Abstract

Decision-making is a dynamic process requiring perception, memory, and reasoning to make choices and find optimal policies. Traditional approaches to decision-making suffer from sample efficiency and generalization, while large-scale self-supervised pretraining has enabled fast adaptation with fine-tuning or few-shot learning in language and vision. We thus argue to integrate knowledge acquired from generic large-scale self-supervised pretraining into downstream decision-making problems. We propose Pretrain-Then-Adapt pipeline and survey recent work on data collection, pretraining objectives and adaptation strategies for decision-making pretraining and downstream inference. Finally, we identify critical challenges and future directions for developing decision foundation model with the help of generic and flexible self-supervised pretraining.

1 Introduction

Human life is all about making decisions. It occurs in a wide variety of scenarios and intelligent agents have been developed to help human with real-world decision-making tasks, such as traffic control [Liang *et al.*, 2019], energy management [Nakabi and Toivanen, 2021], and drug discovery [Zhou *et al.*, 2019]. Dominant paradigms to train agents include reinforcement learning (RL), imitation learning (IL) and planning. Recent advances in these algorithms have achieved superhuman performance in mastering the game of Go [Silver *et al.*, 2017], playing Atari video games directly from pixels [Schwarzer *et al.*, 2023], and autonomous control of robotic locomotion and manipulation from sensory data [Brohan *et al.*, 2022]. However, traditional approaches to agent training suffer from sample efficiency and generalization as numerous interactions with the environment are demanded and the agent is task- and domain-specific. In this paper, we argue that self-supervised pretraining with downstream adaptation is one way to alleviate the issues. We survey recent work especially on multi-task offline pretraining via Transformer [Vaswani *et al.*, 2017] and propose future research directions

towards general large-scale pretraining models for decision-making.

Self-supervised pretraining has enabled large sequence models to realize few-shot or even zero-shot adaptation in natural language processing (NLP) [OpenAI, 2023] and computer vision (CV) tasks [Bai *et al.*, 2023]. Through pretraining on large generic corpora or visual data (images and videos), knowledge about the world and human society is learned which can be utilized in various downstream task learning with few samples so as to improve sample efficiency and generalization. In NLP, self-supervised sequential modeling using the objective of next word prediction or random masking has produced powerful pretrained models for text generation [Brown *et al.*, 2020] or context understanding [Devlin *et al.*, 2018]. In CV, unsupervised contrastive learning [Chen *et al.*, 2020; He *et al.*, 2020] has shown effectiveness in data augmentation to improve visual representation learning. Recently, supervised pretraining and online pretraining have made some progress in decision making by leveraging large-scale expert demonstrations to perform imitation learning [Reed *et al.*, 2022; Brohan *et al.*, 2022; Lee *et al.*, 2023] or involving self-supervised prediction or skill discovery in online exploration [Pathak *et al.*, 2017; Eysenbach *et al.*, 2018]. However, large-scale self-supervised pretraining in multi-task offline settings remains a significant research challenge.

Recent advances in self-supervised (unsupervised) pretraining for decision-making allow the agent to learn without reward signals and in accordance with offline RL [Levine *et al.*, 2020], encourage the agent to learn from sub-optimal offline data. However, previous attempts at self-supervised RL pretraining have mostly been limited to a single task [Yang and Nachum, 2021], or performing pretraining and fine-tuning within the same task [Schwarzer *et al.*, 2021], which is not generic and flexible for adapting to varieties of downstream tasks. Therefore, in this paper, we focus on multi-task offline pretraining for decision foundation model where the pretraining data is task-irrelevant and collected from diverse environments, and the downstream adaptation concerns different tasks with varying dynamics or reward functions and domains with distinct state or action spaces. In addition, we highlight self-supervised representation learning in pretraining for decision-making to probe what knowledge can be learned and whether it can be transferred to solve decision-

* Corresponding author: Junge Zhang

making tasks, despite that fully unsupervised RL training requires learning self-supervised representation as well as general policies via a single model [Laskin *et al.*, 2021; Reed *et al.*, 2022; Brohan *et al.*, 2022].

