

CHARACTER SUMS AND THE RIEMANN HYPOTHESIS

BRIAN CONREY

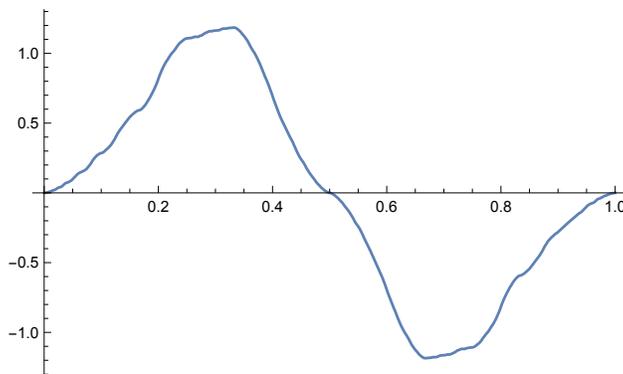

Dedicated to Henryk on his semisesquicentennial

ABSTRACT. We prove that an innocent looking inequality implies the Riemann Hypothesis and show a way to approach this inequality through sums of Legendre symbols.

Let

$$f(x) = \sum_{n=1}^{\infty} \frac{\lambda(n) \sin 2\pi n x}{n^2}$$

where λ is the Liouville lambda-function¹. Since $|\lambda(n)| = 1$, this series is absolutely convergent for real x , so that f is continuous, odd and periodic with period 1 on \mathbb{R} . Here is a plot of $f(x)$ for $0 \leq x \leq 1$ using 1000 terms of the series defining f :

Theorem 1. *If $f(x) \geq 0$ for $0 \leq x \leq 1/4$, then the Riemann Hypothesis is true.*

Theorem 1 is deceptive in that it looks like it should be a simple matter to prove that $f(x)$ is non-negative. A problem is that it is not clear whether $f(x)$ is differentiable or not, and even if it is it would be difficult to estimate the derivative. So, proving that $f(x) > 0$ at some point doesn't immediately tell us about $f(x)$ at nearby points.

The “1/4” in Theorem 1 can be replaced by any positive constant. So the real issue is trying to prove that $f(x) > 0$ for small positive x .

Research supported by an FRG grant from NSF.

¹ λ is completely multiplicative and takes the value -1 on primes so that $\lambda(p_1^{e_1} \dots p_r^{e_r}) = (-1)^{e_1 + \dots + e_r}$.

Note that

$$\left| \sum_{n=N+1}^{\infty} \frac{\lambda(n) \sin 2\pi nx}{n^2} \right| < \int_N^{\infty} u^{-2} du = \frac{1}{N}$$

so that if for some x there is an N such that

$$(1) \quad \sum_{n=1}^N \frac{\lambda(n) \sin 2\pi nx}{n^2} \geq \frac{1}{N}$$

then, it must be the case that $f(x) > 0$. We will use this idea a little later.

We can give an “explicit formula” for f in terms of the zeros $\rho = \beta + i\gamma$ of ζ :

Theorem 2. *Assuming the Riemann Hypothesis,*

$$f(x) = -\frac{4\pi^2 x^{3/2}}{3\zeta(1/2)} - \frac{8\pi^2}{3} x^{3/2} \sum_{n \leq 4x} \frac{\ell(n)}{\sqrt{n}} \left(1 - \frac{n}{4x}\right)^{3/2} + \pi \lim_{T \rightarrow \infty} \sum_{\substack{\rho=1/2+i\gamma \\ |\gamma| \leq T}} \operatorname{Res}_{z=\rho-1} \frac{X(1-z)\zeta(2z+2)x^{1-z}}{(1-z)\zeta(z+1)}.$$

Here $\ell(n)$ is defined through its generating function

$$\sum_{n=1}^{\infty} \ell(n)n^{-s} = \frac{\zeta(2s-1)}{\zeta(s)}$$

for $\Re s > 1$. Also, $X(s)$ is the factor from the functional equation for $\zeta(s)$ which can be defined by

$$X(s)^{-1} = X(1-s) = \frac{\zeta(1-s)}{\zeta(s)} = 2(2\pi)^{-s} \Gamma(s) \cos \frac{\pi s}{2}.$$

