Abstract

Accurately estimating the Remaining Useful Life (RUL) of lithiumion batteries is crucial for maintaining the safe and stable operation of rechargeable battery management systems. However, this task is often challenging due to the complex temporal dynamics. Recently, attentionbased networks, such as Transformers and Informer, have been the popular architecture in time series forecasting. Despite their effectiveness, these models with abundant parameters necessitate substantial training time to unravel temporal patterns. To tackle these challenges, we propose a simple MLP-Mixer-based architecture named "Intra-Inter Patch Mixer" (IIP-Mixer), which is an architecture based exclusively on multi-layer perceptrons (MLPs), extracting information by mixing operations along both intra-patch and inter-patch dimensions for battery RUL prediction. The proposed IIP-Mixer comprises parallel dual-head mixer layers: the intrapatch mixing MLP, capturing local temporal patterns in the short-term period, and the inter-patch mixing MLP, capturing global temporal patterns in the long-term period. Notably, to address the varying importance of features in RUL prediction, we introduce a weighted loss function in the MLP-Mixer-based architecture, marking the first time such an approach has been employed. Our experiments demonstrate that IIP-Mixer achieves competitive performance in battery RUL prediction, outperforming other popular time-series frameworks.

1 Introduction

Lithium-ion batteries are widely used in electric vehicles, unmanned aerial vehicles, and grid energy storage systems. Accurately predicting the Remaining Useful Life (RUL) of a battery plays an important role in managing the health and estimating the state of a lithium-ion battery. [1] [2] However, accurately

^{*}Corresponding author:lfeng@must.edu.mo

predicting the RUL of batteries is highly challenging due to nonlinear degradation mechanisms caused by cycling and varied operational conditions. Generally, battery RUL is defined as the number of cycles when a battery reaches 80% initial capacity. Previous works on battery RUL prediction can be categorized into two main approaches: physics-based approaches and data-driven approaches. [3]

Physics-based approaches such as the single particle model [4] and pseudotwo-dimensional model [5] based on electrochemical principles underlying Lithium-Ion Batteries (LIBs) can simulate a battery's current and voltage characteristics from kinetics and transport equations. Although these models are usually precise and understandable, they come with significant computational demands and difficulties when extending their applicability to different battery cell types. [6]

Conversely, data-driven approaches do not make a priori assumptions about battery degradation mechanisms but instead leverage historical cycling data of batteries. Most of the current data-driven-based approaches integrate intricate structures such as gating mechanisms [6] [7] and attention mechanisms [8] [9]. Though effective, these complex approaches require significant training time to thoroughly explore temporal and intercorrelation patterns, demanding extensive computing resources. [10] Besides, the permutation-invariant self-attention mechanism leads to a loss of temporal information to some extent. [11] Our work aims to design a simple model that does not rely on any form of costly complex gates operation, or attention mechanism, yet performs competitively compared to existing models.

In this work, we introduce the Intra-Inter Patch Mixer (or "IIP-Mixer" for short) architecture. This architecture is exclusively based on the application of multi-layer perceptron across intra-patch and inter-patch. Importantly, IIP-Mixer refrains from employing gating, convolutions [12], or self-attention mechanisms, relying solely on basic matrix multiplication routines, changes to data layout (reshapes and transpositions), and scalar nonlinearities. [13] Our contributions are the following:

- We propose IIP-Mixer, a novel model built on all MLP architecture that leverages intra-inter patch mixing MLP design to capture the local and global temporal patterns in the time series.
- To achieve precise predictions of Remaining Useful Life, we introduce the parallel dual heads to aggregate output information from both intra-patch mixing MLP and inter-patch mixing MLP.
- Considering the varying importance of different variables in battery Remaining Useful Life prediction, we proposed a weighted loss function to further enhance prediction performance.
- The experimental results show that the IIP-Mixer architecture proposed can effectively improve the accuracy of the prediction of battery remaining useful life relying solely on MLP-based structures.

2 Related Work

As rechargeable batteries are a source of power for many devices, such as electric cars, mobile phones, unmanned aerial vehicles, and so on, it is critical to ensure their reliability and safety. Remaining useful life predictions have become increasingly important topics and have received considerable attention in recent years. To predict RUL for rechargeable batteries accurately, many deep-learning models have been proposed. [14]

- MLP: Multi-layer perceptron (MLP) is a kind of artificial neural network with a forward structure, including an input layer, an output layer, and several hidden layers [15]. For RUL prediction, MLP is applied to learn the nonlinear capacity degradation of the battery. However, as the number of layers increases, the number of parameters increases rapidly, which easily leads to overfitting.
- RNN: Recurrent neural network (RNN) is a kind of neural network for processing sequential data [16] [17] [18]. Sharing parameters across different parts of the model makes it possible to apply the model to examples of different lengths. However, recurrent neural networks with a recurrent manner have a high time cost for training, and the performance will degrade due to long-term dependency.
- Transformer: To learn trends from sequential data, the multi-head attention network of the Transformer is used to capture sequential information precisely and improves the training performance of neural networks [9] [19]. However, for a small dataset, it can easily lead to overfitting. Therefore, the performances of Transformer-based models are not always greater than MLP-based or RNN-based frameworks.

