days of production.

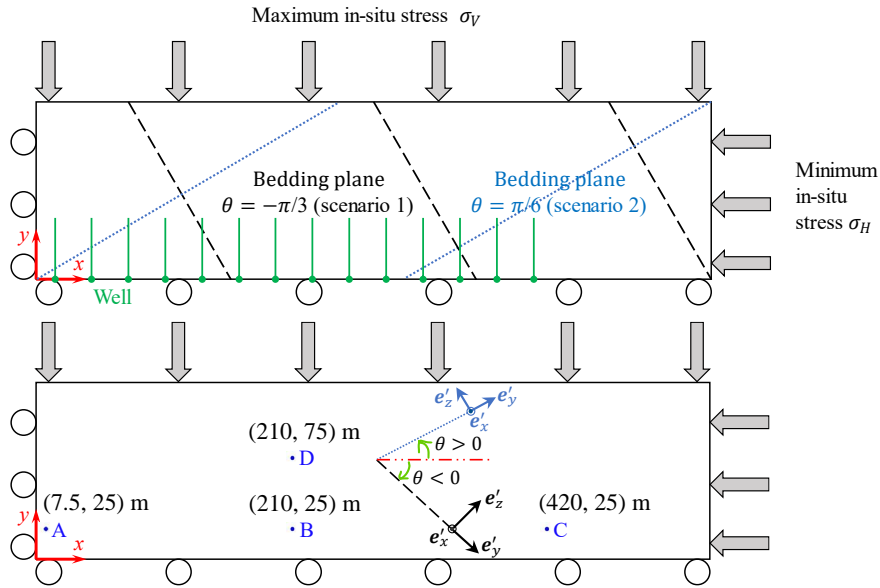

FIGURE 3 Schematic of a horizontal anisotropic 2D shale gas reservoir. The dashed and dotted lines represent the bedding plane orientations. No flux is applied at the outer boundaries, and BHP is prescribed at the intersection points (solid green dots) between the discrete fractures and the horizontal wellbore.

As a result, the fracture aperture cannot be calculated from the deformation field of the fracture surface, and it is updated through the empirical relation using the fracture compressibility c_F ^[33,35]. The numerical details can be found in Appendix A.

The anisotropic material parameters are based on the Trafalgar shale^[38]: $E_v = 17.3$ GPa, $E_h = 20.6$ GPa, $\nu_{hh} = 0.189$, $\nu_{vh} = 0.246$, and $G_{vh} = 7.23$ GPa. We consider two scenarios of bedding plane orientation as shown in Fig. 3 by the dashed line (Scenario 1, $\theta = -\pi/3$) and the dotted line (Scenario 2, $\theta = \pi/6$).

The sign convention of θ is also sketched in Fig. 3. For Scenario 1, we further analyze three values of k_0 , namely $5 \times 10^{-17} \text{ m}^2$, $5 \times 10^{-18} \text{ m}^2$, and $5 \times 10^{-19} \text{ m}^2$. Other model parameters are given in Table 2.

TABLE 2 Simulation parameters for the example of gas production from an anisotropic 2D reservoir. Note the adsorption strain, adsorbed gas mass per solid volume, and surface diffusion are not considered and will be pursued in future studies. The gas apparent permeability (non-Darcy flow) follows Florence et al. [39].

Parameter	Value	Unit
Model length	550	m
Model width	145	m
Model thickness (in z direction)	90	m
Spacing between the left boundary and the 1 st fracture	15	m
Fracture spacing	30	m
Fracture length	50	m
Initial fracture aperture w_0	5×10^{-3}	m
Initial fracture porosity ϕ_{F0}	0.3	1
Initial fracture permeability k_{F0}	10^{-12}	m^2
Fracture compressibility c_F	0.01	MPa^{-1}
Initial reservoir pressure	20	MPa
Bottom-hole pressure (BHP)	3.5	MPa
Maximum in-situ horizontal stress σ_V	-40	MPa
Minimum in-situ horizontal stress σ_H	-35	MPa
Initial matrix intrinsic permeability k_0	5×10^{-19}	m^2
Initial matrix porosity ϕ_0	0.05	1
Bulk modulus of the solid grain K_s	45	GPa
Gas viscosity μ_g	2×10^{-5}	$\text{Pa} \cdot \text{s}$
Reservoir temperature T	353.15	K
Gas molar mass M_g	16.04	g/mol
Langmuir pressure P_L	4	MPa

3.2 | Role of initial matrix intrinsic permeability

Fig. 4 and Fig. 5 present the evolution of gas pressure p under different k_0 . It can be observed that the minimum pressure always occurs around the discrete fracture. However, the diffusion pattern changes when we increase k_0 . From Fig. 4, we can see that when $k_0 = 5 \times 10^{-19} \text{ m}^2$, the pressure propagates from the whole segment of the discrete fracture. In other words, the discrete fracture acts as a line sink. In contrast, when k_0 is increased to $5 \times 10^{-17} \text{ m}^2$ in Fig. 5, we can observe a pressure radiation pattern surrounding the intersection point between the discrete fracture and the horizontal well, similar to a point sink.

3.3 | Impacts of anisotropy on pressure and permeability

Now we discuss the effect of bedding plane orientation. In other words, we want to explore the directional dependence of the hydromechanical responses. While suggested by Fig. 6, we find the gas pressure p distribution is not sensitive to the bedding plane orientation. Instead, the anisotropy affects the permeability evolution. In Fig. 7, we show the evolution of apparent permeability at the same four investigation points (see Fig. 3 for their locations). Now the difference is obvious, the green and red curves get closer in Scenario 2 than in Scenario 1. This reminds us of the fact that the apparent permeability is not only a function of gas pressure but also depends on the porosity change, and the anisotropy could directly control ϕ . As mentioned in Chin et al. [40], the change of effective stress would affect the permeability of the matrix, so we would expect to see some differences in the pattern of σ' with different θ , as discussed next.

FIGURE 4 Evolution of gas pressure distribution in Scenario 1 when $k_0 = 5 \times 10^{-19} \text{ m}^2$. For this figure, we focus on the propagation pattern of p_g and compare with Fig. 5.

