(Dated: 1 May 2024)

We investigate how recent updates to neutrino oscillation parameters and the sum of neutrino masses influence the sensitivity of neutrinoless double-beta ($0\nu\beta\beta$) decay experiments. Incorporating the latest cosmological constraints on the sum of neutrino masses and laboratory measurements on oscillations, we determine the sum of neutrino masses for both the normal hierarchy (NH) and the inverted hierarchy (IH). Our analysis reveals a narrow range for the sum of neutrino masses, approximately $0.06 \text{ eV}/c^2$ for NH and $0.102 \text{ eV}/c^2$ for IH. Utilizing these constraints, we calculate the effective Majorana masses for both NH and IH scenarios, establishing the corresponding allowed regions. Importantly, we find that the minimum neutrino mass is non-zero, as constrained by the current oscillation parameters. Additionally, we estimate the half-life of $0\nu\beta\beta$ decay using these effective Majorana masses for both NH and IH. Our results suggest that upcoming ton-scale experiments will comprehensively explore the IH scenario, while 100-ton-scale experiments will effectively probe the parameter space for the NH scenario, provided the background index can achieve 1 event/kton-year in the region of interest.

I. INTRODUCTION

The revelation of neutrino oscillations in solar and atmospheric neutrino experiments^{1–3} has marked a significant leap in our comprehension of neutrinos, uncovering their mass and mixing within the lepton sector. This breakthrough holds profound implications for extending the standard model of particle physics and pursuing a grand unified theory of nature. Yet, despite this progress, numerous facets of neutrinos remain enigmatic, such as their absolute mass scale, mass hierarchy, and the determination of whether they exhibit a Dirac or Majorana nature⁴.

Various experiments, spanning accelerator-based and reactor-based neutrino oscillation studies, beta decay investigations, and neutrinoless double-beta ($0\nu\beta\beta$) decay research, contribute to our understanding of the absolute mass scale and mass hierarchy of neutrinos. However, it's noteworthy that $0\nu\beta\beta$ decay experiments uniquely offer a practical means to explore the Majorana nature of neutrinos. These experiments aim to address fundamental questions by probing the effective Majorana mass of electron neutrinos and determining the absolute neutrino mass scale, hierarchy, and character^{5–8}.

In a $0\nu\beta\beta$ decay experiment, the connection between the measured half-life ($T_{\beta\beta}^{0\nu}$) and the effective Majorana mass of the electron neutrino, $m_{\beta\beta}$, is approximated by the following expression:

$$(T_{\beta\beta}^{0\nu})^{-1} = G^{0\nu}(E_0, Z) \left| \left(\frac{m_{\beta\beta}}{m_e} \right)^2 |M_f^{0\nu} - \left(\frac{g_A}{g_V} \right)^2 M_{GT}^{0\nu}|^2 \right|. \quad (1)$$

In Equation 1, $G^{0\nu}(E_0, Z)$ includes couplings and a phase space factor, where g_A and g_V represent the axial vector and vector coupling constants, and $M_f^{0\nu}$ and $M_{GT}^{0\nu}$ denote the Fermi and Gamow-Teller nuclear matrix elements, respectively. Consequently, the precision with which $m_{\beta\beta}$ can be determined from the measured half-life relies on the accuracy of the theoretical nuclear matrix elements.

If the $0\nu\beta\beta$ decay process is mediated by light Majorana

neutrinos, the effective neutrino mass is determined by the following coherent sum:

$$|m_{\beta\beta}| = \left| \sum_i m_i U_{\beta i}^2 \right|, \quad (2)$$

where m_i represents the mass of the i th neutrino mass eigenstate, $U_{\beta i}$ are elements of the leptonic matrix U , and the sum extends over all light neutrino mass eigenstates⁹. In the standard three-flavor scheme, U is a unitary matrix and can therefore be parameterized in terms of three flavor mixing angles and three CP-violating phases:

$$U = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{13}s_{23}e^{i\delta} & c_{12}c_{23} - s_{12}s_{13}s_{23}e^{i\delta} & c_{13}s_{23} \\ s_{12}s_{23} - c_{12}s_{13}c_{23}e^{i\delta} & -c_{12}s_{23} - s_{12}s_{13}c_{23}e^{i\delta} & c_{13}c_{23} \end{pmatrix} \quad (3)$$

where $c_{ij} = \cos\theta_{ij}$, $s_{ij} = \sin\theta_{ij}$ (for $ij = 12; 13; 23$), δ represents the Dirac charge-parity (CP) phase.

