Decision Mamba: Reinforcement Learning via Sequence Modeling with Selective State Spaces

Toshihiro Ota¹²

Abstract

Decision Transformer, a promising approach that applies Transformer architectures to reinforcement learning, relies on causal self-attention to model sequences of states, actions, and rewards. While this method has shown competitive results, this paper investigates the integration of the Mamba framework, known for its advanced capabilities in efficient and effective sequence modeling, into the Decision Transformer architecture, focusing on the potential performance enhancements in sequential decision-making tasks. Our study systematically evaluates this integration by conducting a series of experiments across various decision-making environments, comparing the modified Decision Transformer, Decision Mamba, with its traditional counterpart. This work contributes to the advancement of sequential decisionmaking models, suggesting that the architecture and training methodology of neural networks can significantly impact their performance in complex tasks, and highlighting the potential of Mamba as a valuable tool for improving the efficacy of Transformer-based models in reinforcement learning scenarios.

1. Introduction

The interplay between sequence-based decision-making and large-scale model efficiency presents a fascinating subject in the field of modern machine learning. Decision Transformer (Chen et al., 2021) represents a paradigm shift in reinforcement learning, introducing a sequence-to-sequence modeling that replaces traditional reinforcement learning's reliance on value functions with a direct mapping of stateaction-reward sequences to optimal actions using causal self-attention mechanisms. While the use of causal selfattention has been instrumental in achieving remarkable results, the exploration of alternative mechanisms that could further elevate model performance remains an open and compelling question.

Recently, the Mamba framework (Gu & Dao, 2023) has been proposed as an efficient and effective sequence modeling framework endowed with the selective structured state space model. Mamba introduces the data-dependent selection mechanism with efficient hardware-aware design to tackle the data- and time-invariant issues of prior state space models (Gu et al., 2020; 2021; 2022b). This allows the model to selectively extract essential information and filter out irrelevant noise according to the input data, leading to superior sequential modeling performance. Owing to these innovative approaches, it has emerged as a pivotal solution for the efficient training of massive neural networks, optimizing parallel processing of data and models across multiple computing units.

This paper sets out to explore the integration of the Mamba framework as a novel architectural choice within Decision Transformer, with a focus on the potential performance improvements this integration could bring. We introduce Decision Mamba by substituting Mamba for causal selfattention, aiming to investigate the extent to which this modification can enhance the model's ability to capture complex dependencies and nuances in sequential decision-making tasks, potentially leading to superior decision-making capabilities in a variety of challenging environments. While efficiency is a notable benefit, our primary focus in this paper lies in the possible performance gains that Mamba's architecture design might confer on the Decision Transformer's sequence modeling capabilities. Specifically, we hypothesize that Mamba's design could offer a novel way to encode and exploit the temporal dependencies and intricate patterns present in sequential decision-making tasks, potentially resulting in more accurate, robust, and nuanced decision-making outputs.

Through this investigation, we seek to not only expand the tools available for reinforcement learning challenges but also to provide insights into the interplay between different architectural components and their impact on model performance in complex decision-making environments. By examining the performance implications of integrating Mamba into Decision Transformer, this work aims to contribute to

¹AI Lab, CyberAgent, Japan ²RIKEN iTHEMS, Japan. Correspondence to: Toshihiro Ota <ota_toshihiro@cyberagent.co.jp>.

the broader discourse on how best to architect and train models for the nuanced demands of sequential decision-making, offering potential pathways to significant advancements in the field.

2. Preliminaries

2.1. Offline reinforcement learning

In a conventional reinforcement learning (RL) problem, an environment is modeled as a Markov decision process (MDP) $\mathcal{M} = (S, \mathcal{A}, p_0, P, \mathcal{R})$, which consists of states $s \in S$, actions $a \in \mathcal{A}$, the initial state distribution p_0 , the transition probability function P(s', s, a), and the reward function $r = \mathcal{R}(s, a)$. The interaction between an agent and the environment is represented as a trajectory that is a sequence of states, actions, and rewards for each timestep: $\tau = (s_0, a_0, r_0, s_1, a_1, r_1, \dots, s_T, a_T, r_T)$. The goal of conventional RL is to learn a policy π that maximizes the expected return $\mathbb{E}_{\mathcal{M},\pi} \left[\sum_{i=0}^T r_i \right]$. In offline RL, or batch RL, we only have access to a fixed amount of a previously collected dataset and learning is performed without interaction with the environment, which is known to be much harder than online settings (Levine et al., 2020).