FIGURE 5 Evolution of gas pressure distribution in Scenario 1 when $k_0 = 5 \times 10^{-17} \text{ m}^2$. One could clearly see the propagation pattern difference by comparing with Fig. 4. Note the similar phenomenon would be observed if we fix k_0 while decreasing k_{F0} *i.e.*, decrease the permeability contrast.

3.4 | Effective stress evolution

Next, the impact of anisotropy on the effective stress σ' distribution is explored. Fig. 8 and Fig. 9 show the comparisons of σ'_{xx} and σ'_{yy} between Scenario 1 and Scenario 2, respectively. Consequently, transversely isotropic characteristics can have a considerable impact on reservoir stress changes^[41]. For σ'_{xx} , the difference is localized around the lower-left and upper-left corners. For example, the absolute value $|\sigma'_{xx}|$ at the lower-left corner is smaller than the surrounding areas in Scenario 1 when $\theta = -\pi/3$; while it is the opposite in Scenario 2 when $\theta = \pi/6$. This could explain the change of the blue curves between Scenarios 1 and 2 in Fig. 7. In Scenario 1, this corner region with low $|\sigma'_{xx}|$ renders the stress propagation pattern of the first discrete fracture to be different from the remaining discrete fractures (Fig. 8e), and it also leads to several dark red regions between adjacent discrete fractures (Fig. 8c), demonstrating a certain level of heterogeneity. In Scenario 2, the aforementioned features of Scenario 1 are less obvious, but in the later

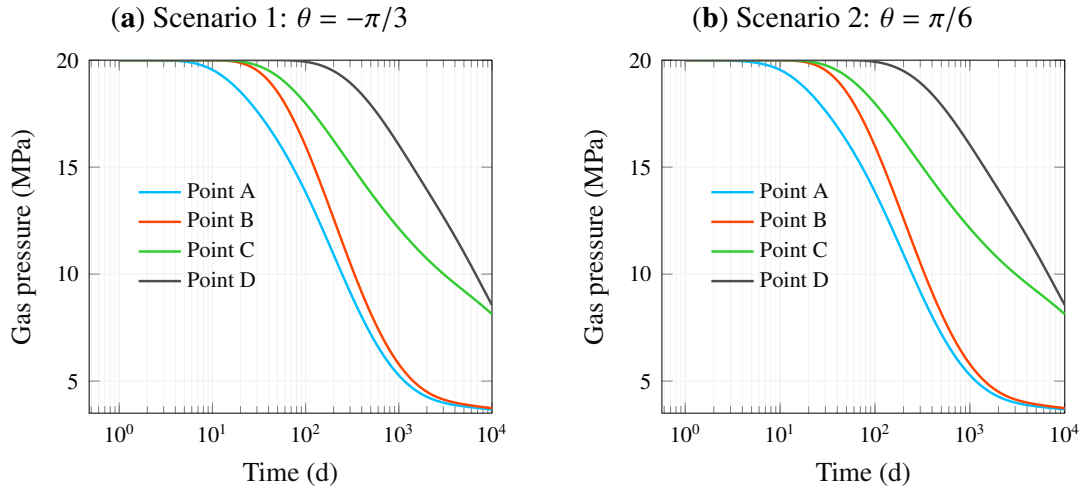

FIGURE 6 Gas pressure decay at four investigation points, which suggests that the elastic anisotropy has negligible influences, as the “driven force” comes from the gas compressibility itself.

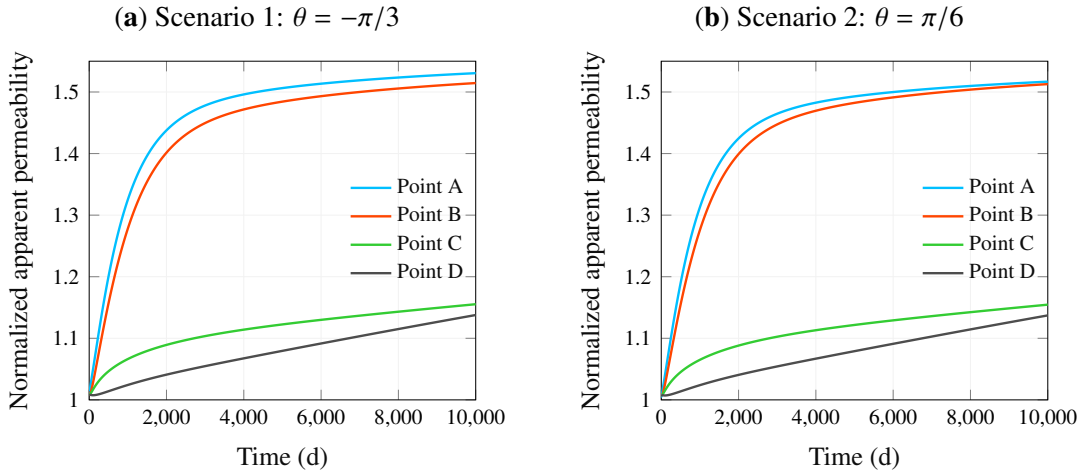

FIGURE 7 Apparent permeability evolution at four investigation points. Due to the “boundary effect” on Points A and B, when we change θ , the porosity evolution is affected, which in turn affects the apparent permeability.

period, the contour line (especially the yellow line) is substantially affected by this change in θ (Fig. 8i and Fig. 8j). For σ'_{yy} , the difference between Scenario 1 and Scenario 2 is only significant in the later period at the lower-left corner (Fig. 9g to Fig. 9j). In other words, the anisotropy has a stronger effect on σ'_{xx} than σ'_{yy} . Furthermore, if we compare the propagation patterns of p , σ'_{xx} , and σ'_{yy} , we may notice that the patterns of p and σ'_{yy} are quite similar to each other since they both spread from the stimulated reservoir domain (SRD) to the non-stimulated reservoir domain (NSRD), instead, for σ'_{xx} , it changes simultaneously in SRD and NSRD. While Fig. 8 and Fig. 9 show the overall trend, in Fig. 10, we plot the effective stress at one observation point (60, 25) m, in which additional useful information can be captured. The bedding plane orientation has an evident effect on the minimum horizontal effective stress evolution, but its effect on the maximum horizontal effective stress evolution is negligible. In addition, at $t = 10^4$ d, the blue curve is almost flat, while the red curves are still increasing, which indicates the occurrence of stress re-orientation during depletion^[42]. Furthermore, the evolution of the minimum horizontal effective stress is not monotonic at this selected point and its surrounding region.