Note that if the zeros of $\zeta(s)$ are simple, then the term with the sum over the zeros of ζ becomes

$$\pi \sum_{\rho} \frac{X(2-\rho)\zeta(2\rho)x^{2-\rho}}{(2-\rho)\zeta'(\rho)}.$$

Theorem 2 is nearly a converse to Theorem 1 in the sense that if RH is true and all the zeros are simple and

$$(2) \quad \sum_{\rho} \left| \frac{X(2-\rho)\zeta(2\rho)}{(2-\rho)\zeta'(\rho)} \right| \leq -\frac{4\pi}{3\zeta(1/2)}$$

then $f(x) \geq 0$ for $0 \leq x \leq 1/4$. Note that

$$-\frac{4\pi}{3\zeta(1/2)} = 2.86834 \dots$$

and

$$\sum_{|\gamma| \leq 1000} \left| \frac{X(2-\rho)\zeta(2\rho)}{(2-\rho)\zeta'(\rho)} \right| = 0.264954 \dots$$

so that the inequality (2) seems plausible.

Finally we remark that the formula of Theorem 2 for $f(x)$ hides very well the fact that $f(x)$ is periodic with period 1!

1. PRIOR RESULTS

There has been quite a lot of work connecting partial weighted sums of the Liouville and the Riemann Hypothesis. We refer to [BFM] for a nice description of past work. In this paper the authors prove that the smallest value of x for which

$$\sum_{n \leq x} \frac{\lambda(n)}{n} < 0$$

is $x = 72185376951205$.

2. CHARACTER SUMS

A possible approach to proving that $f(x) > 0$ for small $x > 0$ lies in the fact that λ is completely multiplicative and takes the values ± 1 . This scenario resembles quadratic Dirichlet characters (for simplicity think Legendre symbols) except that Dirichlet characters can also take the value 0. By the Chinese Remainder Theorem, for any N there is a prime number q such that $\lambda(n) = \left(\frac{n}{q}\right)$ for all $n \leq N$ where $\left(\frac{\cdot}{q}\right)$ is the Legendre symbol² mod q . As an example:

$$\lambda(n) = \left(\frac{n}{163}\right)$$

for all $n \leq 40$, but they differ at $n = 41$.

Let

$$f_q(x) = \sum_{n=1}^{\infty} \frac{\left(\frac{n}{q}\right) \sin 2\pi nx}{n^2}$$

be the Fourier sine series with $\lambda(n)$ replaced by $\left(\frac{n}{q}\right)$. If $f_q(x) \geq 0$ for $0 \leq x \leq 1/4$ for a sufficiently large set of q , then it must also be the case that $f(x) \geq 0$ for $0 \leq x \leq 1/4$. (The proof is that if $f(x_0) < 0$ for some $0 < x_0 < 1/4$, then we can find a q such that $\left(\frac{n}{q}\right) = \lambda(n)$ for all $n \leq N$ where N is chosen so large that $|f(x_0)| > 1/N$; then it must be the case by the analog of (1) for f_q that $f_q(x_0) < 0$.) The same assertion but with q restricted to primes congruent to 3 mod 8 is also valid, since the Legendre symbols for these q can also imitate $\lambda(n)$ for arbitrarily long stretches $1 \leq n \leq N$. We can express this as follows:

Theorem 3. *If*

$$f_q(x) \geq 0$$

for all $0 \leq x \leq 1/4$ and all primes q congruent to 3 mod 8, then the Riemann Hypothesis is true.

² $\left(\frac{n}{q}\right) = 0$ if $(n, q) > 1$; $\left(\frac{n}{q}\right) = +1$ if n is a square mod q ; and $\left(\frac{n}{q}\right) = -1$ if n is not a square modulo q .

Remark 1. *We could just as well have stated this theorem for $q \equiv 3 \pmod{4}$. However, the intention is that we are interested in q for which χ_q imitates λ . Insisting that $\chi_q(2) = -1$ leads to the condition that $q \equiv 3 \pmod{8}$.*

The sums $f_q(x)$ still have the same problem in that it is tricky to prove for sure that they are positive for small positive x . However, the analogue of Theorem 2 above is much simpler, is unconditional, and leads to a straightforward way to check, for any given fixed q , that $f_q(x) \geq 0$ for $0 \leq x \leq 1/4$.

