(Dated: 29 July 2024)

Existing studies have revealed a paradoxical phenomenon in public goods games, wherein destructive agents, harming both cooperators and defectors, can unexpectedly bolster cooperation. Building upon this intriguing premise, our paper introduces a novel concept: constructive agents, which confer additional benefits to both cooperators and defectors. We investigate the impact of these agents on cooperation dynamics within the framework of public goods games. Employing replicator dynamics, we find that unlike destructive agents, the mere presence of constructive agents does not significantly alter the defective equilibrium. However, when the benefits from constructive agents are outweighed by the damage inflicted by destructive agents, the addition of constructive agents does not affect the ability of destructive agents to sustain cooperation. In this scenario, cooperators can be maintained through a cyclic dominance between cooperators, defectors, and destructive agents, with constructive agents adding complexity but not fundamentally changing the equilibrium. Conversely, if the benefits from constructive agents surpass the harm caused by destructive agents, the presence of constructive agents nullifies the ability of destructive agents to foster cooperation. Our results highlight the nuanced role of constructive agents in cooperation dynamics, emphasizing the necessity of carefully assessing incentive balances when encouraging cooperation.

Voluntary participation has been shown to be a critical mechanism that promotes cooperation in one-shot and anonymous games. Recent studies have proposed a variant of voluntary participation strategies called destructive agents, who do not participate in the game but harm public goods, which can unexpectedly sustain cooperation. We propose a parallel concept to destructive agents, termed constructive agents, who choose to exit the public goods game but provide additional benefits to public goods. We investigate how these individuals impact the dynamics of cooperation in an infinite and well-mixed population. The results indicate that constructive agents alone cannot alter the equilibrium of defection. However, when they coexist with destructive agents, they nullify the ability of the latter to maintain cooperation when the benefit exceeds the harm to public goods. Our study demonstrates the importance of carefully assessing the balance between positive and negative incentives in alleviating social dilemmas.

reciprocity, established through repeated interactions¹⁰; indirect reciprocity involving information transfer¹¹; and network reciprocity arising from interaction structures⁹. However, in one-shot games where individuals interact only once, without the possibility of memory or behavioral information transfer, these reciprocity mechanisms are absent, making the maintenance of cooperation still a challenge². To tackle cooperation challenges in one-shot games, researchers have incorporated social mechanisms that allow individuals to engage in additional decision-making stages after contributing to public goods in the public goods game (PGG), unveiling pathways for establishing cooperation^{5,12-14}. These include allowing individuals to impose costly punishments^{12,15,16} and rewards^{17,18} on others based on contribution outcomes, deciding whether to participate in the game before contributing to public goods (or called “loner” strategy)^{19,20}, or exiting from the interaction early for a fixed payoff^{21,22}. From these game interactions, different behaviors can be observed. The framework of social value orientation analyzes and summarizes these behaviors by exploring how individuals balance their own interests with those of others^{23,24}, aiding in understanding cooperation issues in social dilemmas from a perspective of behavioral value orientation.

Recently, attention has been drawn to the impact of sadistic-orientation behavior on the cooperation dynamics, known as destructive behavior (or called “joker” strategy)²⁵⁻²⁷. These “bad guys” not only opt out of contributing to public goods, but also engage in antisocial behaviors that harm the interests of others. Counterintuitively, the presence of these destructive agents can maintain cooperation through a cycle of

I. INTRODUCTION

Cooperation can ensure the maximization of collective interests, but it is also vulnerable to exploitation by “free-riders” who do not bear the costs of cooperation¹⁻³. To explore the emergence and maintenance of cooperation, numerous studies rooted in the framework of evolutionary game theory have revealed the mechanisms that support the evolution of cooperation in individual interactions⁴⁻⁹. These include direct

dominance involving cooperation, defection, and destructive strategies²⁵, and these individuals' positive effects on cooperation remain robust in both infinite and finite populations²⁶. However, in contrast to this sadistic-orientation behavior, altruistic-orientation behavior is more commonly observed in behavioral experiments^{23,28}. For instance, some individuals exhibit a preference for engaging in altruistic rewarding behavior, even at a personal cost²⁹. The complexity of human behavior leads to diversity in actions and strategies in interactions^{23,24}. Taking this into account, research further explores the evolutionary dynamics of coexisting altruistic and antisocial behaviors³⁰. Interestingly, Szolnoki et al.¹⁶ demonstrated that antisocial punishment (punishing those who contribute to the public good) can unexpectedly enhance the effectiveness of prosocial punishment (punishing free-riders) in structured populations, challenging conventional perspectives on prosocial/antisocial behaviors and revealing new pathways for establishing cooperation. Importantly, the dynamics created by diverse interaction strategies provide a crucial perspective for a deeper understanding of the emergence of cooperation in real-life scenarios, which lie in the complexity of human behavior^{31,32}.

Inspired by this, we introduce a new concept—constructive strategy, incorporating this altruistic behavior into the PGG model involving cooperation, defection, and destructive strategies. This approach enables us to expand current research in solving the cooperation issues by exploring the interconnected diverse behaviors of cooperation dynamics. In contrast to the destructive agents, constructive agents withdraw from game interactions but provide additional costly benefits to participants without concern for their own gains or losses. Utilizing replicator dynamics in an infinite population³³, our research reveals that, although constructive agents alone do not alter evolutionary dynamics, when the benefits from constructive agents are outweighed by the damage inflicted by destructive agents, the addition of constructive agents does not affect the ability of destructive agents to sustain cooperation. However, when the benefits provided by constructive agents surpass the harm caused by destructive agents, it can result in negative effects that diminish the capacity of destructive agents to promote cooperation. The role of constructive individuals emphasizes the balancing impact of positive and negative incentive factors in evolutionary game dynamics, thereby enhancing the understanding of the incentive forces shaping cooperation.

II. MODEL

To gain a deep understanding of how constructive agents influence the cooperation dynamics, we first examine a three-strategy model that includes cooperation, defection, and construction within the PGG. We then explore a four-strategy PGG model incorporating cooperation, defection, construction, and destruction to study the evolutionary dynamics of cooperation in the presence of both constructive agents and destructive agents.