The effective Majorana mass is determined by the absolute value of the element $m_{\beta\beta}$ within the mass matrix in the charged lepton flavor basis. This mass matrix characterizes the charged leptons in their diagonal basis. Consequently, the Majorana neutrino mass matrix in the charged lepton flavor basis can be represented as:

$$|m_{\beta\beta}| = |U \cdot D \cdot U^T|. \quad (4)$$

In this context, the diagonal matrix can be denoted as $D = \text{diag}[m_1 e^{i\alpha}, m_2, m_3 e^{i\beta}]$, where both α and β represent the Majorana CP-violating phases.

The results derived from Equation 4 can be expressed as:

$$|m_{\beta\beta}| = |m_{\beta\beta}^{(1)} e^{i\alpha} + m_{\beta\beta}^{(2)} + m_{\beta\beta}^{(3)} e^{i\beta}|, \quad (5)$$

and

$$\begin{aligned}
|m_{\beta\beta}^{(1)}| &= m_1 c_{12}^2 c_{13}^2, \\
|m_{\beta\beta}^{(2)}| &= m_2 s_{12}^2 c_{13}^2, \\
|m_{\beta\beta}^{(3)}| &= m_3 s_{13}^2.
\end{aligned} \tag{6}$$

After years of experimental exploration, significant progress has been made in determining the values of θ_{12} , θ_{13} , and θ_{23} with a high degree of accuracy from current neutrino oscillation data. However, the three phase parameters (δ , α , and β) remain elusive¹⁰. Additionally, while the value of $\Delta m_{21}^2 \equiv m_2^2 - m_1^2$ and the absolute value of $\Delta m_{31}^2 \equiv m_3^2 - m_1^2$ have been measured, the sign of Δm_{31}^2 and the absolute neutrino mass scale remain unknown.

Therefore, the magnitude of $|m_{\beta\beta}|$ is subject to three types of uncertainties, namely the unknown absolute neutrino mass scale (m_1 or m_3), the unknown neutrino mass hierarchy ($\Delta m_{31}^2 > 0$ or $\Delta m_{31}^2 < 0$), and the unknown Majorana phases α and β appearing in $|m_{\beta\beta}|$, even in the absence of new physics contamination. Given that the magnitude of $|m_{\beta\beta}|$ is closely tied to the decay half-life of the $0\nu\beta\beta$ decay process, it is of significant interest to explore how these three uncertainties will influence its value. Evaluating this impact will provide valuable insights into the practical feasibility of conducting an experiment.

Until now, extensive phenomenological endeavors have been dedicated to exploring the parameter space of $|m_{\beta\beta}|$ and evaluating its sensitivity to potential new physics phenomena¹¹. Current experiments have achieved remarkable sensitivities, with half-life measurements reaching levels of $\sim 10^{26}$ years for isotopes such as ^{136}Xe and ^{76}Ge , consequently setting upper limits on the effective Majorana neutrino mass within the range of 36-156 meV^{12,13}.

In this study, we aim to investigate the parameter space of $|m_{\beta\beta}|$ by incorporating the sum of neutrino masses constrained by recent cosmological data¹⁴ and utilizing the best-fitted oscillation parameters derived from global particle physics datasets¹⁰. We will explore several intriguing scenarios, including the allowed regions for the sum of neutrino masses and the minimum neutrino mass m_1 or m_3 , and analyze the behavior of $|m_{\beta\beta}|$ within these regions. Given an allowed sum of neutrino masses, we determine the value of the minimum neutrino mass. We point out that if the minimum neutrino mass falls outside the range of $[2 \times 10^{-3} \text{ eV}/c^2, 7 \times 10^{-3} \text{ eV}/c^2]$, $|m_{\beta\beta}|$ will exceed 1 meV/ c^2 in magnitude. This level of sensitivity can be achieved with a 100-ton experiment over 10 years. This observation elucidates the relationship between neutrino mass constraints and the effective Majorana mass.