Theorem 4. *Let $x \geq 0$. Let $q \equiv 3 \pmod{8}$ be squarefree. Then*

$$f_q(x) = 2\pi x L_q(1) - \frac{2\pi^2 x}{\sqrt{q}} \sum_{n \leq xq} \binom{n}{q} \left(1 - \frac{n}{xq}\right)$$

where

$$L_q(1) = \sum_{n=1}^{\infty} \frac{\binom{n}{q}}{n}.$$

Now Dirichlet's class number formula enters the picture. Let $K = \mathbb{Q}(\sqrt{-q})$ be the imaginary quadratic field obtained by adjoining $\sqrt{-q}$ to the rationals \mathbb{Q} . Let $h(q)$ be the class number³ of K . Dirichlet's formula is

$$h(q) = \frac{\sqrt{q}}{\pi} L_q(1)$$

for squarefree $q \equiv 3 \pmod{4}$ and $q > 3$; (see [D] or [IK]). Thus, the Theorem above can be rephrased in terms of $h(q)$. Moreover, we can express $L_q(1)$ as a finite character sum

$$L_q(1) = -\frac{\pi}{q^{3/2}} \sum_{n=1}^q n \binom{n}{q}.$$

Since $\binom{n}{q}$ is an odd function of q we also have

$$L_q(1) = -\frac{2\pi}{q^{3/2}} \sum_{n=1}^{\frac{q-1}{2}} n \binom{n}{q}$$

and

$$h(q) = S_q\left(\frac{q}{2}\right)$$

where

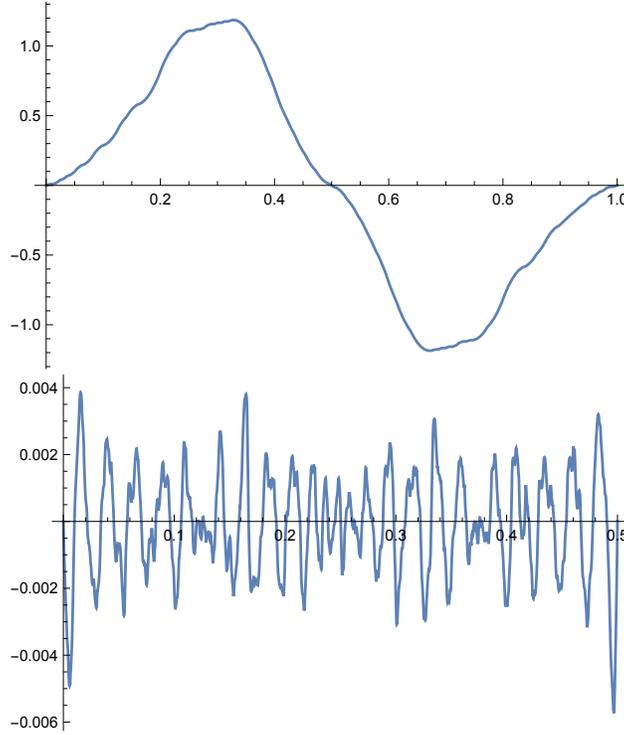

$$S_q(N) := \sum_{n \leq N} \binom{n}{q} \left(1 - \frac{n}{N}\right).$$

³The class number is a measure of how close to unique factorization the integers of K are; $h(q) = 1$ means the integers of K can be factored into primes in only one way.

Corollary 1. *Let $q > 3$ be squarefree with $q \equiv 3 \pmod{8}$. Then*

$$f_q(x) = \frac{2\pi^2 x}{\sqrt{q}} \left(S_q\left(\frac{q}{2}\right) - S_q(qx) \right).$$

Here is a plot of $f_{163}(x) = \frac{2\pi^2 x}{\sqrt{163}}(S_{163}(\frac{163}{2}) - S_{163}(163x))$ for $0 \leq x \leq 1$ and a plot of the difference $f(x) - f_{163}(x)$:

We can use the corollary to prove that $f_{163}(x) \geq 0$ for $0 \leq x \leq 1/2$ and consequently that $f(x) \geq 0$ for $1/4 > x \geq 0.043$ as follows.