A. Public goods game with constructive agents

In a classic PGG involving N players, a cooperator contributes c to the public pool (simplify without loss of generality, set $c = 1$), while a defector contributes nothing. The total amount in the public pool is multiplied by a synergy factor r and then evenly distributed among all participants. Defection is the only Nash equilibrium strategy when the synergy factor for cooperators meets $1 < r < N^3$. When constructive agents are introduced, these individuals neither contribute to nor benefit from the public pool. Instead, they offer an additional benefit of $d_2 > 0$ to the participants (i.e., cooperators and defectors). Let the number of cooperators among the other individuals in the group be N_C , and the number of constructive agents be N_{CA} , satisfying $0 \leq N_C + N_{CA} \leq N - 1$, the payoff for a focal individual adopting cooperation (C), defection (D), and constructive agents strategies (CA) can be respectively expressed as follows:

$$\begin{aligned}\pi_C &= \frac{r(N_C + 1) + d_2 N_{CA}}{S_1} - 1, \\ \pi_D &= \frac{rN_C + d_2 N_{CA}}{S_1}, \\ \pi_{CA} &= 0,\end{aligned}\quad (1)$$

where $S_1 = N - N_{CA}$ is the number of non-constructive agents in the group.

Consider an infinitely large and well-mixed population consisting of cooperators, defectors, and constructive agents, with proportions x , y , z , respectively (satisfy $x + y + z = 1$ and $0 \leq x, y, z \leq 1$). N individuals are randomly selected from the population to form group and play the PGG. The expected payoffs for the C , D , and CA strategies can be calculated as follows:

$$\begin{aligned}P_C &= \sum_{N_{CA}=0}^{N-1} \sum_{N_C=0}^{N-1-N_{CA}} \binom{N-1}{N_{CA}} \binom{N-1-N_{CA}}{N_C} \\ &\quad \cdot x^{N_C} \cdot z^{N_{CA}} \cdot (1-x-z)^{N-1-N_C-N_{CA}} \cdot \pi_C \\ &= r \frac{x}{1-z} \left(1 - \frac{1-(z)^N}{N(1-z)} \right) + d_2 \left(\frac{(1-(z)^N)}{(1-z)} - 1 \right) \\ &\quad + \frac{r[1-(z)^N]}{N(1-z)} - 1, \\ P_D &= \sum_{N_{CA}=0}^{N-1} \sum_{N_C=0}^{N-1-N_{CA}} \binom{N-1}{N_{CA}} \binom{N-1-N_{CA}}{N_C} \\ &\quad \cdot x^{N_C} \cdot z^{N_{CA}} \cdot (1-x-z)^{N-1-N_C-N_{CA}} \cdot \pi_D \\ &= r \frac{x}{1-z} \left(1 - \frac{1-(z)^N}{N(1-z)} \right) + d_2 \left(\frac{(1-(z)^N)}{(1-z)} - 1 \right), \\ P_{CA} &= 0.\end{aligned}\quad (2)$$

By utilizing replicator dynamics³³, and taking into account the existence of mutations where the probability of an individual

mutating to another type is μ ($\mu \ll 1$), the evolutionary dynamics of strategies in this population can be write as:

$$\begin{cases} \dot{x} = x(P_C - \bar{P}) + \mu(1 - 3x) \\ \dot{y} = y(P_D - \bar{P}) + \mu(1 - 3y) \\ \dot{z} = z(P_{CA} - \bar{P}) + \mu(1 - 3z) \end{cases}, \quad (3)$$

where $\bar{P} = xP_C + yP_D + zP_{CA}$ is the expected payoff of the population.

B. Public goods game with constructive agents and destructive agents

When considering the four-strategy model, destructive agents (denoted as DA), like CA , do not participate in public pool allocation and investment, but indiscriminately reduce the payoffs of cooperators and defectors by d_1 ²⁵. Let N_{DA} represent the number of destructive agents, and S_2 denote the individuals who are neither constructive agents nor destructive agents, i.e., $S_2 = N - N_{CA} - N_{DA}$. Similar to Eq. (1), the payoffs of focal players adopting C , D , CA , and DA strategies within a group can be expressed as follows:

$$\begin{aligned} \pi_C &= \frac{r(N_C + 1) + d_2 N_{CA} - d_1 N_{DA}}{S_2} - 1, \\ \pi_D &= \frac{rN_C + d_2 N_{CA} - d_1 N_{DA}}{S_2}, \\ \pi_{DA} &= 0, \\ \pi_{CA} &= 0. \end{aligned} \quad (4)$$

Let the proportion of C , D , CA and DA in an infinitely large and well-mixed population be x , y , z , and w , respectively (satisfy $x + y + z + w = 1$ and $0 \leq x, y, z, w \leq 1$). The expected payoffs for these four types of agents can be calculated as follows:

$$\begin{aligned} P_C &= \sum_{N_{CA}=0}^{N-1} \sum_{N_{DA}=0}^{N-1-N_{CA}} \sum_{N_C=0}^{N-1-N_{CA}-N_{DA}} \binom{N-1}{N_{CA}} \\ &\quad \binom{N-1-N_{CA}}{N_{DA}} \binom{N-1-N_{DA}-N_{CA}}{N_C} \\ &\quad \cdot x^{N_C} \cdot z^{N_{CA}} \cdot w^{N_{DA}} \\ &\quad \cdot (1-x-z-w)^{N-1-N_C-N_{CA}-N_{DA}} \cdot \pi_C \\ &= r \frac{x}{1-z-w} \left(1 - \frac{1-(z+w)^N}{N(1-z-w)} \right) \\ &\quad - d_1 \frac{w(1-(z+w)^{N-1})}{(1-z-w)} + d_2 \frac{z(1-(z+w)^{N-1})}{(1-z-w)} \\ &\quad + \frac{r}{N} \frac{[1-(z+w)^N]}{(1-z-w)} - 1, \end{aligned} \quad (5)$$

$$\begin{aligned} P_D &= \sum_{N_{CA}=0}^{N-1} \sum_{N_{DA}=0}^{N-1-N_{CA}} \sum_{N_C=0}^{N-1-N_{CA}-N_{DA}} \binom{N-1}{N_{CA}} \\ &\quad \binom{N-1-N_{CA}}{N_{DA}} \binom{N-1-N_{DA}-N_{CA}}{N_C} \\ &\quad \cdot x^{N_C} \cdot z^{N_{CA}} \cdot w^{N_{DA}} \\ &\quad \cdot (1-x-z-w)^{N-1-N_C-N_{CA}-N_{DA}} \cdot \pi_D \\ &= r \frac{x}{1-z-w} \left(1 - \frac{1-(z+w)^N}{N(1-z-w)} \right) \\ &\quad - d_1 \frac{w(1-(z+w)^{N-1})}{(1-z-w)} + d_2 \frac{z(1-(z+w)^{N-1})}{(1-z-w)} \end{aligned} \quad (6)$$

$$P_{CA} = 0, \quad (7)$$

$$P_{DA} = 0. \quad (8)$$

Similar to Eq. (3), the evolutionary dynamics in this population can be described as:

$$\begin{cases} \dot{x} = x(P_C - \bar{P}) + \mu(1 - 4x), \\ \dot{y} = y(P_D - \bar{P}) + \mu(1 - 4y), \\ \dot{z} = z(P_{CA} - \bar{P}) + \mu(1 - 4z), \\ \dot{w} = w(P_{DA} - \bar{P}) + \mu(1 - 4w), \end{cases} \quad (9)$$

where $\bar{P} = xP_C + yP_D + zP_{CA} + wP_{DA}$ is the average expected payoff of the population.