II. THE SUM OF NEUTRINO MASSES VERSUS THE MINIMUM NEUTRINO MASS

The most recent cosmological constraints on the sum of neutrino masses¹⁴, coupled with the latest laboratory measurements on oscillations¹⁰, offer valuable insights into the constraints on the effective Majorana neutrino mass. In this work,

we utilize the squared mass splitting constraints obtained from a comprehensive global fit to observations of neutrino oscillations¹⁰.

In the context of the normal neutrino mass hierarchy, often abbreviated as the normal hierarchy (NH), characterized by $m_1 < m_2 < m_3$, the parameters employed in this study are:

$$\left\{ \begin{aligned}
\Delta m_{21}^2 &= (7.41_{-0.20}^{+0.21}) \times 10^{-5} \text{ eV}^2/c^4 \\
\Delta m_{32}^2 &= (2.437_{-0.027}^{+0.028}) \times 10^{-3} \text{ eV}^2/c^4 \\
\theta_{13} &= (8.54_{-0.12}^{+0.11})^\circ \\
\sin^2 \theta_{13} &= (2.203_{-0.059}^{+0.056}) \times 10^{-2} \\
\theta_{23} &= (49.1_{-1.3}^{+1.0})^\circ \\
\sin^2 \theta_{23} &= (5.71_{-0.23}^{+0.18}) \times 10^{-1} \\
\theta_{12} &= (33.41_{-0.72}^{+0.75})^\circ \\
\sin^2 \theta_{12} &= (3.03_{-0.11}^{+0.12}) \times 10^{-1}
\end{aligned} \right. \tag{7}$$

Similarly, in the case of the inverted neutrino mass hierarchy, commonly referred to as the inverted hierarchy (IH), characterized by $m_3 < m_1 < m_2$, the parameters utilized in this study are:

$$\left\{ \begin{aligned}
\Delta m_{21}^2 &= (7.41_{-0.20}^{+0.21}) \times 10^{-5} \text{ eV}^2/c^4 \\
\Delta m_{32}^2 &= (-2.498_{-0.025}^{+0.032}) \times 10^{-3} \text{ eV}^2/c^4 \\
\theta_{13} &= (8.57_{-0.11}^{+0.12})^\circ \\
\sin^2 \theta_{13} &= (2.219_{-0.057}^{+0.060}) \times 10^{-2} \\
\theta_{23} &= (49.5_{-1.2}^{+0.9})^\circ \\
\sin^2 \theta_{23} &= (5.78_{-0.21}^{+0.16}) \times 10^{-1} \\
\theta_{12} &= (33.41_{-0.72}^{+0.75})^\circ \\
\sin^2 \theta_{12} &= (3.03_{-0.11}^{+0.12}) \times 10^{-1}
\end{aligned} \right. \tag{8}$$

Using the measured values of Δm_{12}^2 and Δm_{32}^2 in both the NH and IH cases, we can derive the sum $\Sigma = m_1 + m_2 + m_3$ as follows:

$$\left\{ \begin{aligned}
\Sigma &= m_1 + \sqrt{(7.41_{-0.20}^{+0.21}) \times 10^{-5} + m_1^2 +} \\
&\quad \sqrt{(7.41_{-0.20}^{+0.21}) \times 10^{-5} + (2.437_{-0.027}^{+0.028}) \times 10^{-3} + m_1^2},
\end{aligned} \right. \tag{9}$$

and

$$\left\{ \begin{aligned}
\Sigma &= m_3 + \sqrt{(2.498_{-0.025}^{+0.032}) \times 10^{-3} + m_3^2 +} \\
&\quad \sqrt{(7.41_{-0.20}^{+0.021}) \times 10^{-5} + (2.498_{-0.025}^{+0.032}) \times 10^{-3} + m_3^2}
\end{aligned} \right. \tag{10}$$

The oscillation constraints outlined in Equations 9 and 10 can be visualized in Figure 1, illustrating the permitted region in the $m_L - \Sigma$ plane. Here, m_L denotes the minimum neutrino mass, representing m_1 for NH and m_3 for IH.

