(The Belle II Collaboration)

(Dated: February 5, 2024)

We describe a measurement of charge-parity (CP) violation asymmetries in $B^0 \rightarrow \eta' K_s^0$ decays using Belle II data. We consider $\eta' \rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-$ and $\eta' \rightarrow \rho(\rightarrow \pi^+\pi^-)\gamma$ decays. The data were collected at the SuperKEKB asymmetric-energy e^+e^- collider between the years 2019 and 2022, and contain $(387 \pm 6) \times 10^6$ bottom-antibottom meson pairs. We reconstruct 829 ± 35 signal decays and extract the CP violating parameters from a fit to the distribution of the proper-decay-time difference between the two B mesons. The measured direct and mixing-induced CP asymmetries are $C_{\eta'K_s^0} = -0.19 \pm 0.08 \pm 0.03$ and $S_{\eta'K_s^0} = +0.67 \pm 0.10 \pm 0.04$, respectively, where the first uncertainties are statistical and the second are systematic. These results are in agreement with current world averages and standard model predictions.

I. INTRODUCTION

In the standard model (SM), the only source of charge-parity (CP) violation is an irreducible phase in the Cabibbo-Kobayashi-Maskawa (CKM) quark-mixing matrix [1, 2]. This phase is measured with high precision in tree-dominated $b \rightarrow c\bar{c}s$ decays [3–5], *e.g.*, $B^0 \rightarrow J/\psi K^0$. In contrast, $b \rightarrow sq\bar{q}$ decays, with q indicating $u, d,$ or s quark, are dominated by loop amplitudes, in which additional sources of CP violation from physics beyond the SM could be involved [6, 7]. A comparison between CP asymmetries measured precisely in $b \rightarrow sq\bar{q}$ and $b \rightarrow c\bar{c}s$ transitions can thus probe non-SM physics.

The $B^0 \rightarrow \eta' K_s^0$ decay is of particular interest due to its relatively large branching fraction and limited contribution from tree amplitudes compared to other $b \rightarrow sq\bar{q}$ decays. The deviation of the mixing-induced CP asymmetry ($S_{\eta'K_s^0}$) from $\sin 2\phi_1$ is expected to be 0.01 ± 0.01 [8], in the SM, where $\phi_1 \equiv \arg(-V_{cd}V_{cb}^*/V_{td}V_{tb}^*)$ is an angle of the CKM unitarity triangle and V_{ij} are the CKM matrix elements. The direct CP asymmetry ($C_{\eta'K_s^0}$) is predicted to be zero [9].

Measurements of $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$ have been reported by the Belle [10] and BaBar [11] experiments, yielding the current world averages $C_{\eta'K_s^0} = -0.05 \pm 0.04$ and $S_{\eta'K_s^0} = 0.63 \pm 0.06$ [12]. These are the most precise measurements of CP asymmetries with $b \rightarrow sq\bar{q}$ transitions. However, improved measurements are needed to match the precision of the theoretical prediction of possible deviations from the SM [8]. The sensitivity of experiments operating at hadron colliders, such as LHCb, is limited by the challenge of the reconstruction of neutral final-state particles.

At an e^+e^- flavor-factory, $B^0\bar{B}^0$ pairs are produced via the process $e^+e^- \rightarrow \Upsilon(4S) \rightarrow B^0\bar{B}^0$. We consider the case when one neutral B meson (B_{tag}) decays into a flavor-specific final state at time t_{tag} , and the other B (B_{CP}) decays into a CP eigenstate at time t_{CP} . As the two neutral B mesons remain in a quantum-entangled state until one of them decays, the flavor of B_{CP} is opposite to that of B_{tag} at t_{tag} . We define q_{tag} as the flavor of

B_{tag} at t_{tag} , with q_{tag} taking the value $+1$ (-1) for B^0 (\bar{B}^0). The decay rate for the B_{CP} can be given by

$$\mathcal{P}(\Delta t, q_{\text{tag}}) = \frac{e^{-|\Delta t|/\tau_{B^0}}}{4\tau_{B^0}} [1 + q_{\text{tag}}\mathcal{A}_{CP}(\Delta t)], \quad (1)$$

where $\Delta t = t_{CP} - t_{\text{tag}}$ is the proper-time difference between the B_{CP} and B_{tag} decays, τ_{B^0} is the B^0 lifetime, and \mathcal{A}_{CP} is the time-dependent CP asymmetry, defined as

$$\begin{aligned} \mathcal{A}_{CP}(\Delta t) &= \frac{\Gamma(\bar{B}^0 \rightarrow \eta' K_s^0) - \Gamma(B^0 \rightarrow \eta' K_s^0)}{\Gamma(\bar{B}^0 \rightarrow \eta' K_s^0) + \Gamma(B^0 \rightarrow \eta' K_s^0)} \\ &= S_{\eta'K_s^0} \sin(\Delta m_d \Delta t) - C_{\eta'K_s^0} \cos(\Delta m_d \Delta t), \end{aligned} \quad (2)$$

where Δm_d is the mass difference between the two neutral B -meson mass eigenstates.