We first provide background on sequential decision-making and techniques for sequential modeling and self-supervised learning for RL (§2.1). We then propose Pretrain-Then-Adapt pipeline to formulate the problem of self-supervised pretraining for decision foundation model (§2.2). Based on this pipeline, we review recent work considering three steps: data collection (§3), self-supervised pretraining (§4), and downstream adaptation (§5). For data collection, we summarize environments and tasks for decision-making pretraining and differences between pretraining dataset and downstream data. For self-supervised pretraining, we introduce tokenization strategies and pretraining objectives specifically designed for decision-making tasks used in recent work. For downstream adaptation, we categorize inference tasks to evaluate pretraining performance and introduce two strategies of adapting the pretrained model to downstream inference task including fine-tuning and zero-shot generalization. We conclude by identifying key challenges for general self-supervised pretraining for decision foundation model (§6) and advocate new research methods and evaluation framework for developing intelligent agents utilizing knowledge acquired from the foundation model.

2 Problem Formulation

2.1 Preliminaries

Sequential Decision-Making

Sequential decision-making refers to the process of making a series of decisions to achieve a goal in continuous time, based on previous actions and observations while considering possible future states and rewards. The process can be formulated as a markov decision process (MDP) $M = \langle S, A, T, R, \gamma \rangle$, where S is the state space, A the action space, T the dynamics transition function $T : S \times A \times S \rightarrow [0, 1]$, R the reward function $R : S \times A \times S \rightarrow \mathbb{R}$, and $\gamma \in [0, 1]$ is a discount factor for calculating cumulative rewards. Sometimes the underlying state is not accessible to the agent (e.g. an image-based Atari game), and the process can be modified as a partially observable MDP $M = \langle S, A, T, R, \mathcal{O}, E \rangle$, where \mathcal{O} is the observation space, and $E(o|s)$ denotes the observation emission function. Solutions to sequential decision-making often involve RL [Sutton and Barto, 2018], which aims to learn an optimal policy $\pi(a|s)$ that maximizes the expected discounted cumulative rewards $R = \sum_{k=0}^{\infty} \gamma^k r_{k+1}$.

RL via Sequence Modeling

Conventional RL focuses on online interactions with an environment, where an agent learns to maximize cumulative rewards through trial and error. The agent is able to get instant feedback from the environment but it is sample-inefficient especially in real-world applications. Offline RL can mitigate the issue by reusing past experiences from a static dataset. However, due to error propagation and value overestimation, it is challenging to train an offline RL agent via dynamic programming. By conditioning an autoregressive model on pre-

vious trajectories containing past states, actions and target return tokens, Decision Transformer [Chen *et al.*, 2021] formulates RL as a sequence modeling problem. Such a formulation draws upon the simplicity and scalability of Transformer without the need to fit value functions or compute policy gradients.

Self-supervised Learning for RL

For RL, sample efficiency and generalization are two key properties and can be realized and improved by sufficient representation learning. Similar to pretraining in language [Devlin *et al.*, 2018] and vision [Bao *et al.*, 2021], pretraining on a diverse, large amount of online or offline experiences benefits downstream task adaptation with pretrained representation that can be generalized across domains and tasks. Previous pretraining for RL mostly relies on expert demonstrations [Stooke *et al.*, 2021] for one single task [Schwarzer *et al.*, 2021], yet in real-world scenarios, large amount of unlabeled and sub-optimal data (without task-specific reward) can be collected from multiple environments and tasks. Self-supervised learning is an effective and task-agnostic method to learn representation from numerous unlabeled data as shown in large language or vision model pretraining [Brown *et al.*, 2020; Bai *et al.*, 2023].

Self-supervised learning for RL typically involves representation learning of separate RL components, such as state representation [Yarats *et al.*, 2021], action representation [Chandak *et al.*, 2019], reward representation [Ma *et al.*, 2022], policy representation [Tang *et al.*, 2022] and environment or task representation [Wang *et al.*, 2023a]. However, based on RL via sequence modeling, self-supervised learning for RL can also be formulated as a unified sequence modeling of various RL components, thus simultaneously learn representation and extract knowledge concerning different aspects of sequential decision-making processes, including temporal, causal and dynamics information.

2.2 Pretrain-Then-Adapt

In this survey, we focus on the pretrain-then-adapt pipeline for decision foundation model, involving self-supervised offline pretraining for trajectory representation and downstream adaptation (online or offline) using the pretrained model based on Transformer architecture. For different decision-making environments and tasks, a trajectory can contain different modality information. For example, in robotics, a trajectory usually comprises of proprioceptive states, camera observations, continuous control actions, task description and goal commands. In game, a trajectory may comprise of image observations, discrete actions and reward scalars. Formally, a trajectory can be denoted as

$$\tau = (x_1^1, x_1^2, \dots, x_1^N), \dots, (x_T^1, x_T^2, \dots, x_T^N) \quad (1)$$

where x_t^n refers to the n-th modality at the t-th timestep. Given a sequence of trajectories τ collected from agent’s interactions with environments, the pretraining phase aims to learn a representation function $g : \mathbb{T} \in \mathbb{R}^n \rightarrow \mathbb{Z} \in \mathbb{R}^m$ ($m \ll n$) to extract useful knowledge from trajectories for downstream adaptation. The knowledge can be temporal information about the same data modality (e.g., s_t, s_{t+1}),