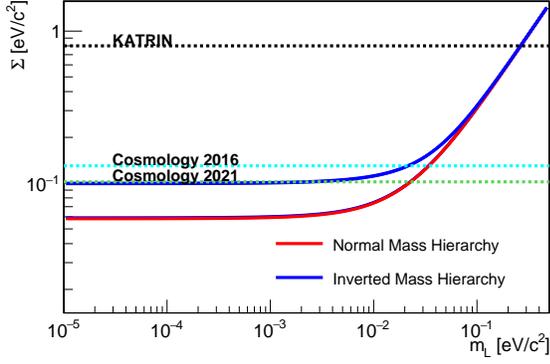

FIG. 1. The sum of masses is represented by the symbol Σ , defined as $\Sigma = m_1 + m_2 + m_3$, and is depicted as a function of the minimum mass of neutrino mass eigenstates. The estimated sensitivity of KATRIN is $\Sigma < 0.8$ eV (95% C.L.) according to reference¹⁵. Cosmology 2016 data is sourced from reference¹⁶, while Cosmology 2021 data is cited from reference¹⁴.

As depicted in Figure 1, the values of Σ fall within two narrow bands: approximately 0.06 eV/c² for NH and ~ 0.102 eV/c² for IH. This suggests a minor influence of the value of the minimum neutrino mass when $m_L < 10^{-2}$ eV/c². It is noteworthy that the Particle Data Group¹⁰ in 2022 provided three additional sets of best-fit parameters. Despite slight differences among these parameters, they do not alter the conclusion regarding the narrow allowed bands for Σ in both NH and IH cases.

It's notable that recent searches in cosmology and accelerator experiments lean towards favoring the NH scenario for neutrino mass^{17–19}. This suggests that the dominant components of $|m_{\beta\beta}|$ would be the lighter neutrino mass eigenstates, leading to longer decay half-lives and increased experimental challenges. While the reliability of the cosmological claim has faced scrutiny²⁰, recent results from experiments such as NOVA¹⁸ and T2K¹⁹ lack statistical significance.

To address the potential preference for the normal hierarchy, Agostini, Benato, and Detwiler¹¹ found that the likelihood of detecting $0\nu\beta\beta$ decay could exceed 50% in the most promising experiments in the absence of neutrino mass mechanisms that drive the mass of the lightest state or the effective Majorana mass to zero. Furthermore, there is consideration of decay facilitated by the exchange of heavy particles^{21,22}, which involves Majorana neutrinos according to the Black-Box Theorem²³, thereby violating lepton number conservation. However, determining the mass scale of the light neutrinos directly from the data in this scenario remains challenging.

Therefore, while the adverse implications of NOVA and T2K results may be overstated, the possibility of exotic heavy particle exchange physics could diminish their significance. Nevertheless, the primary motivation for investigat-

ing decay—testing lepton number conservation and distinguishing between the Dirac or Majorana character of neutrinos—remains compelling.

Given the narrow allowed regions of Σ in both NH and IH cases, we aim to explore the parameter space of $|m_{\beta\beta}|$ versus the minimum neutrino mass m_L for both scenarios, particularly when accounting for the Majorana CP-violating phases.

III. THE PARAMETER SPACE OF $|m_{\beta\beta}|$

In the early 2000s, pioneers developed formulations to calculate $|m_{\beta\beta}|$ as a function of the minimum neutrino mass²⁴. Recently, the coupling-rod diagram of $|m_{\beta\beta}|$, introduced by Zhi-Zhong Xing and Ye-Ling Zhou²⁵, illustrates the key characteristics of $|m_{\beta\beta}|$ in the complex plane. This diagram provides an intuitive understanding of how the neutrino mass ordering and CP-violating phases impact $|m_{\beta\beta}|$. Below, we present a summary of the maximum and minimum values of $|m_{\beta\beta}|$ using Equation 5 for both NH and IH cases.