This paper reports a measurement of CP asymmetries $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$, based on the data collected by the Belle II experiment in 2019–2022 at the SuperKEKB asymmetric-energy e^+e^- collider [13], operating at the $\Upsilon(4S)$ resonance. The total integrated luminosity is $362 \pm 2 \text{ fb}^{-1}$, which corresponds to $(387 \pm 6) \times 10^6$ $B\bar{B}$ pairs.

We reconstruct the signal decay (B_{CP}) by combining the $K_s^0 \rightarrow \pi^+\pi^-$ candidate with the η' meson reconstructed in two channels, $\eta' \rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-$ and $\eta' \rightarrow \rho(\rightarrow \pi^+\pi^-)\gamma$. We also explore the channel $\eta' \rightarrow \eta(\rightarrow \pi^-\pi^+\pi^0)\pi^+\pi^-$, but exclude it from the final result due to its large statistical uncertainty. The B_{tag} flavor is determined with a flavor tagging algorithm [14]. The values of $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$ are extracted via a maximum-likelihood fit to the distributions of Δt and other observables that discriminate signal from background. The analysis technique and the Δt resolution model are tested on the $B^+ \rightarrow \eta' K^+$ control channel, where we do not expect any CP violation. The measurement of the lifetimes of B^0 and B^+ mesons validates Δt resolution modeling. Charge-conjugated modes are implied unless otherwise specified.

II. BELLE II DETECTOR AND SIMULATION

Belle II [15] is a particle physics experiment operating at the SuperKEKB collider in Tsukuba, Japan. Several subsystems, cylindrically arranged around the interaction point, enable reconstruction of heavy flavor particles and τ leptons produced in energy-asymmetric e^+e^- collisions. The innermost part of the detector comprises a two-layer silicon pixel detector (PXD), surrounded by a four-layer double-sided silicon microstrip detector (SVD). Together, they provide information about the charged particle trajectories (tracks) and B decay positions (vertices). The momenta and charge of charged particles are reconstructed with a 56-layer central drift chamber (CDC), which is the main tracking subsystem. Only one sixth of the second PXD layer is installed for the data analyzed in this paper.

Charged particle identification (PID) is accomplished by a time-of-propagation counter and an aerogel ring-imaging Cherenkov counter, located in the barrel and forward-endcap regions, respectively. The CDC provides additional PID information through the measurement of specific ionization. An electromagnetic calorimeter (ECL), made of CsI(Tl) crystals, is used for precise determination of the photon energy and angular coordinates as well as for electron identification. The tracking, PID, and ECL subsystems are surrounded by a superconducting solenoid, providing an axial magnetic field of 1.5 T. A K_L^0 and muon identification system is located outside of the magnet and consists of flux-return iron plates interspersed with resistive plate chambers and plastic scintillators. The central axis of the solenoid defines the z axis of the laboratory frame, pointing approximately in the direction of the electron beam, with respect to which the polar angle θ is defined.

The analysis strategy is tested and optimized on Monte Carlo simulated event samples before being applied to the data. Simulation is also used to determine the signal efficiency and the fit model. Quark-antiquark pairs from e^+e^- collisions are generated using KKMC [16] with PYTHIA8 [17], while hadron decays are simulated with EVTGEN [18]. The detector response and K_s^0 decays are simulated using GEANT4 [19]. Both data and simulated samples are processed using the Belle II analysis software framework [20, 21].

III. EVENT RECONSTRUCTION AND SELECTION

The reconstruction of signal candidates starts by reconstructing the B^0 decay products, $\eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]$, $\eta'[\rightarrow \rho(\rightarrow \pi^+\pi^-)\gamma]$, and $K_s^0 \rightarrow \pi^+\pi^-$.

Charged particles, assumed to be pions, are reconstructed using the tracking algorithm described in Ref. [22], with measurement points from tracking sub-detectors (PXD, SVD, and CDC). Pions are required to be within the CDC angular acceptance ($17^\circ < \theta < 150^\circ$)

and to have a distance of closest approach from the interaction point less than 2.0 cm along the z axis and less than 0.5 cm in the transverse plane, in order to reduce contamination from tracks not produced in the collision. Furthermore, at least one of the two charged pions from η' or ρ , which are used to reconstruct the B_{CP} decay vertex, is required to have at least one PXD measurement point.

The photons are reconstructed from ECL energy deposits not associated to any track. They are required to be in the CDC angular acceptance and have energy deposit in more than one ECL crystal.

The K_s^0 candidates are reconstructed from two oppositely charged pions coming from the same vertex and required to have a momentum direction compatible with the direction defined by the K_s^0 and B_{CP} decay vertices ($\cos\alpha > 0.99$, where α is the angle between the two directions) and have an invariant mass $0.49 < m(\pi^+\pi^-) < 0.51 \text{ GeV}/c^2$.

For the first decay subchannel, the $\eta \rightarrow \gamma\gamma$ candidates are reconstructed from two photons with energies greater than 150 MeV and an invariant mass in the range $0.505 < m(\gamma\gamma) < 0.580 \text{ GeV}/c^2$. The candidate η and two oppositely charged pions are combined to form an η' , which is retained if its mass satisfies $0.945 < m(\eta\pi^+\pi^-) < 0.970 \text{ GeV}/c^2$. The η mass is constrained to its known value to reconstruct the η' candidate.