3 Methods

3.1 **Problem Formulation**

For systems like lithium-ion batteries, the degradation process often spans lots of cycles, with numerous variables collected by various sensors during each cycle. In this work, the battery RUL prediction problem is a case of multivariate time series prediction problem. Specifically, given the historical observations $\boldsymbol{X} \in \mathbb{R}^{C \times L}$, where L is the length of the lookback window, C is the number of variables. We consider the task of predicting $\boldsymbol{Y} \in \mathbb{R}^{C \times N}$, where N is the number of subsequent time steps. [20] In this work, we focus on the case when the values of the target time series are equal to the historical observation.

3.2 The Framework

Inspired by the recent MLP architecture MLP-Mixer [13], The idea behind the IIP-Mixer architecture is to separate the intra-patch mixing and inter-patch mixing to capture local temporal patterns and global temporal patterns simultaneously. Both operations are implemented with MLPs. The central architecture of the IIP-Mixer is an MLP-based design, which aggregates information from both intra-patch and inter-patch within the input series. It is worth noting that, different future has different patch mixers. For univariate time series, as illustrated in Figure 1, this framework contains the following major components:

Figure 1: Intra-Inter Patch Mixing Architecture for Battery Remaining Useful Life Prediction.

Input series transformation: From the perspective of channel independence, the multivariate time series $X \in \mathbb{R}^{C \times L}$ were divided into C univariate series $X^{(i)} \in \mathbb{R}^L$, $i = 1, 2, \dots C$. These univariate series are independently fed into the IIP-Mixer model. This approach breaks down these input univariate series into smaller and structured patches. It transforms each original univariate time series from a 1D series to 2D patches while preserving their original relative positions, expressed as follows:

$$oldsymbol{X}^{(i)} \in \mathbb{R}^L o oldsymbol{X}^{(i)} \in \mathbb{R}^{H imes W}$$

where W represents the patch length, and H denotes the number of patches for each univariate series, which is a tuning hyperparameter.

Intra-patch mixing MLP: The rows in the 2D input univariate series $X^{(i)}$ represent distinct patches, while the columns denote time steps. A trainable intra-patch mixing MLP shared across all patches is employed to map each patch to a hidden space. We utilize a multilayer perceptron with a single hidden layer to capture local temporal patterns within patches. The size of output $O_{intra}^{(i)}$ is the same with input $X^{(i)}$, the process can be summarized as the following

equations:

$$oldsymbol{O}_{ ext{intra}}^{(i)} = oldsymbol{W}_2 \sigma \left(oldsymbol{W}_1 oldsymbol{X}^{(i)}
ight)$$

It is essential to highlight that, the parameters of intra-patch mixing MLP shared across all patches prevent the architecture from growing too fast when increasing the length L of the lookback window and leads to significant memory savings.

Inter-patch mixing MLP: The 2D patches $\boldsymbol{X}^{(i)^{T}}$ is a transposition of $\boldsymbol{X}^{(i)}$. Scilicet, the rows of which represent time steps, while the columns denote distinct patches. A trainable inter-patch mixing MLP shared across all of the time steps is employed to map each time step to a hidden space. The same as intra-patch mixing MLP, inter-patch mixing MLP utilizes a multilayer perceptron with a single hidden layer to capture global temporal patterns across patches. The size of output $\boldsymbol{O}_{inter}^{(i)}$ is the same with input $\boldsymbol{X}^{(i)^{T}}$, the process can be summarized as the following equations:

$$\boldsymbol{O}_{\mathrm{inter}}^{(i)} = \boldsymbol{W}_4 \sigma \left(\boldsymbol{W}_3 \boldsymbol{X}^{(i)^T} \right)$$