For the case of NH where $m_1 < m_2 < m_3$, the equations are:

$$\left\{ \begin{array}{l} |m_{\beta\beta}|_{max} = \sqrt{\Delta m_{21}^2 + m_1^2 \sin^2 \theta_{12} \cos^2 \theta_{13}} \left[1 + \sqrt{1 - \frac{\Delta m_{21}^2}{\Delta m_{21}^2 + m_1^2} \cot^2 \theta_{12}} + \sqrt{1 - \frac{\Delta m_{21}^2}{\Delta m_{21}^2 + m_1^2} + \frac{\Delta m_{21}^2 + \Delta m_{32}^2}{\Delta m_{21}^2 + m_1^2} \frac{\tan^2 \theta_{13}}{\sin^2 \theta_{12}}} \right] \\ |m_{\beta\beta}|_{min}^{(1)} = \sqrt{\Delta m_{21}^2 + m_1^2 \sin^2 \theta_{12} \cos^2 \theta_{13}} \left[1 - \sqrt{1 - \frac{\Delta m_{21}^2}{\Delta m_{21}^2 + m_1^2} \cot^2 \theta_{12}} - \sqrt{1 - \frac{\Delta m_{21}^2}{\Delta m_{21}^2 + m_1^2} + \frac{\Delta m_{21}^2 + \Delta m_{32}^2}{\Delta m_{21}^2 + m_1^2} \frac{\tan^2 \theta_{13}}{\sin^2 \theta_{12}}} \right] \\ |m_{\beta\beta}|_{min}^{(2)} = \sqrt{\Delta m_{21}^2 + m_1^2 \sin^2 \theta_{12} \cos^2 \theta_{13}} \left[\sqrt{1 - \frac{\Delta m_{21}^2}{\Delta m_{21}^2 + m_1^2}} \times \cot^2 \theta_{12} - 1 - \sqrt{1 - \frac{\Delta m_{21}^2}{\Delta m_{21}^2 + m_1^2} + \frac{\Delta m_{21}^2 + \Delta m_{32}^2}{\Delta m_{21}^2 + m_1^2} \frac{\tan^2 \theta_{13}}{\sin^2 \theta_{12}}} \right] \end{array} \right. \quad (11)$$

For the IH case, where $m_3 < m_1 < m_2$, the equations are as follows:

$$\left\{ \begin{array}{l} |m_{\beta\beta}|_{max} = \sqrt{m_3^2 - \Delta m_{32}^2 \sin^2 \theta_{12} \cos^2 \theta_{13}} \left[1 + \sqrt{1 - \frac{\Delta m_{21}^2}{m_3^2 - \Delta m_{32}^2} \cot^2 \theta_{12}} + \sqrt{1 - \frac{\Delta m_{21}^2}{m_3^2 - \Delta m_{32}^2} + \frac{\Delta m_{21}^2 - \Delta m_{32}^2}{m_3^2 - \Delta m_{32}^2} \frac{\tan^2 \theta_{13}}{\sin^2 \theta_{12}}} \right] \\ |m_{\beta\beta}|_{min} = \sqrt{m_3^2 - \Delta m_{21}^2 \sin^2 \theta_{12} \cos^2 \theta_{13}} \left[\sqrt{1 - \frac{\Delta m_{21}^2}{m_3^2 - \Delta m_{32}^2}} \times \cot^2 \theta_{12} - 1 - \sqrt{1 - \frac{\Delta m_{21}^2}{m_3^2 - \Delta m_{32}^2} + \frac{\Delta m_{21}^2 - \Delta m_{32}^2}{m_3^2 - \Delta m_{32}^2} \frac{\tan^2 \theta_{13}}{\sin^2 \theta_{12}}} \right] \end{array} \right. \quad (12)$$

We illustrate the relationship between $|m_{\beta\beta}|$ and the minimum neutrino mass m_L in Figure 2, utilizing the parameters specified in equations 7 and 8. We vary the relevant CP-violating phases within the range of 0 to 2π .

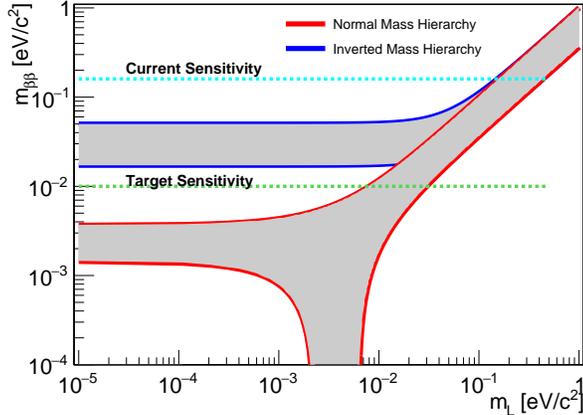

FIG. 2. The variation of $|m_{\beta\beta}|$ with m_L in the NH or IH of three neutrino masses is depicted. The input parameters from equations 7 and 8 are utilized, with the relevant CP-violating phases allowed to range from 0 to 2π . Additionally, the current sensitivities from KamLAND-Zen and GERDA are included, along with the planned ton-scale experiments such as LEGEND-1000²⁶, nEXO²⁷, and CUPID²⁸.