For $\eta' \rightarrow \rho\gamma$ subchannel, we require two charged pions to first form a ρ candidate. For this subchannel, the pions are required to satisfy a PID requirement, computed using all PID capable detectors, which has a π^\pm identification efficiency of about 90%, and a K^\pm mis-identification probability of about 10%. The pion tracks are also required to have at least 20 measurement points in the CDC, which is sufficient to provide high efficiency and a low rate of misreconstructed tracks. The tighter selection for the pions in the second subchannel helps to reduce the larger background as well as the number of misreconstructed signal candidates. A less restrictive requirement is applied on the dipion mass, due to the broad width of the ρ resonance: $0.51 < m(\pi^+\pi^-) < 1.0 \text{ GeV}/c^2$. The lower bound of the invariant mass criterion avoids contamination from K_s^0 decays. An η' candidate is formed combining a ρ and a photon candidate with energy greater than 250 MeV. We require the invariant mass to be in the range $0.92 < m(\rho\gamma) < 0.98 \text{ GeV}/c^2$. This subchannel has broader η' mass resolution due to lack of constraint of ρ mass.

The invariant mass criteria for the η , η' , and K_s^0 candidates correspond to approximately $\pm 1.7\sigma_m$ intervals, where σ_m is the Gaussian mass resolution of each decay mode.

The η' and K_s^0 candidates are combined to form a B^0 candidate. The B^0 vertex is determined by fitting the entire decay chain with the `TreeFitter` algorithm [23, 24], constraining the mass of all intermediate mesons to their known values [25], except for the ρ , due to its large

width, and requiring the fit to converge. The momenta of all particles are updated after this vertex fit. The B^0 vertex is constrained to point back, along the direction of the reconstructed B^0 momentum, to the interaction region, calibrated with $e^+e^- \rightarrow \mu^+\mu^-$.

For each B candidate, the beam-energy constrained mass $M_{bc} = \sqrt{E_{\text{beam}}^{*2}/c^4 - p_B^{*2}/c^2}$ and energy difference $\Delta E = E_B^* - E_{\text{beam}}^*$ are calculated, where $(E, p)_B^*$ is the four-momentum of the B candidate and E_{beam}^* is the beam energy, both calculated in the center-of-mass frame. For correctly reconstructed signal events, M_{bc} peaks at the B^0 invariant mass and ΔE at zero. The requirements $M_{bc} > 5.20 \text{ GeV}/c^2$ and $|\Delta E| < 0.2 \text{ GeV}$ are applied.

In data, the average B candidate multiplicity for events with at least one reconstructed candidate is about 1.4 for $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$ and 1.8 for $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$. The difference is due to the presence of an intermediate, narrow resonance (η) in the first subchannel. If multiple B candidates are present in an event, the one with the smallest B^0 vertex χ^2 value is retained. In the simulation, this criterion selects the correct candidate in more than 99% of the cases when a true one is reconstructed.

The reconstruction efficiencies, determined using simulation, are 28.3% and 19.2% for $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$ and $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$, respectively. The lower efficiency for the second subchannel is mostly due to PID requirements applied to the two pions from the ρ decay in order to suppress background.

The control channel $B^+ \rightarrow \eta'K^+$ uses an η' reconstructed as described above and a charged kaon candidate with $\theta < 136^\circ$, excluding candidates in the backward part of the detector, where the background is higher. The PID selection for the K^+ candidate has an efficiency of about 90% for kaons, and a misidentification probability for pions of about 5%. In the control channel, the K^+ is not used for the B^+ vertex determination in order to have a vertex resolution similar to that of the signal channel.

The B_{tag} candidate is reconstructed using all the charged particles that are not associated to B_{CP} , having measurement points both in the SVD and CDC, and a momenta greater than $50 \text{ MeV}/c$. The RAVE algorithm is used to reconstruct the B_{tag} vertex [26]. This algorithm downweights tracks with large contributions to the vertex χ^2 , which are likely to originate from decays of secondary long-lived charm hadrons. The decay position of B_{tag} is determined by constraining its direction, as determined from its decay vertex and the interaction point, to be collinear with its momentum vector, reconstructed from the B_{CP} and momenta of the colliding beams [27].

The proper-decay-time difference Δt between the two B mesons is determined from the positions of their reconstructed vertices along the Lorentz boost axis, $\Delta t = \Delta z/\beta\gamma c$, where $\beta\gamma = 0.287$ is the boost of the $\Upsilon(4S)$ with respect to the laboratory frame, and $\gamma^* = 1.002$ is the Lorentz factor of the B meson in the center-of-mass

frame. We reject poorly reconstructed events requiring $|\Delta t| < 8 \text{ ps}$ and require the per-event uncertainty $\sigma_{\Delta t}$ to be less than 2 ps.