III. RESULTS

Before presenting our research results, we review the dynamics of the destructive agents in the traditional public goods game^{25,26}. In a population of size M , it is assumed that all individuals hold the same strategy. The invasion analysis in ref.²⁵ indicates that the destructive agents can lead to three patterns of invasion under the parameter conditions $1 < r < r_{\max} = N(M-1)/(M-N)$ and $d_1 > 0$. (i) In the region of $r > 1 + (N-1)d_1$, destructive agents support the emergence of cooperators through a rock-paper-scissors (RPS) cyclic dominance emerges. (ii) In the region of $1 + d_1/(M-1) < r < 1 + (N-1)d_1$, a bistability arises between the destructive agents-cooperators. Here, the destructive agents can prevail over the defector, while the defector dominates the cooperator. However, neither the destructive agents nor the cooperator can invade each other. (iii) In the region of $r < 1 + d_1/(M-1)$, the destructive agents dominates in population.

When introducing the constructive agents solely, a similar invasion analysis is conducted under the conditions $0 < r < r_{\max} = N(M-1)/(M-N)$ and $d_2 > 0$, see Appendix A for detailed analysis. The population's invasion state in the presence of constructive agents is entirely different from that introduced by destructive agents. Figure 1 illustrates that the population consistently favors D , since D consistently maintain a positive expected payoff greater than the other two types. But

the competitive relationship between C and CA is distinct. Region I: when $r < 1 - (N - 1)d_2$, C can not invade constructive agents, but CA agents can invade C , as the expected payoff for the constructive agents is higher than that of cooperators. Region II: When $1 - (N - 1)d_2 < r < 1 - d_2/(M - 1)$, C and CA can invade each other, leading to a state of antagonism. Region III: when $r > 1 - d_2/(M - 1)$, C agents can invade CA , since the expected payoff of C is greater than that of CA . To validate the theoretical analysis, numerical simulations were conducted in three regions, as illustrated in Figure 2. Consistent with theoretical predictions, across the three mentioned parameter regions, there are variations in the competitive dynamics between C and CA , with D consistently holding dominance. These results indicate that when CA exists alone, despite potentially benefiting others, it cannot effectively resolve the social dilemma.

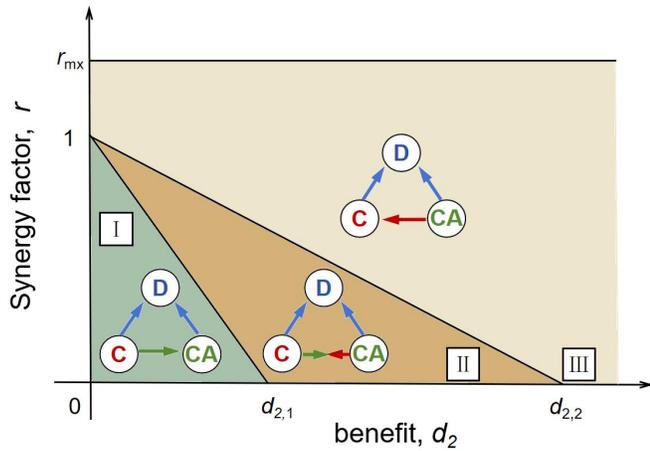

FIG. 1. Three patterns of invasion in the public goods games involving cooperators (C), defectors (D) and constructive agents (CA) under parameter phase r - d_2 . Region I (light green area) satisfies the conditions $r < 1 - (N - 1)d_2$, cooperators are invaded by constructive agents, while both cooperators and constructive agents are invaded by defectors. Region II (light brown area) satisfies the conditions $1 - (N - 1)d_2 < r < 1 - d_2/(M - 1)$, cooperators are invaded by constructive agents, while both cooperators and constructive agents are invaded by defectors. Region III (light yellow area) satisfies the conditions $r > 1 - d_2/(M - 1)$, constructive agents are invaded by cooperators, while both cooperators and constructive agents are invaded by defectors. All these cases are applicable under $N > 1$ and $0 < r < r_{\max} = N(M - 1)/(M - N)$. Critical points are $d_{2,1} = 1/(N - 1)$, $d_{2,2} = M - 1$.

To further explore the impact of constructive agents on cooperation, we investigate the evolutionary dynamics involving the C , D , DA , and CA strategies. The coexistence of strategies obtained through numerical simulation of replicator-mutator equations is depicted in Figure 3. Both the three-strategy model involving C , D and DA strategy and the four-strategy model considered here demonstrate that cooperation occurs only when the synergy factor is sufficiently large (i.e., $r \geq 2$), as shown in Figure 3(a) and (b). In the four-strategy model, for a specific d_2 , as the ‘‘harm’’ inflicted by DA on participants (d_1) increases, the population transitions from a pure D (blue

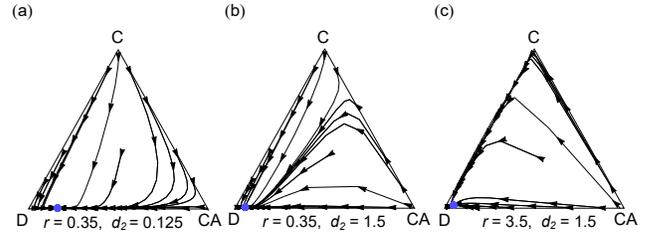

FIG. 2. The evolutionary dynamics of a large, well-mixed population involving strategies C , D , and CA are derived from the replicator-mutator dynamics. Each vertex in the plot represents a homogeneous population where all individuals hold the same strategy. The three vertices correspond to homogeneous populations adopting the strategies of cooperation, defection, and constructive agents, respectively. Arrows indicate the direction of dynamics, while blue-purple dots indicate the convergence states of populations. Proximity to a vertex indicates a higher proportion of the strategy represented by that vertex. Figures (a), (b), and (c) respectively depict the evolutionary dynamics in region I (setting $r = 0.35$ and $d_2 = 0.125$), Region II (setting $r = 0.35$ and $d_2 = 1.5$), and Region III (setting $r = 3.5$ and $d_2 = 1.5$) as shown in Figure 1. The other parameters are set as follows: $N = 5$ and $\mu = 0.005$. The results presented are generated using a modified version of the DeFinetti package³⁴.