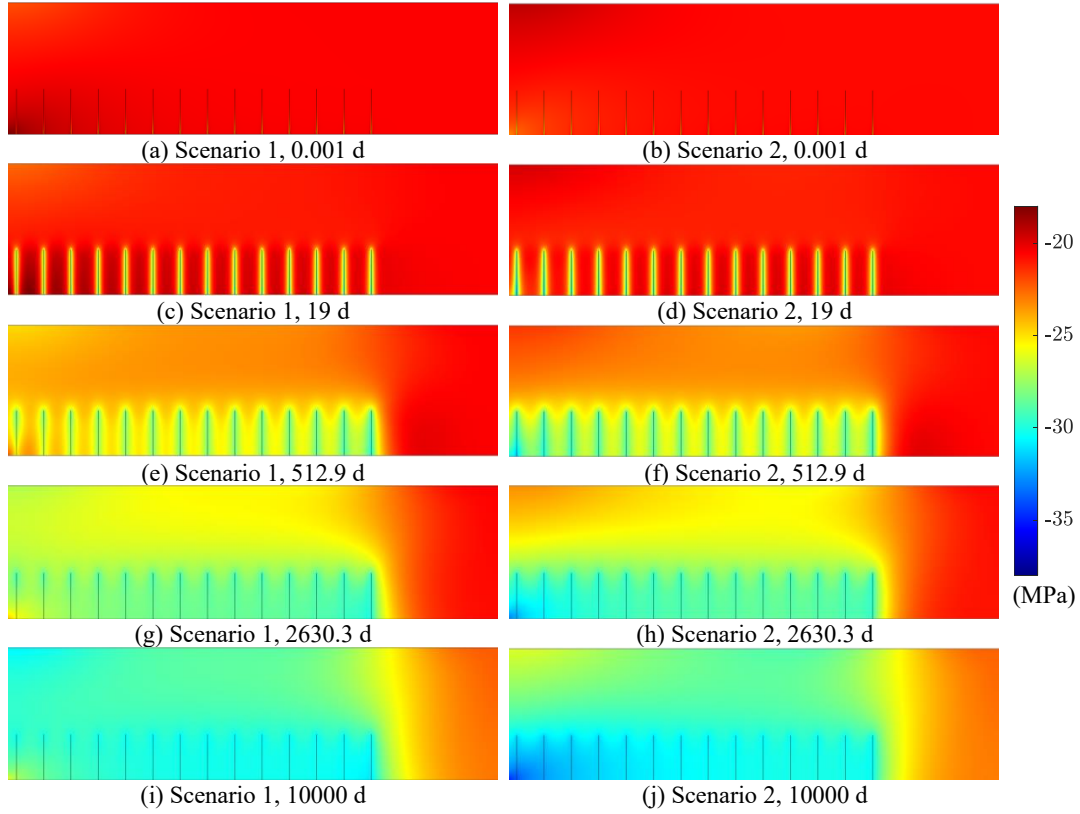

FIGURE 8 Comparison of the effective stress component σ'_{xx} distribution evolution between Scenarios 1 and 2. The differences are attributed to both elastic anisotropy and “boundary constraint effect”.

3.5 | Differences between isotropy and transverse isotropy

Finally, we compare the total stress σ between isotropic and transversely isotropic models, similar to the process in Tang et al. [42]. In this study, we assign $E = 18$ GPa and $\nu = 0.25$ to the isotropic model, as these parameters ensure the same generalized bulk modulus with the anisotropic model [38]. Fig. 11 and Fig. 12 portray the results at two different time slots ($t = 19$ d and $t = 10000$ d) for isotropic and transversely isotropic elastic models. First of all, it is easy to check that the result is consistent with the traction boundary condition, *i.e.*, $|\sigma_{xx}| = 35$ MPa on the right boundary and $|\sigma_{yy}| = 40$ MPa on the top boundary. Second, for isotropic model, our result is consistent with the pattern in Liu et al. [32]. For example, we can observe the stress (σ_{xx}) concentration at the fracture tip that exhibits a bulb shape, similar to that in Fig. 2, $|\sigma_{xx}|$ decreases in the depleted area and increases on the top of the domain, and there are many narrow bands with high values of $|\sigma_{yy}|$ between adjacent fractures in the early production stage. Third, for anisotropic model, the influence range of σ_{xx} is much larger than that of σ_{yy} . As shown in Fig. 11, the anisotropy could affect the σ_{xx} distribution up to 150 m, while in Fig. 12, the difference is only localized around the lower-left corner. This finding is quite consistent with the findings from the work on rock anisotropy when estimating in-situ stresses [43,44,45], *i.e.*, as opposed to the habitually applied isotropic assumption, the minimum horizontal stress $S_{h, \min}$ shows a strong dependency on the anisotropic poroelastic properties, and this $S_{h, \min}$ would control simulated hydraulic fracture geometries and proppant concentration [43,45]. Nevertheless, for both σ_{xx} and σ_{yy} , the formation anisotropy increases the stress distribution heterogeneity, which is unfavorable for wellbore stability and sustainable production [46].