$$\begin{aligned} f(x) &= \sum_{n=1}^{40} \frac{\lambda(n) \sin 2\pi nx}{n^2} + \frac{\Theta}{40} = \sum_{n=1}^{40} \frac{\chi_{163}(n) \sin 2\pi nx}{n^2} + \frac{\Theta}{40} = f_{163}(x) + \frac{\Theta}{20} \\ &= \frac{2\pi^2 x}{\sqrt{163}} \left(S_{163}\left(\frac{163}{2}\right) - S_{163}(163x) \right) + \frac{\Theta}{20} \end{aligned}$$

where Θ denotes a number with absolute value at most 1, not necessarily the same at each occurrence. Now for a an integer, $S_{163}(163x)$ is constant for x in the interval $[\frac{a}{163}, \frac{a+1}{163})$. Therefore, $f_{163}(x) \geq \min\{f_{163}(\frac{a}{163}), f_{163}(\frac{a+1}{163})\}$ for x in this interval. We can tabulate these values:

a	1	2	3	4	5	6	7	8	9	10
$f_{163}(\frac{a}{163})$	0.0095	0.0095	0.019	0.038	0.047	0.066	0.076	0.095	0.12	0.14

Since $\frac{\theta}{20} \leq .05$ it follows from (1) that $f(x) \geq 0$ for $0.25 \geq x \geq \frac{7}{163} = 0.043$.

Corollary 2. $f(x) \geq 0$ for $0.043 \leq x \leq 0.25$.

It seems clear that for any given $\epsilon > 0$ we could replace 0.043 by ϵ in this inequality with enough computation time. Also, if we use Euler products instead of Dirichlet series we can show that $f(x) \geq 0$ for $1/4 \geq x \geq 0.011$.

The following conjecture seems surprising.

Conjecture 1. If $q \equiv 3 \pmod{8}$ is squarefree, then $f_q(x) \geq 0$ for $0 \leq x \leq 1/2$.

Remark 2. J. Bober has checked that this inequality is true for all primes $q \equiv 3 \pmod{8}$ up to 10^9 .

Now we turn to the proofs.

3. USEFUL LEMMAS

Lemma 1. For $y > 0$ we have

$$\frac{1}{2\pi i} \int_{(c)} \frac{X(1-s)y^{1-s}}{1-s} ds = \frac{\sin 2\pi y}{\pi}$$

for any c satisfying $0 < c < 1$ where (c) denotes the path from $c - i\infty$ to $c + i\infty$

The integrand has simple poles at $s = 0, -2, -4, \dots$ with the residue at $s = -2n$ equal to

$$\frac{1}{\pi} \frac{(-1)^n (2\pi y)^{2n+1}}{(2n+1)!}.$$

Summing these leads to the desired formula. See also [T]; the above is the integral of the formula (7.9.5).

Lemma 2. If $c > 0$ and $\Re a > 0$, then

$$\frac{1}{2\pi i} \int_{(c)} \frac{\Gamma(s)\Gamma(a)}{\Gamma(s+a)} x^{-s} ds = \begin{cases} (1-x)^{a-1} & \text{if } 0 < x < 1 \\ 0 & \text{if } x \geq 1 \end{cases}$$

This formula is (7.7.14) of [T].

Lemma 3. If $c > 0$, then

$$\frac{1}{2\pi i} \int_{(c)} \frac{x^s}{s(s+1)} ds = \begin{cases} 1 - \frac{1}{x} & \text{if } x > 1 \\ 0 & \text{if } 0 < x \leq 1 \end{cases}$$

This lemma is well-known and is easy to verify.

4. PROOFS OF THEOREMS

Proof of Theorem 1. This assertion is a consequence of Landau's Theorem: "If $g(n) \geq 0$ then the right-most singularity of $\sum_{n=1}^{\infty} g(n)n^{-s}$ is real." This is theorem 10 of [HR] and Theorem 1.7 of [MV1]. What we actually need is an integral version of this theorem: "If $g(x) \geq 0$ then the right-most singularity of $\int_1^{\infty} g(x)x^{-s} dx$ is real." The proof of this version is essentially the same as that of the first version (see Lemma 15.1 of [MV1]). The application to our situation is slightly subtle. We argue as follows. Since

$$\sum_{n=1}^{\infty} \lambda(n)n^{-s} = \frac{\zeta(2s)}{\zeta(s)}$$

it follows from Lemma 1 that

$$\frac{f(x)}{\pi} = \frac{1}{2\pi i} \int_{(c)} \frac{X(1-s)}{1-s} \frac{\zeta(2s+2)}{\zeta(s+1)} x^{1-s} ds$$

where $0 < c < 1$. The integral is absolutely convergent for $0 < c < 1/2$. By Mellin inversion we have

$$\frac{\pi X(1-s)}{1-s} \frac{\zeta(2s+2)}{\zeta(s+1)} = \int_0^{\infty} f(x)x^{s-2} dx.$$