An approach we can utilize is Behavior Cloning (BC) (Bain & Sammut, 1995), which directly learns the mapping from state to action from the dataset. The offline RL dataset, however, often lacks sufficient expert demonstrations. To resolve this issue, we may adopt return-conditioned BC. This method uses reward information and takes a target future return as input from the dataset. Namely, we define the return of a trajectory at timestep i, $R_i = \sum_{i'=i}^{T} r_{i'}$, which is referred to as the return-to-go (RTG), and feed a model with the following return-conditioned trajectory for autoregressive learning:

$$\tilde{\tau} = (R_0, s_0, a_0, R_1, s_1, a_1, \dots, R_T, s_T, a_T).$$
 (1)

Decision Transformer (DT) (Chen et al., 2021) not only provides a promising approach to return-conditioned BC but also reconceptualizes the RL problems as a sequence modeling task. DT essentially operates as a causal transformer model, taking a sequence of RTGs, states, and actions as inputs, as in Eq. (1). DT autoregressively learns the trajectories for predicting the optimal action given the target RTG. Despite not using traditional RL tools such as the value function or the Bellman operator, DT has demonstrated its effectiveness in empirical studies.

2.2. State Space Models

The State Space Models (SSMs) in deep learning are a class of sequence modeling frameworks based on linear ordinary differential equations. They map an input signal

 $x(t) \in \mathbb{R}^D$ to the output signal $y(t) \in \mathbb{R}^D$ via the latent state $h(t) \in \mathbb{R}^N$:

$$h'(t) = \boldsymbol{A}h(t) + \boldsymbol{B}x(t), \qquad (2)$$

$$y(t) = Ch(t), \tag{3}$$

where $A \in \mathbb{R}^{N \times N}$ and $B, C^{\top} \in \mathbb{R}^{N \times D}$ will be trainable matrices. For application to a discrete input sequence (x_0, x_1, \ldots) instead of a continuous function, Eq. (2) is discretized with a step size Δ , indicating the input's resolution. Various discretization rules can be used such as the Euler method or the so-called Bilinear. We will be considering the discretized SSM using the zero-order hold (ZOH) discretization rule:

$$h_t = \overline{A}h_{t-1} + \overline{B}x_t, \tag{4}$$

$$y_t = Ch_t, \tag{5}$$

where $\overline{A} = \exp(\Delta A)$ and $\overline{B} = (\Delta A)^{-1}(\exp(\Delta A) - I)(\Delta B)$. By converting the continuous SSM to the discrete one and transforming the parameters from (Δ, A, B) to $(\overline{A}, \overline{B})$, the model becomes a sequence-to-sequence mapping framework from $\{x_t\}$ to $\{y_t\}$. Imposing structural conditions on the state matrix A with the HiPPO initialization (Gu et al., 2020), this expression gives rise to the structured state space model (S4) (Gu et al., 2022b), broadly related to recurrent neural networks and convolutional neural networks (Gu et al., 2021; Gupta et al., 2022; Gu et al., 2022a).

Based on the S4 framework, Mamba (Gu & Dao, 2023) introduces a data-dependent selection mechanism while leveraging a hardware-aware parallel algorithm in recurrent mode. The combined architecture of Mamba empowers it to capture contextual information effectively, especially for long sequences, and maintains computational efficiency. Being a linear-time sequence model, Mamba delivers Transformerquality performance with improved efficiency, particularly for long sequences.

3. Decision Mamba

We introduce Decision Mamba (DMamba) by utilizing the Mamba block as a token-mixing module instead of the selfattention module of DT. In this section, we begin with an overview of our architecture and describe DMamba as a variant of the Transformer-type networks.

Network architecture. The network architecture of DMamba adopts the basic Transformer-type neural network, essentially the GPT architectures (Radford et al.). The main module, the Mamba layer, is composed of the token-mixing layer and the channel-mixing layer, both of which consist of the layer normalization, the residual connection, and the corresponding mixing block, see the left-hand side of Fig. 1.

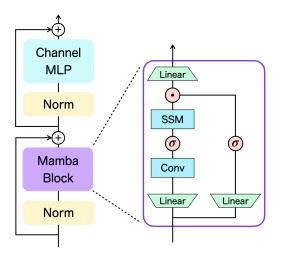

Figure 1: Overview of the Mamba layer. σ is an activation function, for which we use the SiLU function, and \odot denotes the element-wise product.