Linear projection: Linear projection is a trainable linear neural network that projects aggregated output information from the intra-patch mixing MLP and inter-patch mixing MLP to predict future time steps. Additionally, the input of linear projection incorporates skip-connections of $X^{(i)}$, This residual design ensures that IIP-Mixer retains the capacity of temporal linear models while still being able to exploit intra-inter patch information. The linear projection takes input flattened from 2D patches to 1D time series and predicts long time-series sequences in a single forward operation, significantly enhancing inference speed. The process can be summarized as the following equations:

$$\widehat{\boldsymbol{Y}}^{(i)} = W_5 \text{ flatten } \left(\boldsymbol{O}_{\text{intra}}^{(i)} + \boldsymbol{O}_{\text{inter}}^{(i)}{}^T + \boldsymbol{X}^{(i)} \right)$$

Weighted loss function: Considering the varying importance of different variables in battery RUL prediction. To further enhance prediction performance, different from the loss function of traditional multivariate time series prediction, we propose to use the weighted mean square error as our loss function, which can be rewritten as:

WMSELoss =
$$\sum_{i=1}^{C} \alpha_i \left(\frac{1}{N} \sum_{j=1}^{N} \left(\widehat{\boldsymbol{Y}}_j^{(i)} - \boldsymbol{Y}_j^{(i)} \right)^2 \right)$$

where, α_i represents the weight assigned to the *i*-th variable, which is derived from the random forest regressor. It signifies the importance of each variable in predicting the Remaining Useful Life of the battery.

3.3 The Multivariate Time Series

In predicting the remaining useful life of rechargeable lithium-ion batteries, a lot of prior research uses only the capacity feature and barely considers more features of the battery in the charge-discharge cycles [6] [9]. However, the RUL of batteries can vary significantly from the same type of battery among different charge-discharge settings due to different temperatures, voltages, and currents. So, if we predict the RUL of batteries only relying on univariate time series, it will reduce the generalization ability of the prediction model.

To address these issues mentioned above, we propose a multivariate input representation that includes the features of charge and discharge cycles of rechargeable batteries. Scilicet, we predict the RUL of rechargeable batteries from a multivariate time series sequence. It is worth noting that, feature generation and selection are crucial to the prediction performance of our proposed approach. To better capture the evolving trends in time series data, we generate a feature by calculating the mean of the accumulated capacity for each discharge cycle. Moreover, the presence of noise and redundant information in the raw measurements can impede model convergence. To address this, we introduce a random forest regressor [21] to identify and incorporate the most important features, thereby improving both the convergence speed and accuracy of the model.

3.4 Dual-Head MLP

Motivated by PatchMixer [22], we employ the dual forecasting heads design in our IIP-Mixer model, including one intra-patch mixing MLP head and one inter-patch mixing MLP head.

The intra-patch mixing MLP head comprises two fully connected layers and a GeLU nonlinearity, facilitating communication between time steps within a patch and capturing short-term temporal dependencies. The parameters within the intra-patch mixing MLP act as the short-term memory of IIP-Mixer, emphasizing the learning of information among local time steps without considering the entire input sequence.

The structure of the inter-patch mixing MLP head just the same as the intrapatch mixing MLP head, allows communication between different patches and captures temporal dependencies across the whole input sequence. It consistently processes the same time step of each patch independently, extracting long-term temporal dependencies within the entire input sequence.

It is essential to note that, unlike PatchMixer, where serial dual heads are employed, our approach features parallel dual forecasting heads. The forecasting procedure simultaneously incorporates output information from the dual-head MLP and residual connections from past sequences to model future sequences using a linear projection. The training procedure of IIP-Mixer is summarized in Algorithm 1.

4 Experiments

4.1 Datasets

We conduct our experiments using PyTorch on the public dataset: NASA PCoE battery dataset, available from the NASA Ames Research Center website, contains the charge-discharge records of different lithium-ion batteries in multiple settings. Nonetheless, directly inputting battery measurements into a deep neural network poses challenges due to the potentially enormous amount of sampled data per cycle. In the realm of time series analysis, it is common practice to consolidate high-dimensional raw measurements at the cycle level through the application of statistical metrics, like minimum value, maximum value, and mean value at each cycle.

4.2 Baselines

We benchmark our IIP-Mixer models against commonly used basic networks, including MLP, Transformer models, and its newly proposed variants such as DLinear [11] and Informer [23].

- MLP: A multilayer perceptron is just like a mathematical function that maps input values to output values. multiple layers are used to learn the dynamic and nonlinear degradation trend of the battery.
- Transformer: Transformer is a model that uses an attention mechanism for model training, it mainly consists of two components: an Encoder and

a Decoder, with which we can predict the capacity degradation trend of the battery.

- Informer: A variant of transformer architecture, that efficiently handles extremely long input sequences by highlights dominating attention by halving cascading layer input. It predicts the long time-series sequences in one forward operation rather than a step-by-step way, which drastically improves the inference speed.
- DLinear: In consideration of permutation-invariant and "anti-ordering" to some extent of transformer-based architecture [11], DLinear decomposes the time series into a trend and a remainder series and employs two one-layer linear networks to extract the temporal relations among an ordering set of continuous points.