In Figure 2, the gray area represents the allowed regions for $|m_{\beta\beta}|$ concerning m_L . In the IH scenario, when m_L is below 1 meV/c², the allowed region for $|m_{\beta\beta}|$ appears nearly flat. This region is targeted by upcoming ton-scale experiments like LEGEND-1000, nEXO, and CUPID. Conversely, in the NH scenario, the allowed region exhibits a pronounced dependence on m_L . For m_L below $\sim 5 \times 10^{-4}$ eV/c², the $|m_{\beta\beta}|$ region remains almost flat, surpassing 1 meV/c². However, within the range $[\sim 2 \times 10^{-3}, \sim 7 \times 10^{-3}]$ eV/c², $|m_{\beta\beta}|$ tends towards zero.

It's evident from Figure 2 that the planned ton-scale experiments will comprehensively explore the IH region. Therefore, our focus will be on accessing sensitivity for the NH case. We aim to investigate the feasibility of constructing a sensitive experiment capable of detecting the $0\nu\beta\beta$ decay process if neutrino masses adhere to normal ordering.

IV. DISCUSSION ON m_L AND PROSPECTIVE EXPERIMENTS SENSITIVE TO THE NH REGION

To investigate the NH region for the $0\nu\beta\beta$ decay process, it's imperative to avoid m_L falling within the range of $[\sim 2 \times 10^{-3}, \sim 7 \times 10^{-3}]$ eV/c², as indicated in Figure 2. With this consideration, our first step is to examine the value of $m_L = m_1$ for a given allowed Σ . The solution must satisfy the following condition:

$$m_L + \sqrt{\Delta m_{21}^2 + m_L^2} + \sqrt{\Delta m_{32}^2 + \Delta m_{21}^2 + m_L^2} - \Sigma = 0. \quad (13)$$

Equation 13 must be solved numerically for a given value of Σ . Figure 3 illustrates the relationship between m_L and a given Σ .

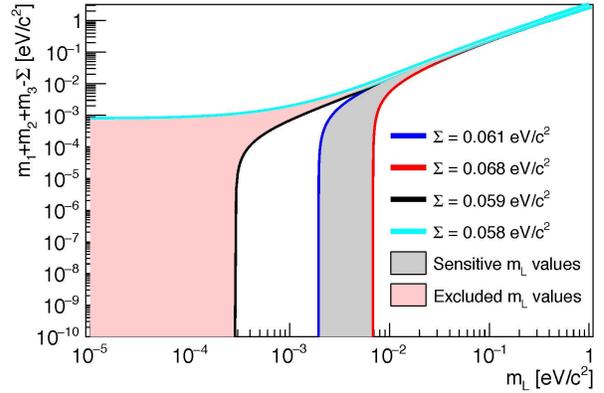

FIG. 3. The plot illustrates the solution for $m_1 + m_2 + m_3 - \Sigma = 0$ when a Σ value is specified. The gray area represents where the value of $|m_{\beta\beta}|$ approaches zero, while the light-red region indicates excluded values of m_L due to the absence of a solution.

Numerical solutions indicate that when Σ ranges between 0.059 and 0.061 eV/c², Equation 13 is satisfied. This corresponds to m_L falling within the region $[3 \times 10^{-4}, 2 \times 10^{-3}]$ eV/c². However, when $\Sigma = 0.058$ eV/c², Equation 13 is violated, indicating no suitable values of m_L exist and thus excluding that range. Furthermore, for Σ in the range $[0.061, 0.068]$ eV/c², m_L drives $|m_{\beta\beta}|$ to zero, as depicted in Figure 2.