The main source of background is random combinations of tracks and photons that arise from continuum $e^+e^- \rightarrow q\bar{q}$ ($q = u, d, s, c$) events. A boosted-decision-tree (BDT) classifier [28] is trained using 26 event-shape variables to separate jet-like continuum events from more spherical $B\bar{B}$ topologies. The variables, in order of decreasing discriminating power, are the cosine of the angle between the B_{CP} and B_{tag} thrust axes [29], the cosine of the angle between the B_{CP} thrust axis and the z axis, the ratio of the second to the zeroth Fox–Wolfram moments [30], the modified Fox–Wolfram moments [31], the B_{tag} thrust magnitude, and the CLEO cones [32]. Variables that exhibit correlations greater than 10% with those used for the CP asymmetry measurement (M_{bc} , ΔE , Δt , and $\sigma_{\Delta t}$) are excluded. The BDT training is performed using simulated signal events and data in the sidebands ($M_{bc} < 5.27 \text{ GeV}/c^2$ and $\Delta E < -0.07$ or $> 0.05 \text{ GeV}$), which are dominated by continuum background. As a consistency check, we repeat the training with the off-resonance data collected at an energy 60 MeV below the $\Upsilon(4S)$ resonance, for an integrated luminosity of 42 fb^{-1} , and find the results to be in agreement with those obtained with the nominal training. A high-efficiency selection on the BDT output C_{BDT} is applied, retaining about 95% of the signal while suppressing 60% of the continuum background.

IV. TIME-DEPENDENT CP ASYMMETRY FIT

The parameters $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$ are extracted with an extended unbinned maximum-likelihood fit using the M_{bc} , ΔE , C_{BDT} , Δt , and tag-flavor q_{tag} observables, plus $\sigma_{\Delta t}$ as a conditional observable for Δt resolution function. The first three observables provide discrimination between signal and continuum background. The Δt and q_{tag} ones provide access to time-dependent CP asymmetry. Four different sample components are considered: signal; self-cross-feed (SxF), where a signal decay is misreconstructed, mostly due to wrong γ associations; background from continuum; and background from $B\bar{B}$. The SxF sample amounts to about 5% of the signal while $B\bar{B}$ amounts to about 1% of the continuum.

The fit is performed in two steps. In the first step the shapes and yields of all sample components are reliably determined in a time-independent fit, using M_{bc} , ΔE , and C_{BDT} distributions in the region $M_{bc} > 5.2 \text{ GeV}/c^2$ and $|\Delta E| < 0.2 \text{ GeV}$, which in turn simplify the time-dependent fit of the second step. In the first step most parameters of the signal and continuum models are allowed to vary, as well as the yields of signal and continuum. The SxF shape is fixed from simulated events, as well as its normalization relative to the signal component. The shape and yields of the $B\bar{B}$ component are fixed from simulation, as their contribution is too small

to be determined from data.

The second step of the fit uses Δt and q_{tag} in addition to the three observables utilized in the first step, and is performed only in the signal region, defined by $M_{bc} > 5.27 \text{ GeV}/c^2$ and $-0.07 < \Delta E < 0.05 \text{ GeV}$, where approximately 98% of signal is present. In this region the SxF amounts to about 3% of signal. In this step, the shapes for M_{bc} , ΔE , and C_{BDT} as well as the yields of all components are fixed from the previous one, so the only free parameters are $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$.

The B_{tag} flavor is determined using the flavor tagging algorithm described in Ref. [14], which uses the properties of particles not associated with the B_{CP} . The algorithm provides the flavor q_{tag} and the tagging quality $r = (1 - 2w)$, where w is the mistagging probability. The range of r varies from $r = 0$ (no flavor information can be obtained) to $r = 1$ (corresponding to unambiguous determination of the flavor).

Both fit steps are performed simultaneously in seven subsets of data (bins) selected according to tagging quality r , with boundaries set at 0, 0.1, 0.25, 0.45, 0.6, 0.725, 0.875, and 1, to gain statistical sensitivity from events with different wrong-tag fractions. In the first step, the signal and continuum yields of each bin are varied independently.

Each observable is modeled independently and hence

$$\mathcal{P}(\Delta t, q_{\text{tag}}) = \frac{e^{-|\Delta t|/\tau_{B^0}}}{4\tau_{B^0}} \left\{ 1 - q_{\text{tag}}\Delta w + q_{\text{tag}}a_\epsilon^{\text{tag}}(1 - 2w) + \left[q_{\text{tag}}(1 - 2w) + a_\epsilon^{\text{tag}}(1 - q_{\text{tag}}\Delta w) \right] \left[S_{\eta'K_s^0} \sin(\Delta m_d \Delta t) - C_{\eta'K_s^0} \cos(\Delta m_d \Delta t) \right] \right\}. \quad (3)$$

The effect of detector resolution on Δt changes Eq. 3 to

$$\mathcal{P}_{\text{exp}}(\Delta t, q_{\text{tag}}) = \int \mathcal{P}(\Delta t', q_{\text{tag}}) \mathcal{R}(\Delta t - \Delta t' | \sigma_{\Delta t}) d\Delta t', \quad (4)$$

where \mathcal{R} is the resolution function for Δt conditional on $\sigma_{\Delta t}$. The \mathcal{R} function has been determined in data using $B^0 \rightarrow D^{(*)-}\pi^+$ decays and it is described in details in Ref. [37]. Like the resolution function, also the flavor tagging parameters w , Δw , and a_ϵ^{tag} are extracted from data using flavor-specific $B^0 \rightarrow D^{(*)-}\pi^+$ decays. In simulation all these parameters from $B^0 \rightarrow D^{(*)-}\pi^+$ are compatible with our expectations based on signal.