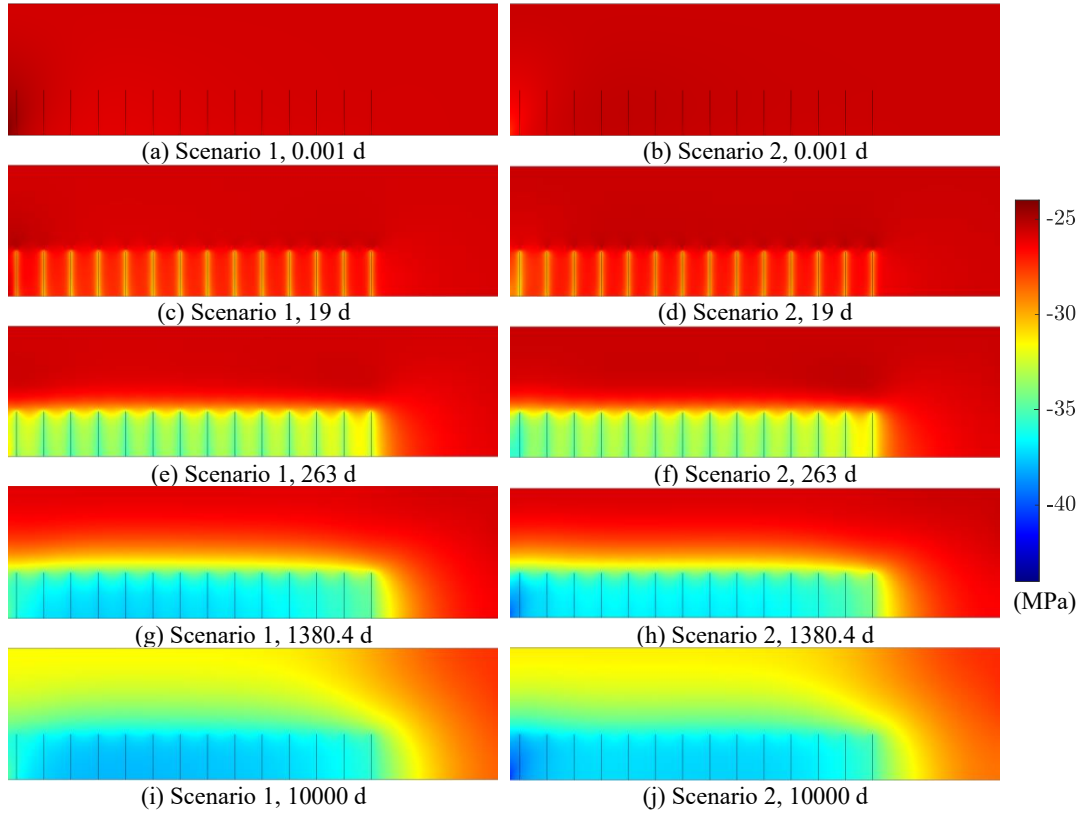

FIGURE 9 Comparison of the effective stress component σ'_{yy} distribution evolution between Scenarios 1 and 2. The differences are mainly attributed to the “boundary constraint effect”.

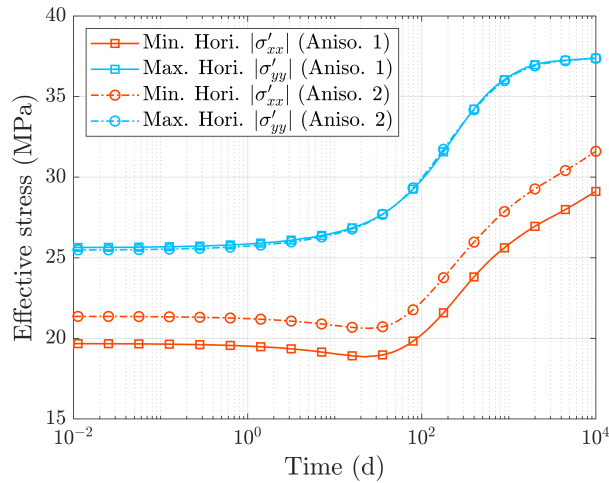

FIGURE 10 Effect of different anisotropy scenarios (Aniso. 1: $\theta = -\pi/3$ and Aniso. 2: $\theta = \pi/6$) on minimum and maximum horizontal effective stress evolutions at (60, 25) m.

4 | STRIP LOAD ON A GAS-SATURATED ELASTOPLASTIC POROUS MEDIUM

We now introduce anisotropy in both the elastic and plastic behaviors through the advanced model proposed by Semnani et al.^[47] and Zhao et al.^[48]. We conduct a plane strain simulation over a rectangular domain of 20 m \times 10 m subjected to a central strip load. The domain is assumed to be transversely isotropic, a type

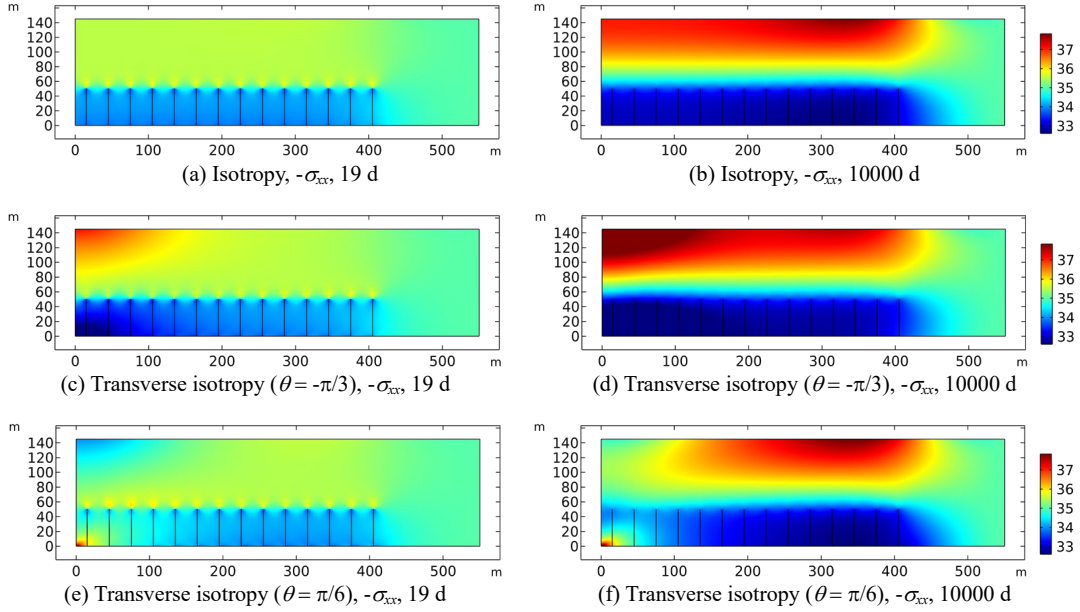

FIGURE 11 Comparison of total stress σ_{xx} (MPa) for isotropic and transversely isotropic elastic models. The differences are attributed to both elastic anisotropy and “boundary constraint effect”.