It's evident that only a narrow range of m_L is viable for determining $|m_{\beta\beta}|$ in future experiments beyond the ton-scale. This viable region spans $m_L = [3 \times 10^{-4}, 2 \times 10^{-3}]$ eV/c². Additionally, the distribution of m_1 , m_2 , and m_3 for a given Σ is visualized in Figure 4.

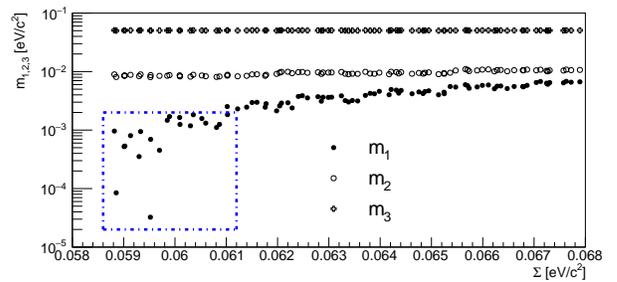

FIG. 4. Displayed is the solution for the neutrino masses m_1 , m_2 , and m_3 for a given allowed Σ . The box outlined by dashed blue lines indicates the potential non-zero values of m_1 .

In the NH scenario, it's noteworthy that the sum of masses falls within the range of 0.059 to 0.061 eV/c², consequently leading to a non-zero m_1 , as depicted in Figure 4.

All the results depicted in Figures 3 and 4 indicate that the minimum neutrino mass is non-zero. This suggests that only the Majorana-violating phases can drive $|m_{\beta\beta}|$ to zero when

m_L falls within the range of $[2 \times 10^{-3}, 7 \times 10^{-3}]$ eV/c². There exists a parameter space for $|m_{\beta\beta}|$ where its value is in the region of ~ 1 meV/c², corresponding to the sensitivity achievable with a 100-ton-scale experiment.

Using ⁷⁶Ge as an example, the sensitivity to the effective neutrino mass is linked to the upper limit of the half-life, determined as:

$$T_{\frac{1}{2}} = 4.17 \times 10^{26} \left(\frac{\varepsilon \cdot a}{W} \right) \frac{M \cdot t}{\mu}, \quad (14)$$

where $T_{\frac{1}{2}}$ is the decay half-life in years, ε is the detection efficiency, a is the isotopic abundance (92% for ⁷⁶Ge), W is the molar mass of the source material, M is the total mass of the source in kg, t is the run time in years, and μ is the Poisson signal mean constrained by the number of background events (B) in the region of interest (ROI). We express B as:

$$B = M \cdot t \cdot b \cdot \Delta E, \quad (15)$$

where b is the number of background events per kg per keV per year, and $\Delta E = 3.0$ keV is the width of the ROI.

A 90% confidence level interval for the Poisson signal mean (μ) is provided in TABLE XII of Ref.²⁹ when the total number of events observed (n_0) and the mean background (b) are known.

Using equation 14 and parameters similar to those of LEGEND-1000²⁶, we demonstrate the sensitivity of such an experiment in Figure 5. It's apparent that achieving a half-life of 10^{30} years with a 10-year exposure requires a background index of 0.001 events/t-y, which presents a considerable challenge. This underscores the necessity for significant research and development (R&D) efforts to be initiated as early as possible.

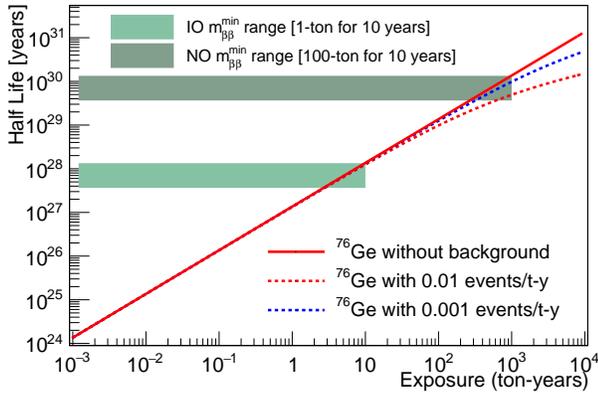

FIG. 5. The sensitivity for measuring the half-life of ⁷⁶Ge decay is illustrated for a future 100-ton scale experiment utilizing similar technology to LEGEND-1000.