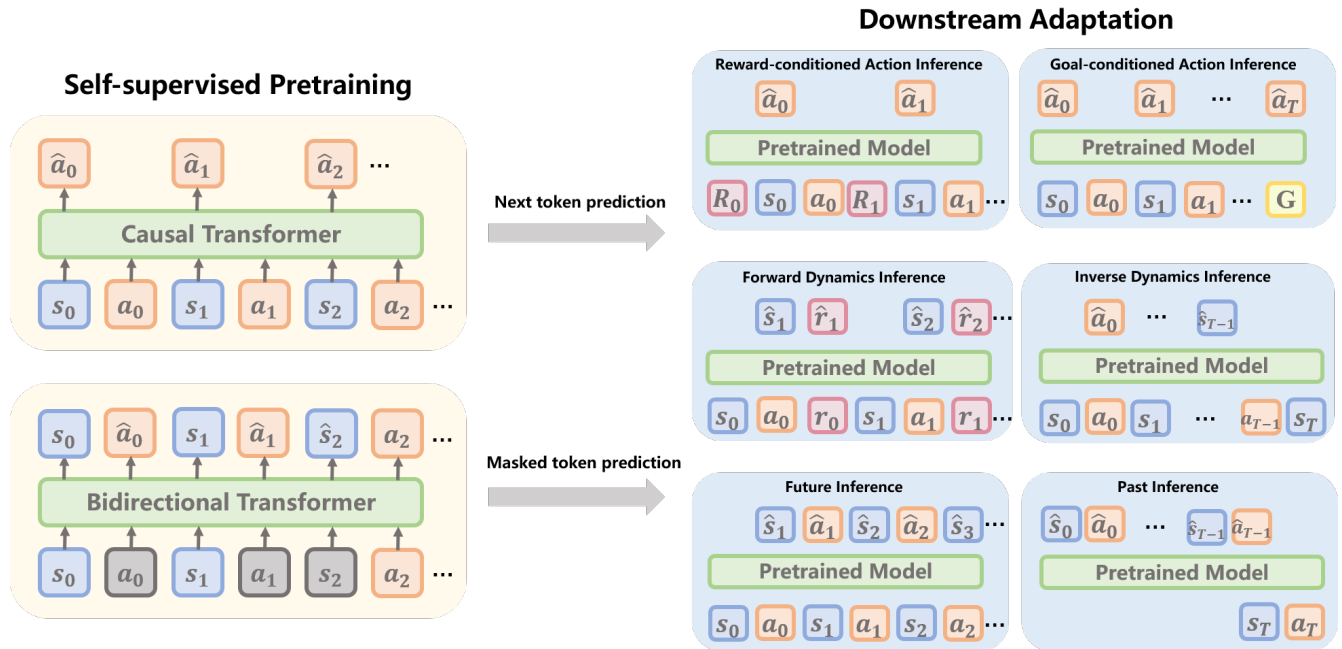

Figure 1: Pretrain-then-Adapt pipeline for decision foundation model. **Left:** Self-supervised pretraining involves two basic pretraining objectives based on Transformer architecture: next token prediction and masked token prediction. However, using different RL components, various pretraining objectives can be proposed for pretraining decision foundation models as introduced in section 4.2. **Right:** Downstream inference tasks can be roughly divided into three categories: action inference, dynamics inference and trajectory inference. Details about each inference task can be referred to section 5.1. Different colors denote different data modality in trajectory sequences. The grey color means the token is masked.

causal information between different data modalities (e.g., s_t, a_t), dynamics information about the environment (e.g., s_t, a_t, s_{t+1}), and reward information about the interaction between agents and environments (e.g., s_t, a_t, r_t).

During the adaptation phase, the knowledge learned by the pretrained model can help to optimize a learning objective $f_\theta(z)$ in downstream decision-making tasks, such as the value function $V(\pi)$ or $Q(s, a)$, policy function $\pi(a|s)$, dynamics function $T(s, a, s)$, and reward function $r(s, a)$. Compared to learning these objectives from scratch in traditional RL, using the pretrained model will improve the sample efficiency and generalization. The relationship between pretraining and adaptation is shown in Figure 1.