We feed the last K timesteps of a trajectory into DMamba, for the total of 3K tokens:

$$\tilde{\tau}_i = (R_{i-K+1}, s_{i-K+1}, a_{i-K+1}, \dots, R_i, s_i, a_i).$$
 (6)

The input trajectory $\tilde{\tau}_i$ is transformed into token embeddings I_i by an embedding layer, which is either a linear layer or a two-dimensional convolutional layer depending on the environments,

$$I_i = \operatorname{Emb}(\tilde{\tau}_i) \in \mathbb{R}^{3K \times D}.$$
(7)

Then the input sequence of tokens is processed by a stack of Mamba layers,

$$U^{l} = X^{l} + \text{MambaBlock}(\text{LayerNorm}(X^{l})), \quad (8)$$

$$X^{l+1} = U^l + \text{ChannelMLP}(\text{LayerNorm}(U^l)), \quad (9)$$

where l runs from 0 to the total number of layers and $X^0 = I_i$. The detail of the Mamba block is described below. The rest of the network is identical to that of DT. To make the comparisons fair in the subsequent section, our Mamba layer involves the channel-mixing MLP in Eq. (9), also known as the point-wise feedforward network, though it is not necessarily included in the original Mamba model in (Gu & Dao, 2023). The pseudo-code of the Mamba layer is provided in Appendix A.1.

Mamba block. The right-hand side of Fig. 1 and Algorithm 1 illustrate the series of operations performed inside the Mamba block. Let us suppose that the input sequence of tokens x has shape (B, L, D), where B is the batch size, L represents the sequence length corresponding to both the indices t of the discretized SSM and to 3K of the trajectory length, and D is the embedding dimension of the channels.

Algorithm 1 Mamba block with selective SSM.Input:
$$x : (B, L, D)$$
Output: $y : (B, L, D)$ 1: $x, z : (B, L, ED) \leftarrow \text{Linear}(x)$ 2: $x : (B, L, ED) \leftarrow \text{SiLU}(\text{Conv1d}(x))$ 3: $A : (D, N) \leftarrow \text{Parameter}$ 4: $B, C : (B, L, N) \leftarrow \text{Linear}(x), \text{Linear}(x)$ 5: $\Delta : (B, L, D) \leftarrow \text{Softplus}(\text{Parameter} + s_{\Delta}(x))$ 6: $\overline{A}, \overline{B} : (B, L, D, N) \leftarrow \text{ZOH}(\Delta, \underline{A}, \underline{B})$ 7: $y : (B, L, ED) \leftarrow \text{SelectiveSSM}(\overline{A}, \overline{B}, C)(x)$ 8: $y : (B, L, ED) \leftarrow y \odot \text{SiLU}(z)$ 9: $y : (B, L, D) \leftarrow \text{Linear}(y)$ 10: return y

The Mamba block first operates linear projections to obtain hidden states x and z, with a controllable expansion factor E. Activated by the SiLU function after the causal one-dimensional convolution along the sequence length, it transforms the hidden state x to make B, C and Δ be functions of the input:

$$\boldsymbol{B} = \operatorname{Linear}(x), \quad \boldsymbol{C} = \operatorname{Linear}(x), \quad (10)$$

$$\Delta = \text{Softplus}(\text{Parameter} + s_{\Delta}(x)), \quad (11)$$

where $s_{\Delta}(x) = \text{Broadcast}(\text{Linear}(x))$. The ZOH discretization gives \overline{A} and \overline{B} , which generate the core of the block, the selective SSM. Finally, the product with the hidden state z applied by another Linear and SiLU functions delivers the output y. In this block, we have several controllable hyperparameters including N, E, and the kernel size of one-dimensional convolution. Instead of searching the best hyperparameters for DMamba, in this paper we employ the default ones of the original implementation, $^1 N = 16$ and E = 2, etc.

Training & inference. In the training phase, we have a dataset of offline trajectories. We sample sub-trajectories of length 3K, $\tilde{\tau}$, from the dataset. Given the current state s_i and the RTG R_i , the model predicts the next action \hat{a}_i . The objective function to optimize depends on the environments: the mean squared error (MSE) for continuous actions or the cross-entropy loss (CE) for discrete actions. The losses for each timestep are then averaged:

$$\operatorname{Loss} = \mathbb{E}_{\tilde{\tau} \sim \mathcal{M}, \pi} \left[\frac{1}{K} \sum_{i=0}^{K-1} \mathcal{L}_{\operatorname{MSE/CE}}(\hat{a}_i; a_i) \right].$$
(12)

In the inference phase, we set a target RTG R_0 , representing the desired performance, as the initial condition. During the inference, the model receives a current trajectory and generates an action. This results in obtaining a next state and a reward r_i . Subsequently, it subtracts this reward from the RTG of the previous timestep, R_{i-1} .