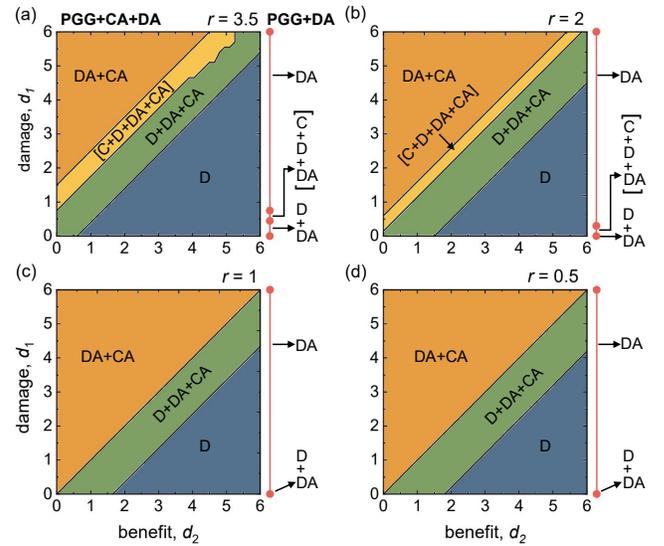

FIG. 3. Depicted are the strategy coexistence in the four-strategy model (involving C , D , DA , and CA) as a function of the damage d_1 caused by destructive agents and the benefit d_2 provided by constructive agents. The red vertical axis on the far right of each subfigure illustrates the coexistence of strategies in the three-strategy model (involving C , D , and DA) under the same parameters. The square brackets denote the presence of cyclic dominance among strategies, while their absence indicates the state of stable coexistence. Due to mutations, a given strategy cannot completely disappear or dominate; therefore, a threshold of greater than 0.05 is used to determine its presence. The values of r are 3.5, 2, 1, and 0.5 for (a)-(d) respectively, with a group size of $N = 5$ and a mutation rate of $\mu = 0.005$.

region) phase to a coexistence phase of $D + DA + CA$ (green region). Furthermore, as d_1 continues to increase, the popula-

tion shifts from the $D + DA + CA$ phase to the $DA + CA$ (orange region) phase when r is low, as illustrated in Figure 3(c) and (d). Interestingly, a narrow region of four-strategy coexistence (yellow region) emerges between the $D + DA + CA$ phase and the $DA + CA$ phase when r is sufficiently large. In contrast to the three-strategy model (shown on the right red vertical axis in Figure 3) where cooperation is limited to low values of d_1 ²⁵, the introduction of CA enables cooperation to emerge under higher values of d_1 . However, the premise for cooperation to be sustained is that d_1 must be greater than d_2 . Once d_2 exceeds d_1 , cooperation diminishes, leading to a transition from the four-strategy coexistence phase to the $D + DA + CA$ phase. Further increases in d_2 ultimately lead to the dominance of strategy D .

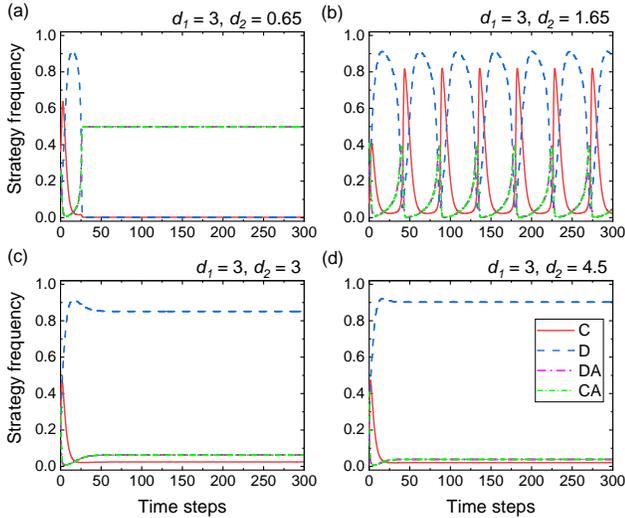

FIG. 4. Depicted are the frequency of the C (cooperator, red solid line), D (defector, blue dashed line), DA (destructive agents, magenta dotted line), and CA (constructive agents, green dash-dotted line) as a function of time steps. d_2 is set to 0.65, 1.65, 3, and 4.5 for (a)-(d), respectively. The other parameters are set as follows: $d_1 = 3$, $N = 5$, $r = 3.5$, and $\mu = 0.005$.

Figure 4 illustrates the temporal evolution of four strategies under a synergy factor of $r = 3.5$, providing insight into the evolving dynamics within the population. In Figure 4(a), the results indicate a transient increase in the proportions of cooperators and defectors in the early stages of evolution. Subsequently, both C and D decrease while the proportions of CA and DA increase until stability is reached, ultimately resulting in a coexistence state of $CA + DA$. Due to the absence of competition between the CA and DA , their proportions in the population are equal at equilibrium. When d_2 is increased to 1.65, the population exhibits cyclic oscillations over time for these four strategies, as shown in Figure 4(b). Specifically, the proportion of D initially rises, then gives way to DA and CA , after which both are gradually replaced by C . Then, C is once again supplanted by D , forming a cycle. It is this dominating cycle that enables the coexistence of cooperators with the other three strategies. When $d_1 = d_2$, as depicted in Figure 4(c), the dominance of the strategy cycle gives way to the co-