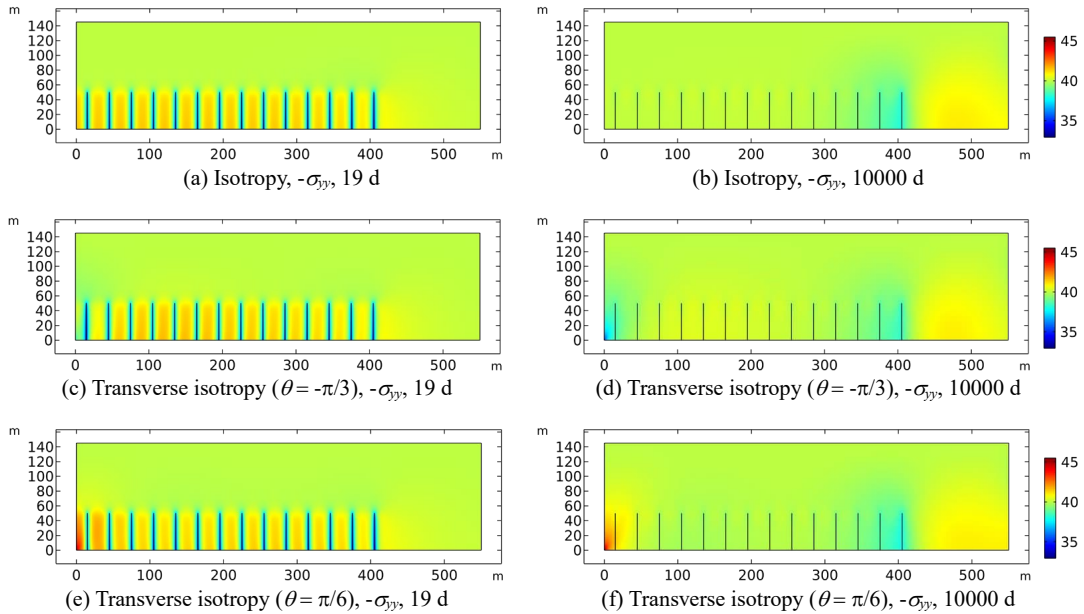

FIGURE 12 Comparison of total stress σ_{yy} (MPa) for isotropic and transversely isotropic elastic models. The differences are mainly attributed to the “boundary constraint effect”. Thus the choice of this example may not be ideal. In principle, we should have a core region that is far away from all the boundaries so that the boundary conditions do not affect the field quantities of interest.

of anisotropy exhibited by many natural materials, and it is always represented by inclined bedding planes where the angle between the bedding plane and the horizontal direction is θ , as shown in Fig. 13. Through this example, we demonstrate how the solutions change with the following factors: (a) non-Darcy flow^[39]; (b) bedding plane orientation θ ; (c) stress history. The uniform pre-load is denoted as $\omega_0 = 22$ MPa, and gravity is ignored in this example. To make the non-Darcy flow more prominent, we assume an initial gas

pressure equal to 2 MPa. In the beginning, a strip load $\omega = 20$ MPa is applied in a very short period over a width of 2 m, which makes the domain globally undrained. The strip load is then held constant for the remaining of the simulation. Mechanical and flow parameters used in the simulation are given as follows: $E_v = 12858$ MPa, $E_h = 21900$ MPa, $G_{vh} = 6510$ MPa, $\theta = \pi/4$, $\lambda^p = 0.0013$, $c_1^p = 0.7$, $c_2^p = -0.36$, $c_3^p = 0.6$, $M_{\text{critical}} = 1.07$, $M_g = 16.04$ g/mol, $p_{c0} = -40$ MPa, $K_s = +\infty$, $\phi_0 = 0.04$, $k_0 = 2 \times 10^{-20}$ m², $\mu_g = 2 \times 10^{-5}$ Pa · s, $T = 293.15$ K, $\epsilon_L = 0$, and $P_L = +\infty$.

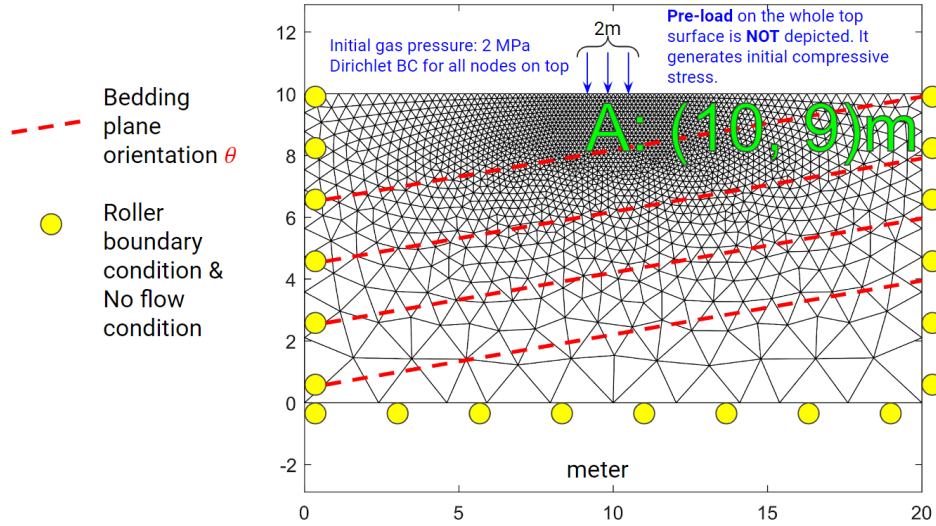

FIGURE 13 Schematic of the gas-saturated transversely isotropic porous medium subjected to a strip load. Gravity is ignored in this example. Note that there is a uniform preloading of 22 MPa.