Dataset	DT	DS4	DC	DMamba
HalfCheetah-m	42.6	42.5	43.0	42.8 ± 0.08
Hopper-m	68.4	54.2	92.5	83.5 ± 12.5
Walker-m	75.5	78.0	79.2	$78.2{\pm}0.6$
HalfCheetah-m-r	37.0	15.2	41.3	39.6±0.1
Hopper-m-r	85.6	49.6	94.2	$82.6{\scriptstyle\pm4.6}$
Walker-m-r	71.2	69.0	76.6	$70.9{\pm}4.3$
HalfCheetah-m-e	88.8	92.7	93.0	$91.9{\pm}0.6$
Hopper-m-e	109.6	110.8	110.4	111.1 ± 0.3
Walker-m-e	109.3	105.7	109.6	108.3 ± 0.5

Table 1: The results for D4RL datasets. We report the expertnormalized returns, following (Fu et al., 2020), averaged across five random seeds.

4. Experiments

In this section, we study the effectiveness of DMamba as a sequence modeling framework for RL. We compare our DMamba with DT variants, including the original DT (Chen et al., 2021), Decision S4 (DS4) (David et al., 2023), and Decision ConvFormer (DC) (Kim et al., 2024). In particular, we adopt the experimental setup from the DC paper to ensure a fair comparison. We evaluate the model on both continuous OpenAI Gym (Brockman et al., 2016) and discrete Atari (Bellemare et al., 2013) control tasks. Details of each domain can be found in the corresponding subsections below. All the training for the model is conducted on a single A100 GPU.²

4.1. OpenAI Gym

We consider here the domain of continuous control tasks from the D4RL benchmark (Fu et al., 2020), which features several continuous locomotion tasks with dense rewards. We conduct experiments in three environments: HalfCheetah, Hopper, and Walker. For each environment, we examine three distinct datasets, each reflecting a different data quality level:

- Medium (m): one million timesteps generated by a policy that achieves approximately one-third the score of an expert policy
- Medium-Replay (m-r): the replay buffer of an agent trained to match the performance of the Medium policy
- Medium-Expert (m-e): one million timesteps generated by the Medium policy added with one million timesteps generated by an expert policy

Table 2: The results for the 1% DQN-replay Atari datasets. We report the gamer-normalized returns, following (Ye et al., 2021), averaged across three random seeds.

Game	DT	DC	DMamba
Breakout	242.4±31.8	352.7±44.7	$239.2{\scriptstyle\pm26.4}$
Qbert	$28.8{\scriptstyle\pm10.3}$	67.0 ± 14.7	42.3 ± 8.5
Pong	$105.6 {\pm} 2.9$	106.5 ± 2.0	$63.2{\pm}102.1$
Seaquest	$2.7{\pm}0.7$	2.6 ± 0.3	$2.2{\pm}0.03$

The overall results are shown in Table 1. The scores are normalized so that a score of 100 represents the performance of an expert policy, following the methodology in (Fu et al., 2020) (see Appendix B for details). The results for DT, DS4, and DC are quoted from the DC paper, Table 1 therein. To ensure a fair comparison with DMamba, we set the hyperparameters identical to those reported in (Kim et al., 2024). The details of the experimental setups are provided in Appendix A.2.

4.2. Atari

The Atari domain is built upon a collection of classic video games (Mnih et al., 2013). In this domain, we have a discrete action space and face the challenge of long-term credit assignment. This challenge arises from the delay between actions and their corresponding rewards. For such types of data, the Mamba framework could potentially offer an advantage over prior SSMs, such as S4. We consider four Atari games: Breakout, Qbert, Pong, and Seaquest, which are evaluated in (Agarwal et al., 2020). Following the setup in (Agarwal et al., 2020), we train the model on 1% of all samples in the DQN-replay dataset. This equates to 500,000 transitions out of the 50 million collected by an online DQN agent during training (Mnih et al., 2015).

Table 2 shows the results in the Atari domain. We normalize the scores based on a professional gamer's score as per (Ye et al., 2021), with 100 representing a professional gamer and 0 a random policy. For DT and DC, we quote the scores directly from Table 3 of the DC paper. The training setups are identical to those reported in (Kim et al., 2024). For the details, see Appendix A.3.

4.3. Ablation study

To investigate the capability of the Mamba block in DMamba, we consider ablation studies on the channelmixing layer and the context length K.