Using equation 1 and defining $F_N = G^{0\nu}(E_0, Z) |M_f^{0\nu} - (\frac{g_A}{g_V})^2 M_{GT}^{0\nu}|^2$, if a nuclear structure parameter $F_N = 7.01 \times 10^{14}/y$ is employed³¹, the effective neutrino mass $|m_{\beta\beta}|$ can

be expressed in terms of the calculated F_N and the measured half-life as:

$$|m_{\beta\beta}| = \frac{m_e}{\sqrt{F_N T_{1/2}^{0\nu}}}, \quad (16)$$

where m_e is the electron mass. The measurable half-life for a 100-ton scale ⁷⁶Ge-based experiment is depicted in Figure 6.

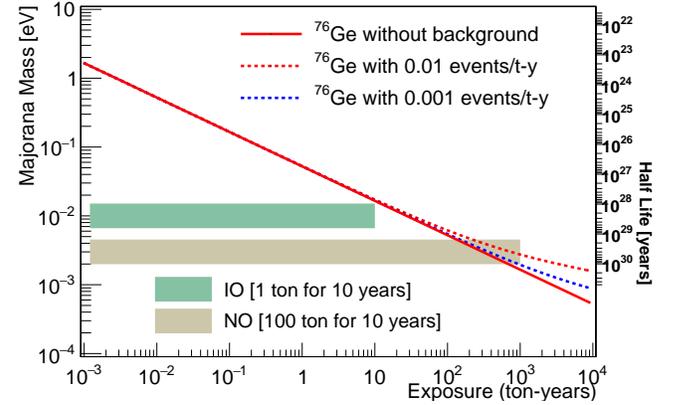

FIG. 6. Displayed is the sensitivity for a prospective 100-ton scale ⁷⁶Ge experiment, leveraging technology akin to that of LEGEND-1000.

As depicted in Figures 5 and 6, constructing a 100-ton scale experiment allows for comprehensive exploration of the ~ 1 meV/c² region in the NH scenario, with the corresponding half-life approaching approximately 10^{30} years. This endeavor entails the preparation of enriched materials over a few years, alongside ongoing R&D efforts aimed at continuously reducing backgrounds. Simultaneously, the scientific community is advancing towards ton-scale experiments to fully investigate the 10 meV/c² region in the IH scenario. Notably, the JUNO Collaboration is investigating the feasibility of dissolving ¹³⁰Te or ¹³⁶Xe isotopes into liquid scintillator to create a 100-ton scale experiment aimed at exploring the $|m_{\beta\beta}| \approx 1$ meV/c² region³⁰. Additionally, the DUNE experiment is contemplating the use of a Xe-Doped liquid argon TPC as a platform for $0\nu\beta\beta$ decay, targeting a sensitivity of $|m_{\beta\beta}| \approx 2$ meV³². The critical aspect for achieving sensitivity to ~ 1 meV in NH with a 100-ton scale experiment lies in reducing the background to a level of 1 event per kiloton per year in the ROI, as illustrated in Figure 5 and 6. Additionally, exceptional energy resolution is essential for discerning events from $2\nu\beta\beta$ decays. Both concepts proposed by JUNO and DUNE will face considerable challenges in meeting these two critical requirements.

V. CONCLUSION

Utilizing constraints from cosmology and neutrino oscillation experiments, we discuss the permissible parameter space

of $|m_{\beta\beta}|$ for both the inverted hierarchy (IH) and normal hierarchy (NH) scenarios. Given the current planned ton-scale experiments aimed at addressing the sensitivity across the entire region of IH, we focus our discussion on the allowed regions of $|m_{\beta\beta}|$ for NH. It becomes evident that the minimum neutrino mass (m_L) is non-zero in the NH case. To explore a non-zero $|m_{\beta\beta}|$, it is imperative to circumvent the region where the minimum mass lies between 3×10^{-4} to 2×10^{-3} eV/c² for NH. An achievable value of $|m_{\beta\beta}|$ is approximately 1 meV/c². We elucidate the importance for future experiments to attain this sensitivity. With such heightened sensitivity, attainable through a high-capacity experiment (100-ton scale), the likelihood of observing signal events of $0\nu\beta\beta$ decays substantially increases.