The simulation goes as follows. Under the pre-load ω_0 , the initial (effective) stress field in x , y , and z directions are -4 MPa, -20 MPa, and -4 MPa, respectively. The strip load ω is then applied in 10 loading steps with $\Delta t = 1$ second, thus generating a transient solution of excess gas pressure. The transient solution continues for additional 50 time steps while holding ω constant. To simulate the whole process, the time increment is increased by a factor of 1.25 from the previous value, *i.e.*, $\Delta t_{n+1} = 1.25\Delta t_n$ ($n = 1, 2, \dots, 49$) and $\Delta t_1 = 31.25$ min. Here, the excess gas pressure is the gas pressure increment from its initial value of 2 MPa. The source code can be downloaded from this [code repository](#).

We first make some quantitative comparisons with the results for slightly compressible fluids such as water^[27,28] of the same strip load problem. For liquid, we can set the initial pressure to 0 and pre-load is therefore $\omega_0 = 20$ MPa, in order to maintain the same initial (effective) stress field. An obvious difference is that for gas or highly compressible fluid, the induced pressure increment is much less than the applied load magnitude ω , as shown in Fig. 14a. In poroelasticity theory, this is known as the Skempton effect^[49], and for highly compressible fluid constituent, the Skempton coefficient B is approaching zero^[49]. We can see that this is also true for poroelastoplasticity. In other words, the porous material behaves as an elastoplastic material without fluid, and that would explain why the undrained deformation in Fig. 14c is larger than that in Fig. 14d. These qualitative consistencies between the numerical simulation and the mathematical theory indicate the correctness of our code implementation. However, we should remark that the plastic deformation of water-saturated porous medium could be greater than the gas-saturated porous medium.

Due to the large undrained deformation, in the remaining 50 time steps, the “driven force” of excess gas pressure dissipation mainly comes from the compressibility of the gas itself, rather than the compression of pore spaces. This could explain why the so-called Mandel-Cryer effect is not prominent in this example,

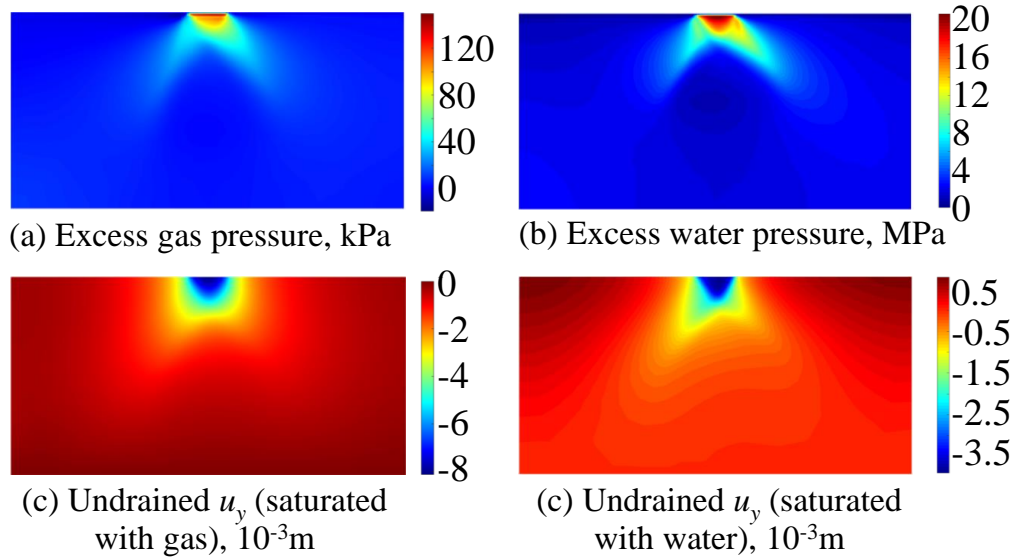

FIGURE 14 Contours of excess pressure and undrained vertical displacement u_y at $t = 10$ s (right after the strip load ω is applied). Constant permeability $k \equiv k_0$ is assumed for both water and gas flows. Left: Gas-saturated porous medium. Right: Water-saturated porous medium.

as shown in Fig. 15. In addition, since the compressibility of gas is much higher than that of water, even though the gas mobility is higher than that of water, the dissipation time is still comparable to that of water, as shown in Fig. 15. In Fig. 15, we also compare the dissipation of excess gas pressure between Darcy and non-Darcy flows, which suggests that non-Darcy flow would enhance the dissipation process because k_a is nearly 10 times of k_0 in this example. We can imagine that if we also include surface diffusion, the descending segment of the blue dashed curve will continue moving to the left.

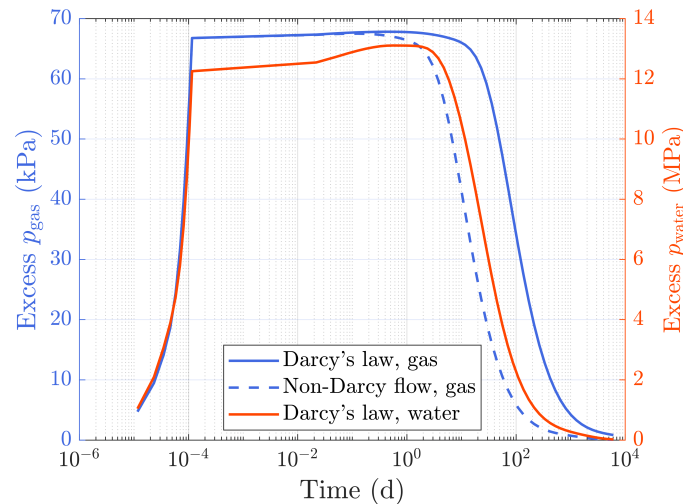

FIGURE 15 Evolution of excess pressure at point A with different permeability models and different kinds of liquids. The Mandel-Cryer effect is not significant on gas, and the Non-Darcy flow^[39] effect is significant in the dissipation stage.