4.3 Implementation

4.3.1 Parameter Settings

Our model has six key parameters: patch size, learning rate, dropout, length of patch, number of mixer blocks, and number of principal features of time series. During our experiments, the hyper-parameters are tuned based on the validation set. its details for the training process are shown in Table 1. Additionally, for a more meaningful comparison, we aligned the size of lookback windows to 16, consistent with the approach in [9].

| Table 1: Hyper-parameter summary. | | | |
|-----------------------------------|-----------------------------|--|--|
| Hyper-Parameter | Range of Values | | |
| Patch Size | $\{2, 4, 8\}$ | | |
| Learning Rate | $\{0.0001, 0.0005, 0.001\}$ | | |
| Dropout | $\{0.05, 0.1, 0.2\}$ | | |
| Length of Patch | $\{2, 4, 8\}$ | | |
| # of Mixer Blocks | $\{1, 2, 3, 4\}$ | | |
| # of Principal Features | $\{1,2,4,6,8,10,12,14,16\}$ | | |

4.3.2 Evaluation Metrics

In our experiments, four evaluation metrics are used. In addition to three comment metrics Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and Mean Absolute Percentage Error(MAPE), [24] we chose the Absolute Relative Error (ARE) [9] to evaluate the prediction performance of battery RUL, which are defined as follow:

$$ARE = \frac{|RUL^{pre} - RUL^{ture}|}{RUL^{ture}} \times 100\%$$

where RUL^{ture} denotes the true RUL of the battery and RUL^{pre} denotes the prediction of RUL from models. Additionally, we conducted each experiment three times using three consecutive seeds and reported the mean of the evaluation metrics.

5 Results

5.1 Performance of IIP-Mixer

Despite its simplicity, IIP-Mixer attains competitive results. To verify the performance of our methods, we conducted our experiments on four baseline methods. The MAE, RMSE, MAPE, and ARE scores obtained for all methods are shown in Table 2, the best results are shown in bold. From the results we conclude the following:

- The Transformer and its variant, the Informer model, excel in modeling both long-term and short-term dependencies, showcasing superior performance on long-time series data. However, it is worth noting that, they can easily lead to overfitting for small datasets, such as the NASA PCoE battery dataset.
- The MPL model is adept at capturing global temporal patterns but may struggle to capture local temporal patterns from time series data. Consequently, its performance remains average across all evaluation metrics compared to other methods.
- The DLinear model decomposes the time series into a trend and a remainder series. It utilizes two one-layer linear networks to extract temporal relations among an ordered set of continuous points, making it adept at capturing both the trend and season of a time series.
- Among all the baseline methods, our proposed model IIP-Mixer achieves the best experimental results. It demonstrates that IIP-Mixer can capture the local and global temporal patterns in time series data, this is a great help for battery RUL prediction.

| Methods | MAE(Ah) | RMSE(Ah) | MAPE(%) | ARE(%) |
|-------------|---------|----------|---------|--------|
| Transformer | 0.055 | 0.073 | 3.697 | 9.589 |
| Informer | 0.049 | 0.063 | 3.281 | 4.110 |
| MLP | 0.050 | 0.066 | 3.402 | 6.393 |
| DLinear | 0.041 | 0.052 | 2.732 | 3.196 |
| IIP-Mixer | 0.037 | 0.048 | 2.480 | 1.370 |

Table 2: Performances of methods on NASA PCoE battery dataset.

5.2 Computation Efficiency

We investigated the computational efficiency of all neural networks mentioned above based on the length L of the input time series. Comparisons of theoretical time complexity and memory usage [23] are summarized in Table 3. It is important to note that, in our model, the patch size W can equal the patch number H, so we have $W \times H = W^2 = H^2 = L$. It is evident that our model, like DLinear, has the lowest cost across all computational metrics.

Table 3: L-related computation statics of each layer.

| Mathada | Trai | Testing | |
|-------------|------------------------|------------------------|------|
| Methous | Time | Memory | Step |
| Transformer | $\mathcal{O}(L^2)$ | $\mathcal{O}(L^2)$ | L |
| Informer | $\mathcal{O}(L\log L)$ | $\mathcal{O}(L\log L)$ | 1 |
| MLP | $\mathcal{O}(L^2)$ | $\mathcal{O}(L^2)$ | 1 |
| DLinear | $\mathcal{O}(L)$ | $\mathcal{O}(L)$ | 1 |
| IIP-Mixer | $\mathcal{O}(L)$ | $\mathcal{O}(L)$ | 1 |

5.3 Ablation Study

5.3.1 Effect of Dual-Head MLP

To evaluate the effectiveness of dual-head MLP, we individually remove the intra-patch mixing MLP head or inter-patch mixing MLP head. Table 4 demonstrates that the dual-head MLP mechanism outperforms all other configurations. This result highlights the effectiveness of the dual-head mechanism in comparison to a single output head.