3 Data Collection

3.1 Pretraining Datasets

For pretraining, the data can be collected from single or multiple environments and tasks. Recent studies [Sun *et al.*, 2023] show that self-supervised multi-task pretraining can be more beneficial to downstream task learning compared to pretraining with only in-task data, as common knowledge can be extracted from diverse tasks. However, this cannot be always true due to the severe discrepancies between pretraining tasks. For instance, pretraining on multiple Atari games may suffer from performance degradation in downstream game play due to the limited visual feature sharing across the games [Stooke *et al.*, 2021].

We summarize the sequential decision-making environments and tasks used for self-supervised pretraining data collection in recent studies in Table 1. To examine the effects of pretraining dataset quality on the self-supervised pretrained model for decision-making, the pretraining datasets can be roughly divided into six categories according to the quality of behavior policy used for data collection. **Expert:** demonstrations from an expert; **Near-expert:** expert demonstrations with some action noises; **Mixed:** transitions collected via multiple checkpoints evenly spread throughout training of an RL algorithm; **Weak:** exploratory rollouts of an expert RL algorithm; **Exploratory:** exploratory rollouts of an exploratory RL algorithm; **Random:** random interactions with environment. In addition, to test the scalability of Transformer-based pretrained model, the pretraining dataset can be of varying sizes, ranging from several to tens of million transition steps for each pretraining task.

3.2 Downstream Data

When fine-tuning the pretrained model on a specific decision-making task, the downstream data can be online interactions with an environment or simply a fixed offline dataset. Different from the large, diverse pretraining dataset where unlabeled and sub-optimal trajectories may compose the most of data, the downstream dataset for fine-tuning is usually in a small size but with reward supervision or expert demonstration for better downstream adaptation. Additionally, the downstream data can be in the same as or different from the

Table 1: Environments and tasks for self-supervised pretraining for decision-making.

Environment	Task	Continuous/Discrete Action
DMControl [Tassa <i>et al.</i> , 2018]	robotic locomotion and manipulation	continuous
Atari [Bellemare <i>et al.</i> , 2013]	arcade-style games	discrete
Gym MuJoCo from D4RL [Fu <i>et al.</i> , 2020]	simulated locomotion	continuous
Adroit [Rajeswaran <i>et al.</i> , 2017]	dexterous manipulation	continuous
Maze2D [Fu <i>et al.</i> , 2020]	goal-conditioned navigation	continuous
MiniGrid [Chevalier-Boisvert <i>et al.</i> , 2018]	2D map navigation with hierarchical missions	discrete
MiniWorld [Chevalier-Boisvert <i>et al.</i> , 2023]	3D visual navigation	continuous
Dark Room [Zintgraf <i>et al.</i> , 2019]	2D goal-oriented navigation	discrete

pretraining data with respect to the domains and tasks. Generally, unseen domains and tasks during downstream adaptation aim to test the generalization of pretrained representation.

4 Self-supervised Pretraining

In this survey, we focus on Transformer-based self-supervised pretraining for decision foundation model. The input to a Transformer architecture is required to be a sequence of discrete tokens, such as word tokens in language or patch tokens in vision. In this section, we first introduce tokenization strategies for learning trajectory tokens and summarize self-supervised pretraining objectives for decision-making proposed in recent work.

4.1 Tokenization Strategies

A trajectory dataset contains multi-modal information as shown in Eq.1. To learn embeddings of different data modalities, separate tokenizer is learned for each modality. In general, tokenization of a trajectory sequence comprises three components:(1) trajectory encoding; (2) timestep encoding; and (3) modality encoding, to allow the Transformer to disambiguate between different elements in the sequence. **Trajectory encoding** aims to transform the raw trajectory inputs into a common representation space for tokens. There are two tokenization granularity for trajectory embedding learning: (1) discretization at the level of data modality [Sun *et al.*, 2023; Wu *et al.*, 2023]; and (2) discretization at the level of data dimensions [Reed *et al.*, 2022; Boige *et al.*, 2023]. [Boige *et al.*, 2023] has suggested that discretization at the level of dimensions can improve pretraining performance compared to that at the level of modality, however, the comparative experiments are conducted only on three locomotion tasks. **Timestep encoding** captures absolute or relative positional information. The timestep embedding can be learned via a learned positional embedding layer or a fixed sinusoidal timestep encoder. **Modality encoding** allows the Transformer to distinguish modality types in the trajectory input, which can be learned via a learnable mode-specific encoder [Wu *et al.*, 2023]. An illustration of tokenization strategies is shown in Figure 2. Effects of different tokenization strategies need to be investigated in future work as well as its corresponding factors.