Fig. 16 portrays the excess gas pressure contours at three different time slots for two different preconsolidation pressures $p_{c0} = -40$ MPa and $p_{c0} = -400$ MPa. The latter case of $p_{c0} = -400$ MPa in fact characterizes an anisotropic poroelastic material. Non-Darcy flow and $\theta = \pi/4$ are assumed for both cases. As a result, we can see that the elastic porous medium generates a lower excess gas pressure than the elastoplastic porous medium. Apart from this finding, the spatial variation of the excess gas pressure for the elastoplastic porous medium has an arch shape, as opposed to the typical bulb shape generated by the elastic porous medium. The arch shape might be attributed to the shape of the plastic zone. Both the arch shape and the bulb shape are skewed because of an inclined bedding plane orientation. The final deformation of the anisotropic elastoplastic material is greater than the anisotropic elastic material. Fig. 17 depicts the final vertical displacement and norm of plastic strain tensor ϵ^p . Non-Darcy flow and $p_{c0} = -40$ MPa are assumed for all cases. We find that a change in θ would affect the shape of the skewed $\|\epsilon^p\|$ contours. For $\theta = \pi/4$, the contour of $\|\epsilon^p\|$ is skewed to the right, while for $\theta = \pi/15$, it is skewed to the left. This is because ϵ^p is influenced by the plastic flow direction, and for the above two values of θ , the corresponding plastic flow directions are opposite, as proved in Zhao et al.^[48]. For $\theta = 7\pi/18$, one dominant shear band that is nearly parallel to the bedding plane is generated from our simulation. The irregular patterns of $\|\epsilon^p\|$ for $\theta = \pi/4$ and $\theta = 7\pi/18$ are also revealed in the example of bearing capacity of anisotropic soil by using the DEM-MPM multiscale approach^[50].

FIGURE 16 Contours of excess gas pressure at three different time slots. Left: $p_{c0} = -40$ MPa (elastoplastic deformation). Right: $p_{c0} = -400$ MPa (elastic deformation). Color bars are pressures in kPa.

Finally, we observe that the plastic deformation for the medium bedding plane orientation Fig. 17(b) is greater than other two orientations, which reminds us the U-shaped variation of the rock strength with respect to the bedding plane orientation θ ^[48]. To give a more intuitive result, we have plotted $\|\epsilon^p\|$ and Δp_{gas} (excess gas pressure) at point A with respect to θ when $t = 10$ s in Fig. 18. Now it becomes more

FIGURE 17 Contours of $\|\epsilon^p\|$ and vertical displacement u_y at the end of the simulation (excess gas pressure is almost zero). Left: $\theta = \pi/15$. Middle: $\theta = \pi/4$. Right: $\theta = 7\pi/18$.

clear that $\|\epsilon^p\|$ firstly increases and then decreases to zero when θ goes from 0 to $\pi/2$. The asymmetry between $\theta = 0$ and $\theta = \pi/2$ implies a higher strength in the bed-parallel direction than in the bed-normal direction. For excess gas pressure, it monotonically decreases as θ goes from 0 to $\pi/2$.

FIGURE 18 Variation of $\|\epsilon^p\|$ and excess gas pressure at point A versus bedding plane orientation θ ($t = 10$ s). The left figure is consistent with the U-shaped variation of the rock strength with respect to the bedding plane orientation^[48].

5 | CLOSURE

By integrating the anisotropic elasticity model and the advanced anisotropic elastoplasticity model into conventional gas production and strip footing problems, this study has provided valuable insights into the unique characteristics of unconventional shale. The analysis of gas production has uncovered new stress patterns, underscoring the significance of considering material anisotropy to enhance the fitting of field data and to exercise caution when applying isotropic results to real shale gas reservoirs. Moreover, the investigation of strip footing has revealed the substantial impact of small fluid compressibility on the undrained hydromechanical response and Mandel-Cryer effect. Furthermore, the study has identified a strong correlation between the bedding plane orientation and both the excess gas pressure and plastic strain tensor. Notably, in the anisotropic elastoplastic model, an arch-shaped pressure contour emerges when the orientation angle (θ) approaches $\pi/4$. These findings deepen our understanding of gas flow and solid deformation in unconventional shale, paving the way for more precise and accurate modeling of shale behavior. Through this research, we have gained valuable insights that contribute to the advancement of knowledge in the field of unconventional shale mechanics.

□

APPENDIX

A FINITE ELEMENT EQUATIONS OF THE FRACTURE FLOW MODEL

We consider the 1D fracture domain $\bar{\Omega}_F$, as shown in Fig. A1, which has one starting point and one ending point, and they are regarded as the boundary of $\bar{\Omega}_F$, denoted as $\partial\bar{\Omega}_F = \{\text{Point}_{\text{start}}, \text{Point}_{\text{end}}\}$. In the fracture flow model, the gas pressure must be continuous at the fracture-matrix interface, and the discrete fracture elements must be located on the edges of porous matrix elements, sharing the same nodes^[51,52]. By using this strategy, the mass exchange between the fracture and porous matrix is not required to evaluate explicitly^[51], and $\partial\bar{\Omega}_F$ belongs to the type of Dirichlet boundary. Therefore, in the finite element method (FEM), the weighting function δp_F would vanish at $\partial\bar{\Omega}_F$.