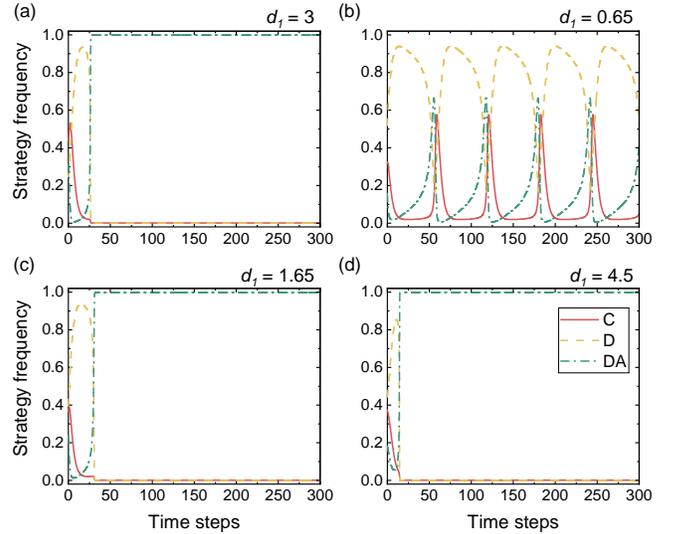

FIG. 5. Depicted are the frequency of the C (cooperator, red solid line), D (defector, yellow dashed line), and DA (destructive agents, green dotted line) as a function of time steps. d_1 is set to 3, 0.65, 1.65, and 4.5 for (a)-(d), respectively. The other parameters are set as follows: $N = 5$, $r = 3.5$, and $\mu = 0.005$. In (a), the frequency of C briefly increases before giving way to D . Strategy DA dominates the entire population eventually. In (b), strategies C , D , and DA exhibit cyclic dominance. The evolutionary process of strategy proportions in (c) and (d) resemble that of Figure (a), with the eventual dominance of strategy DA .

existence of $D + DA + CA$. Finally, when the benefits brought by CA outweigh the damage caused by DA (i.e., $d_2 > d_1$), Figure 4(d) shows that defectors eventually dominate the population. In contrast, we examine the temporal evolution dynamics involving three strategies— C , D , and DA . It is noteworthy that when $d_1 < 1$, the cycle dominance can emerge with C , D , and DA , as shown in Figure 5(b). However, when $d_1 > 1$, the results in Figures 5(a), (c), and (d) show that cycle dominance disappears and DA ultimately comes to dominate. Overall, when both d_1 and d_2 are larger, the cyclic dominance among strategies can occur (see Figure 4), but it must satisfy $d_1 > d_2$. However, as the increasing benefits from CA in the population, the cyclic dominance among strategies induced by destructive agents disappears when $d_2 \geq d_1$, indicating that the introduction of constructive agents weakens the ability of destructive agents to maintain cooperation within the population. The results remain consistent even when constructive and destructive agents are integrated (see Appendix B).

To further investigate the impact of d_1 and d_2 on the dynamics of strategy evolution, we examine the coexistence of four strategies (C , D , DA , and CA) under varying combinations of d_1 and d_2 . Results from Figures 6(a) and (b) indicate that, for a fixed d_1 , a slight increase in d_2 leads to a reduction in the peak amplitude of C during cyclic dominance oscillations (red solid line). Particularly, this weakening trend becomes more pronounced when d_1 is slightly decreased, as illustrated in Figures 6(c) and (d). This suggests that the increase in benefit (d_2) brought by the constructive agents weakens the ad-

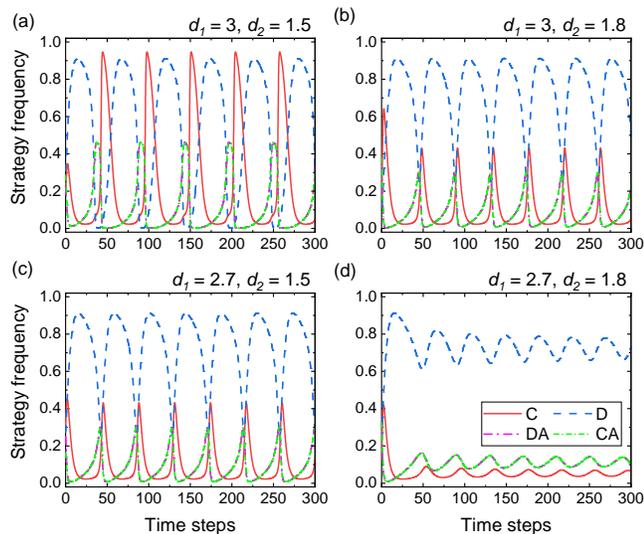

FIG. 6. Depicted are the frequencies of C (cooperator, red solid line), D (defector, blue dashed line), DA (destructive agents, magenta dotted line), and CA (constructive agents, green dash-dotted line) as a function of time steps under different d_1 - d_2 parameter combinations [$d_1 = 3$ and $d_2 = 1.5$ for (a); $d_1 = 3$ and $d_2 = 1.8$ for (b); $d_1 = 2.7$ and $d_2 = 1.5$ for (c); $d_1 = 2.7$ and $d_2 = 1.8$ for (d)]. The other parameters are set as follows: $N = 5$, $r = 3.5$, and $\mu = 0.005$. In (a) and (c), a decrease in d_1 leads to a reduction in the peak frequencies of strategies C , DA , and CA within the cyclic dominance. In (c) and (d), an increase in d_2 weakens the peak frequencies of all four strategies within the cyclic dominance.

vantage of destructive agents in inducing cooperators to dominate in the population's cyclic dynamics. Decreasing d_1 also weakens the advantage of cooperators in cyclic dominance.

The impact of mutation rate on the cyclic dominance phenomenon is depicted in Figure 7. When $\mu = 0.005$, it can be observed that the peak cooperation frequency within the cyclic dominance reaches approximately 0.92. However, as the mutation rate increases to 0.01, the peak values for the dominance of all four strategies decrease. Specifically, the peak value for cooperators drops from 0.92 to 0.188. When mutation rate increases to 0.1, while all four strategies still coexist within the population, the cyclic dominance phenomenon disappears, with the proportion of defectors surpassing that of cooperators. Moreover, the proportions of CA and DA stabilize at a low level. In the scenario of very rare mutations, specifically $\mu = 10^{-8}$, cyclic dominance disappears entirely, and defectors overwhelmingly dominate, pushing the frequencies of strategies C , CA , and DA nearly to zero.