4.2 Pretraining Objectives

To leverage large-scale offline dataset with unlabeled samples, self-supervised pretraining has achieved notable success

Figure 2: Tokenization strategies for self-supervised pretraining on decision-making tasks. Here the raw trajectory data comprises observations and actions. Note that in-principle, the tokenization can handle any modality.

in various domains, such as language [Brown *et al.*, 2020], vision [Bai *et al.*, 2023], speech [Chen *et al.*, 2022], and control [Yang and Nachum, 2021]. The self-supervised learning objective is a key component during pretraining, as it allows the model to learn the underlying structure and deep semantics of the data by predicting future information or filling in missing information. Usually, the pretraining objective is designed specifically for certain domain tasks and model architecture. With Transformer which can model long-range dependencies and capture temporal information from input sequence, self-supervised pretraining objectives can be roughly divided into two categories: (1) **next token prediction**, and (2) **masked token prediction**. Based on the two patterns, varieties of self-supervised learning objectives are proposed for decision-making task pretraining, as summarized in Table 2.

As shown in Table 2, the simplest pretraining objective is to predict next action conditioned on previous trajectories and the state or observation at current timestep. It also relies on the least requirements for the data modality of offline pretraining dataset. However, by conditioning on various variables contained in a trajectory sequence, the action prediction can be empowered with different sources of information in the sequential decision process, such as the reward or value signals [Chen *et al.*, 2021; Lee *et al.*, 2022], next state or observation [Sun *et al.*, 2023] and latent future sub-trajectory information [Xie *et al.*, 2023]. Besides learning the control information with action as the predicted target, dynamics information can also be exploited during pretraining via state representation learning which has been proven effective in improving sample efficiency in many RL tasks [Yang and Nachum, 2021]. In addition to next token prediction, ran-

Objective	Loss Function	Base Pattern
Next action prediction	$-\log P_\theta(a_t \tau_{0:t-1}, s_t)$	Next token prediction
Reward-conditioned action prediction	$-\log P_\theta(a_t \tau_{0:t-1}, s_t, R_t)$	Next token prediction
Future value and reward prediction	$-\log P_\theta(a_t, \hat{R}_t, r_t \tau_{0:t-1}, s_t)$	Next token prediction
Future-conditioned action prediction	$-\log P_\theta(a_t \tau_{0:t-1}, s_t, z)$	Next token prediction
Forward dynamics prediction	$-\log P_\theta(s_t \tau_{0:t-1})$	Next token prediction
Inverse dynamics prediction	$-\log P_\theta(a_t s_t, s_{t+1})$	Next token prediction
Multiple proportion random masking	$-\log P_\theta(\text{masked}(\tau) \text{unmasked}(\tau))$	Masked token prediction
Reward-conditioned random mask prediction	$-\log P_\theta(\text{masked}(\tau) \text{unmasked}(\tau), R_0)$	Masked token prediction
Random masked hindsight prediction	$-\log P_\theta(\text{masked}(a) \text{unmasked}(\tau), a_T)$	Masked token prediction
Random autoregressive mask prediction	$-\log P_\theta(\text{masked}(\tau, a_T) \text{unmasked}(\tau))$	Masked&Next token prediction

Table 2: Self-supervised pretraining objectives for decision-making based on Transformer architecture. P_θ is the prediction of the pretrained model. $\tau_{0:t-1}$ denotes the previous trajectories before timestep t . s_t is the state or observation at timestep t and a_t is the action at timestep t . R_t is the return (cumulative rewards) at timestep t , while \hat{R}_t is the predicted return at timestep t and r_t is the immediate reward at timestep t . g_T refers to the goal at the final timestep T , and z denotes the encoded future trajectory with the same sequence length as the input trajectory. s_{t+i} is the state or observation at future timestep after t and before the end of sequence length T . Note that the conditional variables in each loss function are encoded by either a causal Transformer [Brown *et al.*, 2020] when applying next token prediction or a masked Transformer [Devlin *et al.*, 2018] when applying masked token prediction.