The Δt distribution for the continuum component is modeled with three Gaussian functions and is determined using the data sidebands described earlier. The Δt distribution of the $B\bar{B}$ background is also modeled with the sum of three Gaussian functions and a component with

the total probability density function (PDF) is the product of the four independent PDFs. The correlation between M_{bc} and ΔE (10% and 20% for the two subchannels, respectively), due to the presence of photons in the final state, is considered as a source of systematic uncertainty.

The M_{bc} distribution is modeled with a sum of two Gaussian functions with a common mean for signal, a Crystal Ball function [33–35] for SxF, an ARGUS function [36] for continuum, and an ARGUS plus a Gaussian function for $B\bar{B}$. In the case of ΔE , two Gaussian functions are used for signal and SxF, with the addition of a linear function for $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$. For continuum, we use an exponential for $B^0 \rightarrow \eta'(\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-)K_s^0$ and the sum of an exponential and a wide Gaussian function for $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$. For $B\bar{B}$, we use an exponential plus a Gaussian function. For C_{BDT} , the sum of an asymmetric and a regular Gaussian function is used for signal, SxF, and $B\bar{B}$, and two Gaussian functions for continuum.

The Δt model for the signal and SxF components is derived from Eq. 1. Taking into account the probability of assigning the wrong flavor, w , its difference between B^0 and \bar{B}^0 , Δw , and the tagging efficiency asymmetry for B^0 and \bar{B}^0 , a_ϵ^{tag} , Eq. 1 becomes

an effective lifetime, that accounts for the sizable B lifetime, convolved with the same three Gaussian functions. Its parameters are determined from simulation.

To validate the resolution function, we determine the B meson's lifetime on data, using a simultaneous fit to both η' subchannels, separately for charged $B^+ \rightarrow \eta'K^+$ and neutral $B^0 \rightarrow \eta'K_s^0$ decays. The results are $\tau_{B^+} = 1.63 \pm 0.04 \text{ ps}$ and $\tau_{B^0} = 1.55 \pm 0.07 \text{ ps}$, where the uncertainties are statistical. Both are in agreement with their world averages [25].

The fit is further validated measuring the CP asymmetry on the charged B decay, which is expected to be negligible, with a simultaneous fit to the two η' subchannels. The same flavor tagger used for the neutral channels is used also for the control ones. In the signal region we find 1345 ± 39 and 1694 ± 64 signal events for $B^+ \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K^+$ and $B^+ \rightarrow \eta'[\rightarrow \rho\gamma]K^+$ subchannels with purities (which is the ratio of signal events over the total number of events in the signal region) 77% and 24%, respectively. The resulting CP

violation parameters are $C_{\eta'K^+} = -0.018 \pm 0.044$ and $S_{\eta'K^+} = -0.083 \pm 0.059$, where the uncertainties are statistical. The results are consistent with expectations of zero CP asymmetry. The Δt distributions are shown separately for B and \bar{B} tagged events in Fig. 1, along with the asymmetry as defined in Eq. 2.

Figure 1: Distribution of Δt for control channels $B^+ \rightarrow \eta'K^+$ separately for B and \bar{B} tags, combining the two subchannels $B^+ \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K^+$ and $B^+ \rightarrow \eta'[\rightarrow \rho\gamma]K^+$. The background contribution is also shown as a shaded area. The fit projections corresponding to B ($q_{\text{tag}} = 1$) and \bar{B} ($q_{\text{tag}} = -1$) tags are shown as solid red and dashed blue curves, respectively. The bottom panel shows the asymmetry as defined in Eq. 2, after subtracting the background using the $sPlot$ technique [38].

We then apply the fit to our signal, the neutral B samples. The distributions of the fit observables, M_{bc} , ΔE , and C_{BDT} in the signal region are shown in Fig. 2 for the $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$ subchannel, and in Fig. 3 for $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$ together with the fit results of the four components. The Δt distributions are shown separately for B^0 and \bar{B}^0 tagged events in Figs. 4 and 5 for subchannels $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$ and $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$, respectively, and in Fig. 6 for both, along with the asymmetry as defined in Eq. 2.

The resulting signal yield is 358 ± 20 for $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$, and 471 ± 29 for $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$. The purities for the two subchannels are 79% and 30%, respectively. Results for CP parameters from a simultaneous fit of the two subchannels are $C_{\eta'K_s^0} = -0.19 \pm 0.08$ and $S_{\eta'K_s^0} = +0.67 \pm 0.10$, where the uncertainties are statistical and obtained from a scan of the likelihood ratio. The results for individual channels are summarized in Table I. The correlation between $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$ is +3.4%.