IV. DISCUSSION

The intertwined evolutionary dynamics of diverse behaviors could deepen understanding of how cooperation is sustained amidst the complexity of human behavior. In this work, we introduce constructive behaviors into the traditional PGG, and consider the intertwined evolutionary dynamics of

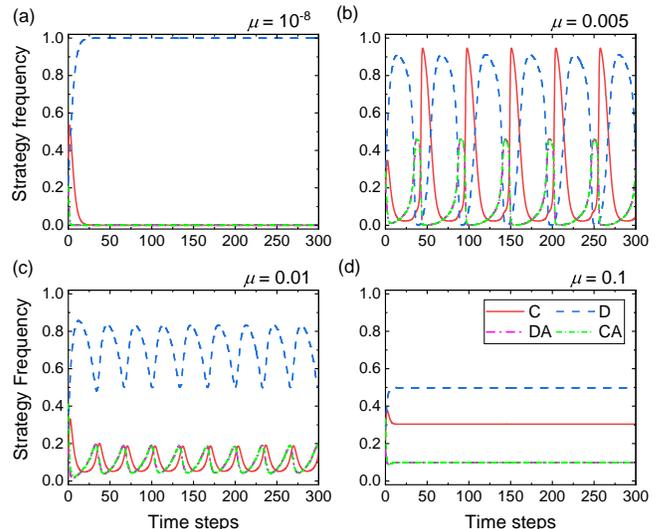

FIG. 7. Depicted are the frequencies of C (cooperator, red solid line), D (defector, blue dashed line), DA (destructive agents, magenta dotted line), and CA (constructive agents, green dash-dotted line) as a function of time steps. The mutation rates are 10^{-8} , 0.005, 0.01, and 0.1 for (a)-(d) respectively. The other parameters are set as follows: $N = 5$, $r = 3.5$, $d_1 = 3$, and $d_2 = 1.5$. As the mutation rate increases, the cyclic dominance among the four strategies gradually diminishes.

constructive agents and destructive agents. These constructive agents do not influence contributions and allocations in the public pool. Instead, they directly benefit participants in the PGG group (i.e., cooperators and defectors). Through mean-field results derived from the replicator-mutator equation and numerical simulations, our research reveals significant differences in the impact of constructive agents compared to destructive agents on the cooperation dynamics. While the presence of destructive agents can contribute to sustaining cooperation by facilitating a strategy cycle dominance, the sole participation of constructive agents in the evolutionary dynamics fails to resolve cooperation issues in a one-shot game, with defection still prevailing in the population (see Figure 1). However, introducing constructive agents into the cooperation-defection-destruction model can maintain cooperation through a cyclic dominance process among strategies in evolution (see Figure 3).

Although constructive agents themselves cannot directly alter the evolutionary outcomes of the population, together with destructive agents, they can engage in a cyclic dominance induced by destructive agents to sustain cooperation (see Figure 3). Moreover, constructive agents act as a buffer, allowing cooperation to be maintained even when the damage from destructive agents is larger. However, as the benefits provided by constructive agents increase, the efficiency of destructive agents in promoting cooperation decreases. When the benefits provided by constructive agents exceed the “harm” caused by destructive agents to individuals, it breaks the cyclic dominance and weakens the ability of destructive agents to sustain cooperation (see Figure 4). Furthermore, an increased mutation rate can weaken the peak cooperation frequency in cyclic

dominance. Conversely, in the limit of rare mutation rates, the phenomena of cyclic dominance among strategies completely disappear, with the defective strategy being the unique Nash equilibrium. Neither destructive nor constructive agents derive any benefits from a common pool of funds. However, relying solely on altruistic behavior from constructive agents is insufficient to support the establishment of cooperation in one-shot games. Importantly, the altruistic behavior of constructive agents provides positive incentives for others in society, while the behavior of destructive agents generates negative incentives. By simultaneously considering these positive and negative incentive behaviors^{13,14,16}, the dynamics of cooperation maintenance are altered. Therefore, our study highlights the importance of balancing the interaction of positive and negative incentive behaviors.

In our study, constructive and destructive agents represent two typical orientations towards the interests of others: benefiting others and causing harm to others. However, individual self-interest considerations have been overlooked. Considering that self-interest is a characteristic of rational human behavior, an integration of individual actions build upon two dimensions of behavioral orientation within the social value orientation framework²³—preference for one’s own gains and preference for opponent’s gains—will contribute to a more comprehensive understanding of cooperation emergence and promotion under diverse behavioral frameworks. On the other hand, in this challenging one-shot game scenario, cooperation cannot be sustained by relying solely on the constructive agents. In conjunction with reciprocity mechanisms, can the altruistic behaviors exhibited by constructive agents, promote the development of cooperation? Furthermore, by integrating behavioral information transmission, analyzing the biased strategies of constructive and destructive agents towards defectors or cooperators becomes feasible, aiding in a deeper understanding of how diverse behaviors affect the cooperation dynamics. Future research focusing on direct reciprocity, indirect reciprocity, and network reciprocity mechanisms will offer valuable insights into the complex interplay between diverse individual value orientations and the maintenance of cooperation.

AUTHOR DECLARATIONS

Conflict of Interest

The authors have no conflicts to disclose.

Author Contributions

Y.D. and C.S. conceptualised, designed the study, formal analysis, methodology, validation, and visualization; Y.D., Z.H., and C.S. writing original draft; L.S. and J.T. provided overall project supervision, review and editing; All authors approved the final version and agreed to be accountable for the work conducted in the work.

DATA AVAILABILITY STATEMENT

The data that support the findings of this study are available from the corresponding authors upon reasonable request.

Appendix A: Finite populations: invasion analysis among cooperation, defection and constructive agents

Considering a homogeneous population of size M , where individuals adopt strategy Y . Suppose one individual undergoes a mutation, shifting from strategy Y to strategy X . The successful invasion of this homogeneous population by the X individual is contingent upon the condition that the expected payoff from adopting strategy X exceeds that of individuals adopting strategy Y (i.e., $P_X > P_Y$). In this population, composed of one individual adopting strategy X and $N - 1$ individuals adopting strategy Y , the expected payoff for the individuals using strategy X can be represented as follows:

$$P_X = \pi_X(1X, (N - 1)Y). \quad (\text{A1})$$

During the game, individuals adopting strategy Y face two possible population states: one where one individual holds strategy X and $N - 1$ individuals hold strategy Y , and the other where all individuals hold strategy Y . Let’s denote the probabilities of these two states as p_1 and p_2 respectively. The expected payoff for strategy Y can be expressed as:

$$P_Y = \pi_Y(1X, (N - 1)Y) \cdot p_1 + \pi_Y(0X, NY) \cdot p_2, \quad (\text{A2})$$

where,

$$p_1 = \frac{\binom{M-2}{N-2} \binom{1}{1}}{\binom{M-1}{N-1}} = \frac{N-1}{M-1}, \quad (\text{A3})$$

$$\begin{aligned}
p_2 &= \frac{\binom{M-2}{N-1} \binom{1}{0}}{\binom{M-1}{N-1}} \\
&= \frac{M-N}{M-1}.
\end{aligned} \tag{A4}$$

In a model involving C , D , and CA strategies, considering the pairwise interaction of these strategies, there are six distinct scenarios regarding population composition, as outlined below:

(A) $1D + (M-1)C$

$$\begin{aligned}
P_D &= \pi_D(1D, (N-1)C) \\
&= r - \frac{r}{N}, \\
P_C &= \pi_C(1D, (N-1)C) \cdot \frac{N-1}{M-1} + \pi_C(0, NC) \cdot \frac{M-N}{M-1} \tag{A5} \\
&= r - 1 - \frac{r}{N} \cdot \frac{N-1}{M-1}.
\end{aligned}$$

Strategy D will successfully invade the population of strategy C , satisfying the $P_D > P_C$, the condition can be derived as follows:

$$r < N \cdot \frac{M-1}{M-N}. \tag{A6}$$

In the limit $M \rightarrow \infty$, the above condition is reduced to $r < N$, thereby encompassing the condition for the social dilemma: $0 < r < N$. In the subsequent analysis, we will proceed under the assumption that inequality (A6) holds.