dom masking helps to understand the semantics of trajectory data during pretraining by filling in random masked information given context around masked tokens. [Liu *et al.*, 2022a] randomly mask a proportion of input trajectory data using a randomly sampled mask ratio ranging from 15% to 95%. Besides, varieties of masking schemes have been proposed inspired by different components in RL. Reward-conditioned random mask prediction aims to predicted masked tokens in input trajectory conditioned on unmasked token sequence and the first return token. In [Carroll *et al.*, 2022], the first return token can be masked with probability 1/2 and all the subsequent return tokens are masked. Random masked hindsight prediction [Sun *et al.*, 2023] only learns to recover masked action tokens conditioned on unmasked trajectory tokens and the action at the final timestep T to capture global temporal relations for multi-step control. In contrast, random autoregressive mask prediction [Wu *et al.*, 2023] only conditions on unmasked trajectory sequence and learns to recover the masked trajectory tokens with a constraint that the last element in the sequence (e.g., a_T) must be necessarily masked to force the pretrained model to be causal at inference time.

In pretraining for decision-making, contrastive self-prediction is another effective self-supervised objective, especially in data augmentation strategies for sample efficiency. Different from sequence modeling, contrastive prediction particularly learns state representation by applying a contrastive loss between encoded state (e.g., $\phi(s_t)$) and target encoded state (e.g., $\phi_{\text{target}}(s_{t+i})$). The parameters of target state encoder is non-trainable and usually defined as an exponential moving average of the weights of ϕ [Stooke *et al.*, 2021; Schwarzer *et al.*, 2021; Cai *et al.*, 2023].

5 Downstream Adaptation

In the pretrain-then-adapt pipeline, a model is first pretrained on a large-scale offline dataset containing trajectories from various domains and decision-making tasks. Then the pretrained model acts as a knowledge base to provide meaningful representation for downstream task learning so as to im-

prove sample efficiency and generalization when adapting to a new task or domain. In this section, we first summarize inference tasks in sequential decision-making problems during downstream learning, and introduce two ways of downstream adaptation using a pretrained model for decision-making: (1) fine-tuning and (2) zero-shot generalization.

5.1 Inference Tasks in Sequential Decision-Making

Action prediction: Predict action based on various trajectory information. For example, reward-conditioned action inference predicts next timestep action using the returns-to-go (RTG) information $R = \sum_{k=t}^T r_k$. Goal-conditioned action inference predicts action using the goal information usually provided in goal reaching tasks. It can be a single-goal reaching task given a future state at the end of trajectory sequence $P_\theta(a_t | \tau_{0:t-1}, s_t, g_T)$, or a multi-goal reaching task given several goal states at random future timesteps [Liu *et al.*, 2022a]. The multi-goal reaching task can also be seen as a variant of waypoint-conditioned action inference [Carroll *et al.*, 2022; Badrinath *et al.*, 2023] where some subgoals (or waypoints) are specified at particular timesteps $P_\theta(a_t | \tau_{0:t-1}, s_t, s_{t+i})$.

Dynamics prediction: Predict forward or inverse dynamics based on previous or future trajectory information. Forward dynamics inference aims to predict future state s_{t+1} (and reward r_{t+1}) based on current state s_t and action a_t or previous state-action sequences $(s_{0:t}, a_{0:t})$. This inference process models the environment dynamics and it is not restricted to Markovian dynamics in theory. Inverse dynamics inference aims to predict previous action a_{t-1} (or state s_{t-1}) based on current state s_t and previous state s_{t-1} (or action a_{t-1}). This inference process tries to recover action (or state) sequences that track desired reference state (or action) trajectories.

Trajectory prediction: Predict future or past trajectories based on previous or future trajectory information. Particularly, future inference task predicts future state-action sequences based on previous state-action sequences $P_\theta(\tau_{t:T} | \tau_{0:t-1})$. Conversely, past inference task predict pre-

vious state-action sequences based on future state-action sequences $P_{\theta}(\tau_{0:t-1}|\tau_{t:T})$.

Downstream Evaluation

The pretrained model for decision-making is desired to learn representation of various RL components and extract knowledge from the representation to improve sample efficiency and generalization when adapting to a downstream inference task. For example, when the inference task is action prediction, a pretrained model can perform policy initialization. When performing dynamics inference, the model can act as a world model for model-based RL algorithms or an inverse dynamics model. For trajectory inference, the pretrained model can provide sufficient trajectory representation to accelerate the learning of traditional RL algorithms.