We also explore the subchannel $B^0 \rightarrow \eta'(\rightarrow \eta\pi^+\pi^-)K_s^0$ with $\eta(\rightarrow \pi^+\pi^-\pi^0)$. We reconstruct this final state

Figure 2: Distributions of M_{bc} , ΔE , and C_{BDT} on data for $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$, with fit projections overlaid. The bottom panel shows the pull, which is the difference between data and fit, normalized to the statistical uncertainty on data.

combining four charged pions, selected using the same criteria for the second subchannel, and one neutral

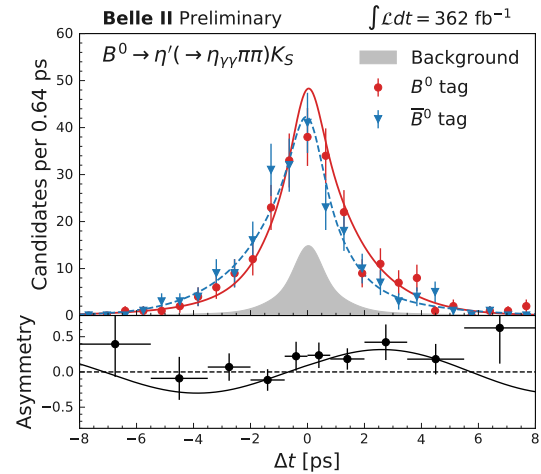

Figure 4: Distribution of Δt for signal channels separately for B^0 and \bar{B}^0 tags, for $B^0 \rightarrow \eta'([\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-])K_S^0$. The background contribution is also shown as a shaded area. The fit projections corresponding to B^0 ($q_{tag} = +1$) and \bar{B}^0 ($q_{tag} = -1$) are shown as solid and dashed curves, respectively. The bottom panel shows the asymmetry as defined in Eq. 2, after subtracting the background using the $sPlot$ technique [38]. The horizontal bars represent the widths of the variable-size bins used.

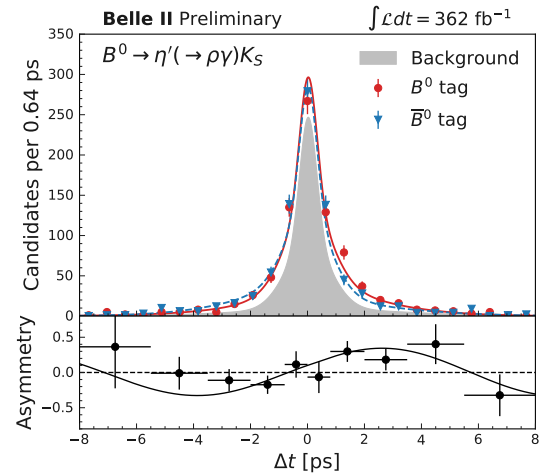

Figure 5: Distribution of Δt for signal channels separately for B^0 ($q_{tag} = +1$) and \bar{B}^0 ($q_{tag} = -1$) tags, for $B^0 \rightarrow \eta'([\rightarrow \rho\gamma])K_S^0$. The background contribution is also shown as a shaded area. The fit projections corresponding to B^0 and \bar{B}^0 are shown as solid and dashed curves, respectively. The bottom panel shows the asymmetry as defined in Eq. 2, after subtracting the background using the $sPlot$ technique [38]. The horizontal bars represent the widths of the variable-size bins used.

pion decaying to a pair of photons, with an invariant mass $0.120 < m(\gamma\gamma) < 0.145 \text{ GeV}/c^2$. We require

Figure 6: Distribution of Δt for signal channels separately for B^0 ($q_{\text{tag}} = +1$) and \bar{B}^0 ($q_{\text{tag}} = -1$) tags, combining the two subchannels, $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$ and $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$. The background contribution is also shown as a shaded area. The fit projections corresponding to B^0 and \bar{B}^0 are shown as solid and dashed lines, respectively. The bottom panel shows the asymmetry as defined in Eq. 2, after subtracting the background using the $sPlot$ technique [38]. The horizontal bars represent the widths of the variable-size bins used.

$E_\gamma > 80$ MeV for photons detected in the forward region, 30 MeV for the barrel region, and 60 MeV for the backward region, to account for the different levels of background in the three ECL regions. The selection on E_γ are looser than for the other subchannels to improve efficiency. The η candidate is required to have an invariant mass in the range $0.52 < m(\pi^+\pi^-\pi^0) < 0.57$ GeV/ c^2 while the mass difference Δm between η' and η candidates must satisfy $0.40 < \Delta m < 0.42$ GeV/ c^2 . The other selection criteria for the K_s^0 and B^0 candidates are the same as for the other subchannels. The signal yield is 55 ± 8 , and the purity is 55%. We perform the vertex fit and determine the resolution model, whose functional form is similar to that used in Ref. [39]. The measured CP asymmetries, $C_{\eta'(3\pi)K_s^0} = 0.11^{+0.32}_{-0.31}$ and $S_{\eta'(3\pi)K_s^0} = 0.25^{+0.47}_{-0.53}$ (the uncertainties are statistical) are consistent with those determined in the other two subchannels, but significantly less precise. Figure 7 shows the results of the CP asymmetry fit on the $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \pi^+\pi^-\pi^0)\pi^+\pi^-]K_s^0$ subchannel. The results of this subchannel are not used for final results since their statistical significance is negligible.

V. SYSTEMATIC UNCERTAINTIES

We consider several sources of possible systematic uncertainties, which are listed in Table II.

Table I: Summary of results on $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$ for the three subchannels, identified by the η' decay. The last subchannel is not included in the simultaneous fit. The uncertainties are statistical only.