We first study the contribution of the channel-mixing blocks of the Mamba layers. As mentioned in the previous section, we included the channel-mixing layers in DMamba to make the experimental setups equivalent to the baselines. Given

²The code of our experiments is available at https://github.com/Toshihiro-Ota/decision-mamba.

Table 3: Ablation study for the channel-mixing blocks in DMamba for D4RL datasets. We report the expertnormalized returns averaged across five random seeds. (1) Remove channel-mixing layer, and (2) Remove channelmixing layer and double the total number of layers.

Mamba layer	HalfCheetah	Hopper	Walker
Default	42.8 ± 0.08	$83.5{\scriptstyle\pm12.5}$	$78.2{\pm}0.6$
(1) RC	$42.9{\pm}0.01$	$82.9{\pm}5.8$	$78.0{\scriptstyle\pm2.0}$
(2) RC & 2L	$42.8{\scriptstyle\pm0.06}$	$85.2{\pm}14.9$	$77.0{\scriptstyle \pm 1.1}$

that the channel-mixing layer is not a core component of the original Mamba model—the Mamba block itself integrates both token- and channel-mixing functions—we remove the channel-mixing blocks from all the Mamba layers. We then train the whole network on the D4RL datasets from scratch in two configurations, keeping the rest unchanged:

- 1. Remove the channel-mixing layer (RC)
- 2. Remove the channel-mixing layer and double the total number of layers (2L)

Table 3 shows the results. We here consider only the Medium type datasets. From Table 3, we observe that DMamba really demonstrates the comparable performance without the channel-mixing layers. This suggests, as expected from the Mamba paper discussion, that the Mamba block suffices for RL sequence modeling tasks within this empirical scope.

We also examined the effect of context length K on DMamba. As discussed in the Mamba paper, the Mamba block generically exhibits robust performance for longer sequence lengths. To explore the implications of context length K, we utilize datasets from the Atari domain, specifically Breakout and Qbert. This choice was made because, in OpenAI Gym environments, context length is not expected to significantly affect performance due to their MDP formulation.

Table 4: Ablation study for the context length K for DMamba in the Atari domain. We report the gamer-normalized returns averaged across three random seeds.

K	Breakout	Qbert
10	231.6±16.2	$56.4{\scriptstyle\pm16.6}$
30	$239.2{\scriptstyle\pm26.4}$	42.3±8.5
40	$295.9{\scriptstyle\pm34.7}$	$28.1{\pm}4.5$
60	$271.1{\scriptstyle\pm70.8}$	$15.7{\pm}5.5$

The results are shown in Table 4. We set the context lengths K = 10, 40, and 60, where K = 30 is the default, and train

the model from scratch. The rest of the training configurations is taken exactly the same as in the previous subsection. Table 4 tells us that for Breakout the longer context lengths generically improve the performance. The results for Qbert show that the longer context lengths significantly degrade the performance. This may imply that in training the model for Qbert, the selection mechanism in the Mamba block does not work well for a longer context. Rather, it might hinder generalization by removing indispensable tokens.

5. Conclusion and Discussion

In this work, we examined the capabilities of the recently proposed Mamba for sequence modeling in RL. We introduced Decision Mamba, which incorporates the Mamba block based on the selective SSM, into the DT-type neural network architecture. Our empirical study shows that DMamba is competitive to existing DT-type models, suggesting an effectiveness of Mamba for RL tasks. We hope this investigation offers insights into sequential decisionmaking, potentially paving the way for significant advancements in the field.

In this paper, we have not explored the efficiency perspectives of the model, one of the key contributions of Mamba enabled by a hardware-aware parallel algorithm (Gu & Dao, 2023). In fact, merely applying the Mamba block to DT-type networks does not enhance efficiency due to numerous interactions between CPUs and GPUs for RL tasks considered in this paper, as seen in both training and inference phases. Although we adhere to DT's experimental setups for fair comparison, it is desirable to reconsider the implementation to leverage Mamba's advantages efficiently.

Another limitation of this study is the absence of a hyperparameter search and an analysis of how to use the Mamba block more effectively to reflect the data structure of RL tasks. Unlike the typical one-dimensional sequential data found in natural language processing, for instance, a trajectory from an MDP features a unique structure comprising states, actions, and rewards sequentially. Furthermore, in conventional RL problems, immediate states and rewards are crucial for decision-making due to the inherent nature of MDPs. To fully explore Mamba's potential in RL problems, one approach could be to adapt the network architecture to better suit the RL data structure or preprocess trajectory datasets into a format more compatible with Mamba. Another avenue to explore is applying Mamba to non-Markov decision processes, notorious for their complexity due to long-range interactions within trajectories. We leave these aspects, including parameter tuning, for future work. A comprehensive study with an exploration of improved Transformer-type network architectures for RL will be released elsewhere.