On $\bar{\Omega}_F$, a local coordinate system denoted by ζ axis is built, and the strong form of the fracture flow equation is given as

$$w \frac{\partial(\phi_F \rho_g)}{\partial t} + \frac{\partial(\rho_g w q_F)}{\partial \zeta} = 0, \quad (\text{A1})$$

FIGURE A1 A schematic demonstration of the 1D fracture domain $\bar{\Omega}_F$. The domain has one starting point and one ending point, and they are regarded as the boundary of $\bar{\Omega}_F$.

$$q_F = -\frac{k_F}{\mu_g} \frac{\partial p_F}{\partial \zeta}, \quad (\text{A2})$$

where w is the fracture aperture, ϕ_F is the fracture porosity, ρ_g and μ_g are calculated in the same way as before, k_F is the fracture permeability. Note that we use p_F to emphasize the fracture flow, but it is just the matrix gas pressure p at the fracture-matrix interface including the shared nodes. In addition, experimental results suggest that w , ϕ_F , and k_F could be functions of p_F , and some empirical relations such as the exponential function have been used to determine these parameters. The relation between the local and global coordinate systems is also mentioned here. For example, fracture flow velocity q_F in the global coordinate system is decomposed as a vector given as

$$\mathbf{q}_F = -\frac{k_F}{\mu_g} \underbrace{\left(\frac{\partial p_F}{\partial x} \cos \theta + \frac{\partial p_F}{\partial y} \sin \theta \right)}_{\partial p_F / \partial \zeta} \begin{bmatrix} \cos \theta \\ \sin \theta \end{bmatrix} = q_F \begin{bmatrix} \cos \theta \\ \sin \theta \end{bmatrix}. \quad (\text{A3})$$

It is easy to check that this vector is aligned with the 1D fracture segment, which is intuitively consistent. Similarly, the second-order derivative $\partial^2 p_F / \partial \zeta^2$ is equivalent to

$$\frac{\partial^2 p_F}{\partial \zeta^2} = \frac{\partial^2 p_F}{\partial x^2} \cos^2 \theta + \frac{\partial^2 p_F}{\partial y^2} \sin^2 \theta + 2 \frac{\partial^2 p_F}{\partial x \partial y} \sin \theta \cos \theta. \quad (\text{A4})$$

To obtain the weak form corresponding to Eq. (A1), we multiply Eq. (A1) by the weighting function δp_F and integrate on $\bar{\Omega}_F$, the result reads

$$\int_{\bar{\Omega}_F} (\delta p_F) w \frac{\partial (\phi_F \rho_g)}{\partial t} d\zeta + \int_{\bar{\Omega}_F} \delta p_F \frac{\partial (\rho_g w q_F)}{\partial \zeta} d\zeta = 0. \quad (\text{A5})$$

It is assumed that inside the fracture, all variables remain constant in the lateral direction (the direction perpendicular to the 1D element segment), and the aperture w of the fracture appearing as a factor in the 1D integral ensures the unit consistency with the 2D integral of the porous matrix^[53]. By using the integration by part, the second term could be simplified as

$$\begin{aligned} \int_{\bar{\Omega}_F} \delta p_F \frac{\partial (\rho_g w q_F)}{\partial \zeta} d\zeta &= (\delta p_F) (\rho_g w q_F) \Big|_B^A - \int_{\bar{\Omega}_F} (\rho_g w q_F) \frac{\partial (\delta p_F)}{\partial \zeta} d\zeta \\ &= - \int_{\bar{\Omega}_F} \frac{\partial (\delta p_F)}{\partial \zeta} (\rho_g w q_F) d\zeta, \end{aligned} \quad (\text{A6})$$

where A and B in $(\cdot) \Big|_B^A$ represent the starting and ending points in $\partial\bar{\Omega}_F$, and this term vanishes because the weighting function δp_F is zero at the Dirichlet boundary $\partial\bar{\Omega}_F$. Next, by adopting the backward Euler time integration scheme, Eq. (A5) could be rewritten as

$$\int_{\bar{\Omega}_F} (\delta p_F) w \frac{(\phi_F \rho_g) - (\phi_F \rho_g)_{t_n}}{\Delta t} d\zeta - \int_{\bar{\Omega}_F} \frac{\partial(\delta p_F)}{\partial \zeta} (\rho_g w q_F) d\zeta = 0, \quad (\text{A7})$$

where the subscript t_n implies the quantity at the previous time step, and other quantities are by default evaluated implicitly.

In this work, we assume a 1D linear element which means that for one element with local coordinates ζ_1^e and ζ_2^e , the shape function $[N_F^e]$ and its derivative in the local coordinate system $[E_F^e]$ are

$$[N_F^e] = \begin{bmatrix} \zeta - \zeta_2^e & \zeta_1^e - \zeta \\ \zeta_1^e - \zeta_2^e & \zeta_1^e - \zeta_2^e \end{bmatrix}, \quad [E_F^e] = \begin{bmatrix} 1 & -1 \\ \zeta_1^e - \zeta_2^e & \zeta_1^e - \zeta_2^e \end{bmatrix}. \quad (\text{A8})$$

Through the assembly operation of the element shape functions and derivatives, the global matrix equation in the residual form derived from Eq. (A7) is given as

$$\mathcal{R}_F = \int_{\bar{\Omega}_F} [N_F]^T w \frac{(\phi_F \rho_g) - (\phi_F \rho_g)_{t_n}}{\Delta t} d\zeta - \int_{\bar{\Omega}_F} [E_F]^T (\rho_g w q_F) d\zeta. \quad (\text{A9})$$

By using the global $[N_F]$ and $[E_F]$ matrices, we have $p_F = [N_F][p_F]$ and $\partial p_F / \partial \zeta = [E_F][p_F]$. The size of $[N_F]$ (row vector), $[E_F]$ (row vector), and $[p_F]$ (column vector) is equal to the number of nodes (or the number of elements plus one) in $\bar{\Omega}_F$. The residual \mathcal{R}_F is generally nonlinear with respect to the unknown nodal pressure vector $[p_F]$ and is best solved using Newton's method^[28]. As a result, the algorithmic tangent operator \mathcal{K}_F is given as

$$\mathcal{K}_F = \int_{\bar{\Omega}_F} [N_F]^T \frac{(\phi_F w \rho_g)'}{\Delta t} [N_F] d\zeta + \int_{\bar{\Omega}_F} [E_F]^T \chi [E_F] d\zeta + \int_{\bar{\Omega}_F} [E_F]^T \frac{\partial p_F}{\partial \zeta} \frac{\partial \chi}{\partial p_F} [N_F] d\zeta, \quad (\text{A10})$$

where $(\cdot)'$ implies a partial derivative with respect to p_F , and $\chi = \rho_g w k_F / \mu_g$. Note that the \mathcal{R}_F and \mathcal{K}_F should be superimposed to the finite element equations of the porous matrix^[51], in order to satisfy the solvability requirements.