Channel	Signal yield	$C_{\eta'K_s^0}$	$S_{\eta'K_s^0}$
$\eta' \rightarrow \eta\gamma\pi^+\pi^-$	358 ± 20	-0.10 ± 0.13	0.69 ± 0.14
$\eta' \rightarrow \rho\gamma$	471 ± 29	-0.24 ± 0.10	0.65 ± 0.13
$\eta' \rightarrow \eta_{3\pi}\pi^+\pi^-$	55 ± 8	0.11 ± 0.32	0.25 ± 0.50
Sim. fit	829 ± 35	-0.19 ± 0.08	0.67 ± 0.10

Figure 7: Distribution of Δt for the $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \pi^+\pi^-\pi^0)\pi^+\pi^-]K_s^0$ channel, separately for B^0 ($q_{\text{tag}} = +1$) and \bar{B}^0 ($q_{\text{tag}} = -1$) tagged events. The fit projections corresponding to B^0 and \bar{B}^0 are shown as solid and dashed lines, respectively. The background is also shown as a shaded area. The bottom panel shows the asymmetry as defined in Eq. 2, using the $sPlot$ technique [38] to subtract the background. The horizontal bars represent the widths of the variable size bins used.

To determine most of the systematic uncertainties, we use ensembles of simulated samples. For signal and SxF events we use sampling with replacement [40] from the available simulated samples, while continuum and $\bar{B}\bar{B}$ backgrounds are sampled from the PDF used for modeling, due to the limited size of simulated samples.

To evaluate the impact of the uncertainties of signal and continuum yields in the second fit step, we vary them individually by assuming alternate values, corresponding to ± 1 -standard-deviation fluctuations of the first fit results. We then consider the difference between the values of $C_{\eta'K_s^0}$ and $S_{\eta'K_s^0}$ from the nominal results as a systematic uncertainty.

The SxF and $\bar{B}\bar{B}$ yields are fixed to their values obtained in simulation. To estimate the systematic uncertainties, we let the fit determine the $\bar{B}\bar{B}$ yield for all r bins, one at a time to ensure the fit convergence. The average ratio between the fit result and expectation is

Table II: Summary of systematic uncertainties for $C_{\eta'K_S^0}$ and $S_{\eta'K_S^0}$.

Source	$C_{\eta'K_S^0}$	$S_{\eta'K_S^0}$
Signal and continuum yields	< 0.001	0.002
SxF and $B\bar{B}$ yields	< 0.001	0.006
C_{BDT} mismodeling	0.004	0.010
Signal and background modeling	0.020	0.014
Observable correlations	0.008	0.001
Δt resolution fixed parameters	0.005	0.009
Δt resolution model	0.004	0.019
Flavor tagging	0.007	0.004
τ_{B^0} and Δm_d	< 0.001	0.002
Fit bias	0.003	0.002
Tracker misalignment	0.004	0.006
Momentum scale	0.001	0.001
Beam spot	0.002	0.002
B -meson motion in the $\Upsilon(4S)$ frame	< 0.001	0.017
Tag-side interference	0.005	0.011
$B\bar{B}$ background asymmetry	0.008	0.006
Candidate selection	0.007	0.009
Total	0.027	0.037

0.9 ± 0.2 , and the average uncertainty of $B\bar{B}$ yield in each bin is about 50%. We vary the $B\bar{B}$ yield by this uncertainty and take the variations in the CP asymmetry parameters as a systematic uncertainty. We also vary the SxF yield by the same uncertainty (50%), and evaluate the variations on CP asymmetry parameters.

The impact of any C_{BDT} mismodeling is evaluated by comparing the results obtained using the data sidebands for its training with those in which the training is performed on continuum simulated events.

Similarly to what is done for yields, the parameters of PDF shapes used to model the various components are varied within their statistical uncertainties if they are determined in the first step of the fit. This is the case for the signal and continuum components. The variations of $C_{\eta'K_S^0}$ and $S_{\eta'K_S^0}$ due to alternative values of each parameter are summed linearly, to account for possible correlation, and used as a systematic uncertainty. The parameters fixed from simulation are allowed to vary, individually, in the CP asymmetry fit. We take the difference of $C_{\eta'K_S^0}$ and $S_{\eta'K_S^0}$ from the nominal results as a systematic uncertainty, summing the differences in quadrature.

The impact of the correlation between the fit observables, mostly between M_{bc} and ΔE , is estimated using ensembles of signal events simulated with correlation, sampled with replacement from the available simulated samples, and without correlation, by sampling the PDFs, and comparing the two sets of results.

The systematic uncertainty due to the Δt resolution model is estimated by repeating the fit under alternative assumptions for values of the resolution parameters within the uncertainties obtained from the fit on the $B \rightarrow D^{(*)-}\pi^+$ control sample. We also compare the result of a fit using the resolution parameters obtained by

fitting the simulated $B \rightarrow \eta'K_S^0$ signal events with the nominal fit, and take the difference on $C_{\eta'K_S^0}$ and $S_{\eta'K_S^0}$ as a systematic uncertainty.

The flavor-tagging parameters are varied within their statistical uncertainties. The same is done for the physics parameters τ_{B^0} and Δm_d , using the uncertainties on their world-average values. Small fit biases found on $C_{\eta'K_S^0}$ and $S_{\eta'K_S^0}$ by fits to large simulated samples are also included.