The performance of decision foundation model can be evaluated from different dimensions depending on the downstream adaptation setting. Generally, the evaluation can be considered from three perspectives: (1) representation learning performance; (2) generalization performance; and (3) robustness performance. For representation learning, the downstream inference tasks and domains are seen during pretraining, while for generalization, the downstream tasks or domains are unseen during pretraining. For robustness, the downstream tasks can be designed to test the model’s ability of resilience to corrupted observations or environment variations. [Boige *et al.*, 2023] evaluates the robust representation by disabling one of eleven sensors or introducing four gravity changes during inference.

5.2 Fine-Tuning

Fine-tuning is one way to adapt a pretrained model to a downstream inference task. Particularly, there are two cases demanding fine-tuning: (1) when the pretraining data is mixed comprising a small proportion of near-expert data and a large proportion of exploratory trajectories; and (2) when the pretraining objective is quite different from the learning objective of downstream task. For example, in traditional RL, the learning objective is to maximize the total reward for a task specified by a reward function, whereas the self-supervised pretraining task is usually reward-free.

Policy Learning Methods

When fine-tuning a pretrained model to adapt to a new decision-making task, it is required to learn a new policy on the downstream dataset using an RL algorithm, since the pretrained model is to provide useful representation rather than a general policy. When the downstream dataset is in high quality, **imitation learning** algorithms such as behavior cloning (BC) [Sun *et al.*, 2023; Yang and Nachum, 2021] can be applied whose learning objective is consistent with the action prediction target in pretraining. When the downstream data is an offline dataset, the pretrained model can be fine-tuned with **offline RL** algorithms, such as RTG-conditioned BC [Sun *et al.*, 2023; Xie *et al.*, 2023; Lee *et al.*, 2022; Wu *et al.*, 2023], BARC [Yang and Nachum, 2021] and TD3-BC [Boige *et al.*, 2023; Liu *et al.*, 2022a]. In online settings, traditional **online RL** algorithms including SAC [Yang and Nachum, 2021; Cai *et al.*, 2023], DQN with forward dynamics losses [Schwarzer *et al.*, 2021] and Rainbow [Cai *et al.*,

2023] can be used to learn the policy for downstream inference task.

Fine-tuning Methods

When learning a new policy on the downstream dataset, the weights of pretrained model are changed. According to the proportion of weights changed, fine-tuning methods can be roughly divided into three categories: (1) **Entirely fine-tuning**: the whole parameters of pretrained model are changed during downstream fine-tuning; (2) **Probing**: append policy heads to the pretrained model which generate embeddings with frozen weights and only the policy head introduces new parameters. [Cai *et al.*, 2023; Schwarzer *et al.*, 2021] show that in some cases freezing pretrained weights performs better than entirely fine-tuning; (3) **Parameter-efficient fine-tuning (PEFT)**: introduce a limited number of weights to the pretrained model which has seen notable success in fine-tuning large language models, such as LoRA [Hu *et al.*, 2021], Prefix Tuning [Li and Liang, 2021], P-Tuning [Liu *et al.*, 2022c] and (IA)³ [Liu *et al.*, 2022b; Boige *et al.*, 2023].

5.3 Zero-shot Generalization

In addition to fine-tuning, zero-shot generalization directly adapts a pretrained model to downstream tasks without the need to change or introduce any parameters to the pretrained model. This adaptation method performs well when there is a small gap between self-supervised pretraining objectives and downstream inference task objective and the pretraining data is near-expert. Typically, two strategies can be used for zero-shot generalization: (1) **Aligning** the pretraining objective and downstream inference objective, and (2) **Prompting** the pretrained model with demonstrations from corresponding downstream task [Xu *et al.*, 2022; Reed *et al.*, 2022; Laskin *et al.*, 2022].

For example, using a random masking pretraining objective where the mask ratio varies from goal to goal, [Liu *et al.*, 2022a] achieves better performance on goal reaching task compared to using the next token prediction objective. The reason is that the masking pretraining objective naturally fits the goal reaching scenario as the model is required to learn to recover masked actions based on remaining states. However, when the downstream inference task is a generation task, the next token prediction objective can be more appropriate for pretraining. By simply prompting the pretrained model with a few state-action pairs of a skill (e.g., walk/stand/run), the model can generate future trajectories in the same skill pattern [Liu *et al.*, 2022a].

6 Challenges and Future Directions

Despite the success of pretraining in deep RL [Laskin *et al.*, 2021; Xie *et al.*, 2022; Wen *et al.*, 2023], self-supervised pretraining for decision foundation model is a relatively new area. In this section, we discuss some main challenges and highlight several future directions towards general large-scale self-supervised pretraining for decision foundation model.