(B) $1C + (M-1)D$

$$\begin{aligned}
P_C &= \pi_C(1C, (N-1)D) \\
&= \frac{r \cdot 1}{N} - 1, \\
P_D &= \pi_D(1C, (N-1)D) \cdot \frac{N-1}{M-1} + \pi_D(0, ND) \cdot \frac{M-N}{M-1} \tag{A7} \\
&= \frac{r \cdot 1}{N} \cdot \frac{N-1}{M-1}.
\end{aligned}$$

Since $0 < r < N$, we have $P_C < 0$ and $P_D > 0$, indicating $P_C < P_D$. Therefore, strategy C can never invade a population of strategy D .

(C) $1CA + (M-1)C$

$$\begin{aligned}
P_{CA} &= 0, \\
P_C &= \pi_C(1CA, (N-1)C) \cdot \frac{N-1}{M-1} + \pi_C(0, NC) \cdot \frac{M-N}{M-1} \\
&= r - 1 + \frac{d_2}{M-1}.
\end{aligned} \tag{A8}$$

If $P_{CA} > P_C$, then:

$$0 < r < 1 - \frac{d_2}{M-1}, \tag{A9}$$

strategy CA can invade the population of strategy C iff condition (A9) holds.

On the contrary, let $P_{CA} < P_C$ derive :

$$r > 1 - \frac{d_2}{M-1}, \tag{A10}$$

when r satisfies condition (A10), the strategy CA can never invade the population of strategy C .

(D) $1C + (M-1)CA$

$$\begin{aligned}
P_{CA} &= 0, \\
P_C &= \pi_C(1C, (N-1)CA) \\
&= r - 1 + (N-1) \cdot d_2.
\end{aligned} \tag{A11}$$

If $P_C > P_{CA}$, thus:

$$r > 1 - (N-1) \cdot d_2, \tag{A12}$$

strategy C will invade the population of strategy CA iff condition (A12) holds.

On the contrary, if $P_C < P_{CA}$, i.e.,

$$r < 1 - (N-1) \cdot d_2, \tag{A13}$$

in this case, the strategy C will not invade the population of strategy CA .

(E) $1D + (M-1)CA$

$$\begin{aligned}
P_{CA} &= 0, \\
P_D &= \pi_D(1D, (N-1)CA) \\
&= d_2 \cdot (N-1).
\end{aligned} \tag{A14}$$

Since $d_2 > 0$ and $N > 1$, it follows that $d_2(N-1) > 0$, i.e., $P_D > P_{CA}$. When this condition is satisfied, the strategy D will inevitably invade the population of strategy CA .

(F) $1CA + (M-1)D$

$$\begin{aligned}
P_{CA} &= 0, \\
P_D &= \pi_D(1CA, (N-1)D) \cdot \frac{N-1}{M-1} + \pi_D(0, ND) \cdot \frac{M-N}{M-1} \\
&= \frac{d_2}{M-1}.
\end{aligned} \tag{A15}$$

Since $d_2 > 0$ and $M \gg 1$, it follows that $P_D > 0$. In this case, $P_{CA} < P_D$ must hold, so the strategy CA will never invade the population of strategy D .

According to the invasion analysis described above, we have obtained the distinct invasion regions for three strategies as shown in Figure 1. In scenarios (A), (B), (E), and (F), it is evident that when conditions $0 < r < N \cdot \frac{M-1}{M-N}$ and $d_2 > 0$ are satisfied, both strategy C and strategy CA are consistently invaded by strategy D . From scenarios (C) and (D), although $r > 1 - \frac{d_2}{M-1}$ is satisfied, strategy CA does not invade strategy C . However, when $r > 1 - (N-1) \cdot d_2$, strategy CA is invaded by strategy C . Notably, the range of r values

in the former falls within that of the latter, thus, as long as the condition $r > 1 - \frac{d_2}{M-1}$ holds, the latter will definitely occur, namely, strategy CA being invaded by strategy C . Similarly, although $r < 1 - (N-1) \cdot d_2$ is satisfied, strategy C does not invade strategy CA . However, when $0 < r < 1 - \frac{d_2}{M-N}$, strategy C is invaded by strategy CA . The range of r values in the former is contained within the range of the latter, thus, when $r < 1 - (N-1) \cdot d_2$ is satisfied, strategy C will eventually be invaded by strategy CA . In contrast, when $1 - (N-1) \cdot d_2 < r < 1 - \frac{d_2}{M-1}$, strategies CA and C invade each other, leading to a state of antagonism.

Appendix B: Finite populations: invasion analysis of a simplified three-strategy model involving cooperation, defection and integrated exiter

The effects that constructive agents and destructive agents have on other group members are opposite, while their own payoffs are zero. According to the replicator-mutator equation (9), once the proportions of these two types reach equilibrium, the presence of one CA (who increases the payoffs of both cooperators and defectors by d_2) and one DA (who decreases their payoffs by d_1) is mathematically equivalent to the presence of one agent who alters the payoffs of cooperators and defectors by $d = d_2 - d_1$. Therefore, we simplify the four-strategy model into a three-strategy model: cooperation (C), defection (D), and integrated exiter strategies (E). Here, each integrated exiter has an effect of $d = d_2 - d_1$, which is equally shared among all cooperators and defectors. In other words, it provides a benefit of d_2 while also inflicting damage of d_1 on non-exiters. We conduct a strategy invasion analysis similar to Appendix A for this population of three strategies, examining six distinct combinations through pairwise interactions.