The impact of tracker misalignment is estimated with dedicated simulation samples with four different misalignment scenarios. The effects on charged-particle momentum scale due to imperfect modeling of the magnetic field, and the uncertainty on the beam spot determination, were studied in a previous analysis that used similar reconstruction strategies [41].

We estimate the effect of neglecting the small motion of the B meson in the $\Upsilon(4S)$ rest frame by calculating Δt from simulated signal events and comparing the true Δt with that based on true Δz .

The Δt model in Eq. 2 assumes that the B_{tag} decays into a flavor-specific mode. The impact of tag-side interference, namely the presence of Cabibbo-suppressed $b \rightarrow u\bar{c}s$ decays in the B_{tag} with different weak phase [42], is estimated by correcting for the observed asymmetry using previous measurements [12]. We conservatively assume that all events are tagged by hadronic B decays, where the effect is largest. We use the difference with respect to the nominal asymmetry as a systematic uncertainty.

The $B\bar{B}$ background is small and dominated by $b \rightarrow c$ decays. The possible presence of CP violation in the $B\bar{B}$ background is estimated conservatively by assuming that all this background has a CP asymmetry with $(C_{CP}, S_{CP}) = (\pm 0.2, 0)$ or $(0, \pm 0.2)$ and taking the largest variation on $C_{\eta'K_S^0}$ and $S_{\eta'K_S^0}$ as a systematic uncertainty.

Finally, the impact of the candidate selection is evaluated by repeating the full analysis with all multiple candidates and comparing with the results obtained using only the one with best vertex- χ^2 .

VI. SUMMARY

A measurement of CP asymmetries in $B \rightarrow \eta'K_S^0$ decays is conducted using e^+e^- collision data collected in 2019–2022 by the Belle II experiment at the SuperKEKB collider. We find 829 ± 35 signal decays in a sample of $(387 \pm 6) \times 10^6$ $B\bar{B}$ events and measure the CP asymmetries to be

$$\begin{aligned} C_{\eta'K_S^0} &= -0.19 \pm 0.08 \pm 0.03, \\ S_{\eta'K_S^0} &= +0.67 \pm 0.10 \pm 0.04, \end{aligned} \quad (5)$$

where the first uncertainties are statistical and the second systematic. This measurement is based on the sub-

channels $B^0 \rightarrow \eta'[\rightarrow \eta(\rightarrow \gamma\gamma)\pi^+\pi^-]K_s^0$ and $B^0 \rightarrow \eta'[\rightarrow \rho\gamma]K_s^0$.

This is the first measurement of CP violation in this channel at Belle II. The results are in agreement with the current world averages, and have sensitivities close to those of Belle [10] and BaBar [11], despite the smaller data size.

VII. ACKNOWLEDGEMENTS

This work, based on data collected using the Belle II detector, which was built and commissioned prior to March 2019, was supported by Higher Education and Science Committee of the Republic of Armenia Grant No. 23LCG-1C011; Australian Research Council and Research Grants No. DP200101792, No. DP210101900, No. DP210102831, No. DE220100462, No. LE210100098, and No. LE230100085; Austrian Federal Ministry of Education, Science and Research, Austrian Science Fund No. P 31361-N36 and No. J4625-N, and Horizon 2020 ERC Starting Grant No. 947006 “InterLeptons”; Natural Sciences and Engineering Research Council of Canada, Compute Canada and CANARIE; National Key R&D Program of China under Contract No. 2022YFA1601903, National Natural Science Foundation of China and Research Grants No. 11575017, No. 11761141009, No. 11705209, No. 11975076, No. 12135005, No. 12150004, No. 12161141008, and No. 12175041, and Shandong Provincial Natural Science Foundation Project ZR2022JQ02; the Czech Science Foundation Grant No. 22-18469S; European Research Council, Seventh Framework PIEF-GA-2013-622527, Horizon 2020 ERC-Advanced Grants No. 267104 and No. 884719, Horizon 2020 ERC-Konsolidator Grant No. 819127, Horizon 2020 Marie-Sklodowska-Curie Grant Agreement No. 700525 “NIOBE” and No. 101026516, and Horizon 2020 Marie Skłodowska-Curie RISE project JENNIFER2 Grant Agreement No. 822070 (European grants); L’Institut National de Physique Nucléaire et de Physique des Particules (IN2P3) du CNRS and L’Agence Nationale de la Recherche (ANR) under grant ANR-21-CE31-0009 (France); BMBF, DFG, HGF, MPG, and AvH Foundation (Germany); Department of Atomic Energy under Project Identification No. RTI 4002, Department of Science and Technology, and UPES SEED funding programs No. UPES/R&D-SEED-INFRA/17052023/01 and No. UPES/R&D-SOE/20062022/06 (India); Israel Science Foundation Grant No. 2476/17, U.S.-Israel Binational Science Foundation Grant No. 2016113, and Israel Ministry of Science Grant No. 3-16543; Istituto Nazionale di Fisica Nucleare and the Research Grants BELLE2; Japan Society for the Promotion of Science, Grant-in-Aid for Scientific Research Grants No. 16H03968, No. 16H03993, No. 16H06492, No. 16K05323, No. 17H01133, No. 17H05405, No. 18K03621, No. 18H03710, No. 18H05226,