A. Implementation Details of DMamba

A.1. Code of the Mamba layer

We implement DMamba using the official DT code³ and incorporate the Mamba module. The pseudo-code of the Mamba layer is shown in Algorithm 2 below. The full set of code of our experiments is available at https://github.com/Toshihiro-Ota/decision-mamba.

Algorithm 2 Pseudo-code of the Mamba layer, PyTorch-like code.

from mamba_ssm import Mamba

```
class Block (nn. Module):
    def __init__(self, config):
        super().__init__()
        self.ln1 = nn.LayerNorm(config.n_embd)
        self.mamba = Mamba(config.n_embd)
        self.ln2 = nn.LayerNorm(config.n embd)
        self.mlp_channels = nn.Sequential(
            nn.Linear(config.n_embd, 4 * config.n_embd),
            nn.GELU(),
            nn.Linear(4 * config.n_embd, config.n_embd),
            nn.Dropout(config.resid_pdrop),
        )
    def forward(self, x):
        x = x + self.mamba(self.lnl(x))
        x = x + self.mlp_channels(self.ln2(x))
        return x
```

A.2. OpenAI Gym

For the training on the OpenAI Gym tasks, the hyperparameters are adopted from (Chen et al., 2021) and (Kim et al., 2024). The common hyperparameters are shown in Table 5.

Hyperparameter	Value
Number of layers	3
Batch size	64
Context length K	20
Return-to-go conditioning	6000 HalfCheetah
	3600 Hopper
	5000 Walker
Dropout	0.1
Nonlinearity function	GELU
Grad norm clip	0.25
Weight decay	10^{-4}
Learning rate decay	Linear warmup
Total number of updates	10^5

Table 5: Hyperparameters of DMamba on the D4RL datasets.

³https://github.com/kzl/decision-transformer. We also employ the DC code for some considerations, which is available as a supplementary material at https://openreview.net/forum?id=af2c8EaKl8.

Some of the hyperparameters are adapted for each dataset as in (Kim et al., 2024):

- Embedding dimension: 256 for Hopper-m, Hopper-m-r. 128 for other environments
- Learning rate: 10^{-4} for Hopper-m, Hopper-m-r, Walker-m. 10^{-3} for other environments

A.3. Atari

Similarly to the OpenAI Gym tasks, the hyperparameters for the Atari domain follow those from (Kim et al., 2024), as listed in Table 6.

Hyperparameter	Value	
Number of layers	6	
Embedding dimension	128	
Batch size	256	
Context length K	30 Breakout, Qbert, Seaquest	
	50 Pong	
Return-to-go conditioning	90 Breakout	
	14000 Qbert	
	20 Pong	
	1150 Seaquest	
Nonlinearity	ReLU Encoder	
	GELU Otherwise	
Max epochs	10	
Dropout	0.1	
Learning rate	6×10^{-4}	
Adam betas	(0.9, 0.95)	
Grad norm clip	1.0	
Weight decay	0.1	
Learning rate decay	Linear warmup and cosine decay	
Warmup tokens	512×20	
Final tokens	$2 \times 500000 \times K$	

Table 6: Hyperparameters of DMamba on the Atari games.

B. Task Scores and Normalization

In the main text, we report the normalized scores for each domain calculated by the following rule with baseline random and expert scores:

$$score_{normalized} := 100 \times \frac{score_{raw} - score_{random}}{score_{expert} - score_{random}}.$$
(13)

For OpenAI Gym tasks, we employ the protocol from (Fu et al., 2020). For Atari games, we have raw and baseline scores as in Table 7, which are used for normalization in (Ye et al., 2021), Table 1 therein. The column of DMamba in Table 7 shows the raw scores corresponding to Table 2 in the main text.

Table 7: The mean and variance of raw scores for the 1% DQN-replay Atari datasets across three seeds. "Random" and "Expert" indicate the Atari baseline scores used for normalization.

Game	DMamba	Random	Expert
Breakout	70.6±9.3	1.7	30.5
Qbert	5780.0 ± 1295.2	163.9	13455.0
Pong	1.6 ± 15.3	-20.7	14.6
Seaquest	1006.0 ± 57.7	68.4	42054.7