(A) $1D + (M-1)C$

$$\begin{aligned} P_D &= \pi_D(1D, (N-1)C) \\ &= r - \frac{r}{N}, \\ P_C &= \pi_C(1D, (N-1)C) \cdot \frac{N-1}{M-1} + \pi_C(0, NC) \cdot \frac{M-N}{M-1} \quad (\text{B1}) \\ &= r - 1 - \frac{r}{N} \cdot \frac{N-1}{M-1}. \end{aligned}$$

If $P_D > P_C$, strategy D successfully invades the population of strategy C , consistent with (A6), i.e., when

$$r < N \cdot \frac{M-1}{M-N}. \quad (\text{B2})$$

(B) $1C + (M-1)D$

$$\begin{aligned} P_C &= \pi_C(1C, (N-1)D) \\ &= \frac{r \cdot 1}{N} - 1, \\ P_D &= \pi_D(1C, (N-1)D) \cdot \frac{N-1}{M-1} + \pi_D(0, ND) \cdot \frac{M-N}{M-1} \quad (\text{B3}) \\ &= \frac{r \cdot 1}{N} \cdot \frac{N-1}{M-1}. \end{aligned}$$

Since inequality (B2) includes the condition $0 < r < N$, it follows that $P_C < P_D$, indicating that strategy C will never invade the population of strategy D .

(C) $1E + (M-1)C$

$$\begin{aligned} P_E &= 0, \\ P_C &= \pi_C(1E, (N-1)C) \cdot \frac{N-1}{M-1} + \pi_C(0, NC) \cdot \frac{M-N}{M-1} \quad (\text{B4}) \\ &= r - 1 + \frac{d_2 - d_1}{M-1}. \end{aligned}$$

If $P_E > P_C$, strategy E will invade the population of strategy C , i.e.,

$$0 < r < 1 - \frac{d_2 - d_1}{M-1}, \quad (\text{B5})$$

Conversely, if the following condition is satisfied, i.e.,

$$r > 1 - \frac{d_2 - d_1}{M-1}, \quad (\text{B6})$$

strategy E will not invade the population of strategy C .

(D) $1C + (M-1)E$

$$\begin{aligned} P_E &= 0, \\ P_C &= \pi_C(1C, (N-1)E) \quad (\text{B7}) \\ &= r - 1 + (N-1) \cdot (d_2 - d_1). \end{aligned}$$

If $P_C > P_E$, then strategy C will invade the population of strategy E , i.e.,

$$r > 1 - (N-1) \cdot (d_2 - d_1), \quad (\text{B8})$$

Conversely, if $P_C < P_E$, strategy C will not invade the population of strategy E , i.e.,

$$r < 1 - (N-1) \cdot (d_2 - d_1), \quad (\text{B9})$$

(E) $1D + (M-1)E$

$$\begin{aligned} P_E &= 0, \\ P_D &= \pi_D(1D, (N-1)E) \quad (\text{B10}) \\ &= (d_2 - d_1) \cdot (N-1). \end{aligned}$$

In the above equation (B10), if $d_2 - d_1 > 0$, then $P_D > P_E$, and strategy D will invade the population of strategy E . Conversely, if $d_2 - d_1 < 0$, then $P_D < P_E$, and strategy D does not invade the population of strategy E . When $d_2 = d_1$, strategy D and strategy E cannot invade each other.

(F) $1E + (M-1)D$

$$\begin{aligned} P_E &= 0, \\ P_D &= \pi_D(1E, (N-1)D) \cdot \frac{N-1}{M-1} + \pi_D(0, ND) \cdot \frac{M-N}{M-1} \\ &= \frac{d_2 - d_1}{M-1}. \quad (\text{B11}) \end{aligned}$$

Similarly, in equation (B11), if $d_2 - d_1 < 0$, then $P_E > P_D$, and strategy E will invade the population of strategy D . Conversely, if $d_2 - d_1 > 0$, then $P_E < P_D$, and strategy E does not invade the population of strategy D . When $d_2 = d_1$, strategy D and strategy E cannot invade each other.

The above strategy invasion analysis demonstrates that the evolutionary dynamics of the population depend on the relative magnitudes of d_2 and d_1 . When $d_2 - d_1 < 0$, a $C \rightarrow D \rightarrow E \rightarrow C$ cycle dominance emerges under the condition $r > 1 - (N - 1) \cdot (d_2 - d_1)$. For $1 - \frac{d_2 - d_1}{M - 1} < r < 1 - (N - 1) \cdot (d_2 - d_1)$, strategy C and strategy E cannot invade each other, resulting in a bistable state. When $0 < r < 1 - \frac{d_2 - d_1}{M - 1}$, strategy E invades both the populations of strategy C and strategy D , ultimately leading to the dominance of strategy E . Thus, a population consisting of strategies C , D , and E can sustain cooperation through a cyclic dominance process, primarily attributed to the destructive effect caused by the integrated exiters, i.e., when $d_2 - d_1 < 0$.

Conversely, when $d_2 - d_1 > 0$, if $r < 1 - (N - 1) \cdot (d_2 - d_1)$, strategy E will invade the population of strategy C , and both strategies E and C will be invaded by strategy D . If $1 - (N - 1) \cdot (d_2 - d_1) < r < 1 - \frac{d_2 - d_1}{M - 1}$, strategy E and strategy C will invade each other, but both will be invaded by strategy D . If $r > 1 - \frac{d_2 - d_1}{M - 1}$, strategy C will invade the population of strategy E , and strategy D will invade both strategy C and strategy E .

However, when $d_2 - d_1 = 0$, it follows from (B10) and (B11) that $PE = PD = 0$, indicating that strategies D and E cannot invade each other, and there is no competition between them. For strategies C and E , according to (B4) and (B7), we have $P_C = r - 1$ and $P_E = 0$. Therefore, when $r > 1$, strategy E does not invade the population of strategy C ; instead, strategy C invades the population of strategy E . Additionally, based on (B1) and (B3), strategy D always invades the population of strategy C . Thus, this leads to $E \rightarrow C \rightarrow D$, resulting in the dominance of strategy D . Conversely, when $r < 1$, strategy C does not invade strategy E , while strategy E invades strategy C . Combined with (B1) and (B3), since strategy D always invades strategy C , both strategies E and D invade strategy C , ultimately leading to the coexistence of strategies E and D .

The evolutionary dynamics involving cooperators, defectors, and integrated exiters in the simplified three-strategy model depend on $d = d_2 - d_1$. Cooperation can still be sustained through a three-strategy cyclic dominance involving cooperators, defectors, and integrated exiters when $d_2 - d_1 < 0$, indicating the critical role of destructive agents in maintaining cooperation. However, when $d_2 - d_1 > 0$, the presence of integrated exiters does not alter the equilibrium of defection. In other words, when the benefits provided by constructive agents surpass the damage caused by destructive agents, constructive agents nullify the ability of destructive agents to maintain cooperation.