6.1 Pretraining

Three key components of self-supervised pretraining for decision foundation model include (1) tokenization strategies, (2) pretraining objectives, and (3) data collection. Currently, the tokenization scheme in pretraining for decision-making mainly borrows ideas from large language or vision models by transforming input data into token sequences. However, one difference between decision-making and language or visual pretraining is that the input trajectory data is multi-modality, whereas the language or visual data is single modality. A challenge then is to align different modalities, which is also a key problem in recent multi-modal pretraining [Wang *et al.*, 2023b]. In addition, the tokenization is first proposed for language modeling as language data is naturally discrete token sequences. However, many decision-making tasks handle continuous data (e.g., continuous control tasks for robot learning) and whether existing tokenization methods can fully make use of the information in trajectory data need further exploration.

Besides tokenization, the design of self-supervised pretraining objective also depends on the form of input data as well as the transformer architecture. The next token prediction and masked token prediction have achieved notable success in language pretraining, since the pretraining objective can naturally align the language data and language task well. As a result, all language tasks including translation, classification and question-answering can be unified as a text-to-text transfer learning [Raffel *et al.*, 2020]. Inspired by the two pretraining objectives for language modeling, multiple pretraining objectives have been proposed for decision-making using various RL components as shown in Table 2. Some studies have shown that using a combination of pretraining objectives can encourage the agent to learn various aspects of environment dynamics [Schwarzer *et al.*, 2021] or short-term and long-term control information [Sun *et al.*, 2023]. However, the relationships between these pretraining objectives are under-explored and whether there exists a general pretraining objective for decision-making tasks remains an open question.

The size and quality of pretraining data is another important factor for model performance. Currently, most studies on pretraining for decision-making rely on task-relevant expert demonstrations [Reed *et al.*, 2022; Lee *et al.*, 2023], showing that the model scales well with higher-quality pretraining data [Schwarzer *et al.*, 2021]. However, in real-world scenarios, it is more common to collect a large amount of unlabeled and sub-optimal data. Additionally, in traditional online RL setting, the agent is not required to learn from expert demonstrations but to find an optimal policy through interactions with the environment. Therefore, how to learn from large-scale unsupervised sub-optimal data is a key challenge for decision-making pretraining and future work can be explored in reference to traditional RL algorithms such as Q-learning or policy gradient methods.

6.2 Fine-tuning

When there is a gap between pretraining objectives and downstream inference objective, fine-tuning the pretrained model can help to adapt to the downstream task. As introduced in section 5.2, different fine-tuning methods change or introduce

parameters in different proportions. Yet the effects of different fine-tuning methods on inference performance have been underestimated. Future work can explore under what conditions that a fine-tuning method should be considered, and the factors influencing the fine-tuning performance, such as the type of inference tasks, the similarities and differences between pretraining objective and fine-tuning objective, or the downstream data structure, etc.

While fine-tuning can help the pretrained model to adapt to a new task, it can also cause catastrophic forgetting of the knowledge acquired from pretraining [French, 1999] as it changes the pretrained weights due to the distribution shift between pretraining data and downstream data. Therefore, the capacity of continual learning [Ring and others, 1994] is also a key challenge for pretraining in decision-making tasks. To resolve this issue, a universal interface between different decision-making tasks can be developed in future work to unify distinct state and action spaces as well as a dynamic model architecture to support continuously added features.

6.3 Downstream Evaluation

The performance of a pretrained model can be evaluated by downstream tasks. In language or vision, downstream tasks have been clearly defined and classified as benchmarks for evaluation. For example, BERT [Devlin *et al.*, 2018] has been evaluated on eleven NLP tasks including summarization, question answering and commonsense inference. [Bai *et al.*, 2023] builds a large vision model and adapts to a range of visual tasks including semantic segmentation, depth estimation, surface normal estimation, edge detection, object detection and colorization.

However, in pretraining for decision foundation model, there lacks of a unified evaluation framework for fair comparison despite of the URLB benchmark [Laskin *et al.*, 2021] for online pretraining. On the one hand, downstream inference tasks are usually mixed with policy learning methods and the distinction and relations between them are unclear. On the other hand, evaluation metrics are used for specific decision-making tasks, such as normalized score for games and average return for locomotion tasks. Therefore, a principled evaluation framework for decision foundation model needs to be established in future work. In addition, to assess the capabilities of pretrained decision models from different dimensions, desired properties of the model need to be defined as well as corresponding downstream tasks.