It is worth noting that, the performance of architecture without an intrapatch mixing MLP head is better than that without inter-patch mixing MLP head. Scilicet, inter-patch mixing MLP that captures global temporal patterns performs better than intra-patch mixing MLP that captures local temporal patterns in battery RUL prediction.

| Table 1. Holdsfoll Study of dual field will . | | | | |
|-----------------------------------------------|---------|----------|---------|--------|
| Methods | MAE(Ah) | RMSE(Ah) | MAPE(%) | ARE(%) |
| w/o inter | 0.081 | 0.095 | 5.443 | 34.703 |
| w/o intra | 0.044 | 0.055 | 2.940 | 5.023 |
| IIP-Mixer | 0.037 | 0.048 | 2.480 | 1.370 |

Table 4: Ablation study of dual-head MLP.

5.3.2 Serial vs Parallel Heads

Unlike the serial structure of dual-head MLP in MLP-Mixer and PatchMixer, we introduce a parallel structure for dual heads. To evaluate the effectiveness of the parallel heads structure, we compare the performance of serial heads (intra-first), serial heads (inter-first), and parallel heads. As shown in Table 5, it is evident that the parallel heads structure outperforms the serial structure in battery RUL prediction.

Table 5: Comparison of serial and parallel heads. Methods MAE(Ah) RMSE(Ah) MAPE(%) ARE(%)Serial Heads (inter-first) 0.063 4.2580.07615.068Serial Heads (intra-first) 0.0450.0563.0324.110Parallel Heads 0.0370.048 2.4801.370

5.3.3 Effect of Weighted Loss Function

In the majority of recent research on MLP-based models, the loss functions have not taken into account the varying importance of different variables. As shown in Table 6, it is evident that the weighted loss function outperforms the loss function without weighting, resulting in relative improvements of 5%, 2%, and 3% in Mean Absolute Error (MAE), Root Mean Square Error (RMSE) and Mean Absolute Percentage Error (MAPE), respectively.

Table 6: Comparison of loss function: with weighted vs. w/o weighted.

| Methods | MAE(Ah) | RMSE(Ah) | MAPE(%) | ARE(%) |
|--------------|---------|----------|---------|--------|
| w/o weighted | 0.039 | 0.049 | 2.562 | 1.370 |
| w weighted | 0.037 | 0.048 | 2.480 | 1.370 |

5.3.4 Effect of Multivariate

We investigate the impact of multivariate time series in Table 7. The learning performance with principal multivariate time series surpasses that of univariate time series. Specifically, predicting the Remaining Useful Life of batteries using a multivariate time series of principal features significantly enhances the generalization ability of the prediction model.

It's important to highlight that training with multivariate time series containing all features may lead to a reduction in model performance. Therefore, the feature selection pipeline plays a critical role in determining prediction performance.

Table 7: Comparison of time series: univariate vs. multivariate

| Table 1. Comparison of time series. univariate vs. materialiate. | | | | | |
|------------------------------------------------------------------|---------|----------|---------|--------|--|
| Methods | MAE(Ah) | RMSE(Ah) | MAPE(%) | ARE(%) | |
| Univariate | 0.042 | 0.054 | 2.822 | 3.653 | |
| Multivariate(full) | 0.052 | 0.064 | 3.510 | 7.306 | |
| Multivariate (principal) | 0.037 | 0.048 | 2.480 | 1.370 | |

6 Conclusion

In this paper, we present IIP-Mixer, an innovative MLP-Mixer-based architecture designed to predict Remaining Useful Life in batteries. IIP-Mixer incorporates parallel dual-head MLP: the intra-patch mixing MLP and inter-patch mixing MLP. The intra-patch mixing MLP independently applies MLP to each patch, capturing local temporal patterns in the short-term period. On the other hand, the inter-patch mixing MLP applies MLP across all patches from the input sequence, capturing global temporal patterns in the long-term period. Moreover, recognizing the varying importance of features in RUL prediction, we propose a weighted mean square error loss function to enhance prediction accuracy. Our experiments demonstrate that IIP-Mixer achieves competitive performance in battery RUL prediction, outperforming other popular time-series frameworks.