We split the integral into two integrals at $x = 4$ so that

$$\frac{\pi X(1-s)}{1-s} \frac{\zeta(2s+2)}{\zeta(s+1)} = \int_0^4 f(x)x^{s-2} dx + \int_4^{\infty} f(x)x^{s-2} dx = I_1(s) + I_2(s),$$

say. The integral defining $I_1(s)$ is absolutely convergent for $\sigma > 1$ and the second integral is absolutely convergent for $\sigma < 1$. Using the periodicity of f we can show that the second integral converges for $\sigma < 2$. Indeed, let

$$F(x) = \int_0^x f(t) dt.$$

Then $F(n) = 0$ for all integers n and F is bounded. Therefore,

$$\begin{aligned} I_2(s) &= \sum_{n=4}^{\infty} \int_n^{n+1} f(x)x^{s-2} dx = \sum_{n=4}^{\infty} \left(F(x)x^{s-2} \Big|_{x=n}^{x=n+1} - (s-2) \int_n^{n+1} F(x)x^{s-3} dx \right) \\ &= -(s-2) \int_4^{\infty} F(x)x^{s-3} dx. \end{aligned}$$

This integral converges for $\Re s < 2$. So, we now have I_2 analytic for $\Re s < 2$. Clearly, $I_1 + I_2$ is analytic for $\Re s > \max\{-1/2, \rho - 1\}$ i.e. for $\Re s > 0$. (The pole of $X(1-s)$ at $s = 0$ is canceled by the zero of $1/\zeta(s+1)$ at $s = 0$.) It follows that $I_1(s) = (I_1(s) + I_2(s)) - I_2(s)$ is analytic for $\Re s > 0$. It follows that $I_2(s)$ is also analytic for $\Re s > 0$, and since we already knew it was analytic for $\Re s < 2$ it follows that $I_2(s)$ is entire. Now, we can write I_1 as

$$I_1(s) = \int_{1/4}^{\infty} f(1/x)x^{-s} dx.$$

Recall we have assumed that $f(1/x) \geq 0$ for $x \geq 4$. Therefore, by Landau's theorem, the rightmost singularity of $I_1(s)$ is real. Since I_2 is entire, it follows that the rightmost pole of $I_1(s) + I_2(s)$ must also be real. But the rightmost real pole of

$$I_1(s) + I_2(s) = \frac{\pi X(1-s) \zeta(2s+2)}{1-s \zeta(s+1)}$$

is at $s = -1/2$. This must be the rightmost pole. Therefore the poles at $\rho - 1$ must all have their real parts less than or equal to $-1/2$. In particular, $\Re \rho \leq 1/2$, which is RH.

Proof of Theorem 2. We start again from

$$\frac{f(x)}{\pi} = \frac{1}{2\pi i} \int_{(c)} \frac{X(1-s) \zeta(2s+2) x^{1-s}}{(1-s) \zeta(s+1)} ds$$

where $0 < c < 1/2$. The integrand has poles only at $s = -\frac{1}{2}$ and at $s = \rho - 1$ where ρ is a complex zero of $\zeta(s)$ and nowhere else in the s -plane. The residue at $s = -\frac{1}{2}$ is

$$\frac{X(\frac{3}{2})}{\frac{3}{2}\zeta(\frac{1}{2})} x^{3/2} = -\frac{4\pi}{3\zeta(\frac{1}{2})} x^{3/2}.$$

Assuming that the zeros are simple, the residue at $s = \rho - 1$ is

$$\frac{X(2-\rho) \zeta(2\rho) x^{2-\rho}}{(2-\rho) \zeta'(\rho)}.$$

We (carefully) move the path of integration to (c) where $-2 < c < -1$. To do this we have to cross through a field of poles arising from the zeros of the zeta function. To do this we use Theorem 14.16 of [T1] (see also [R]) to find a path on which $1/\zeta(s+1) \ll T^\epsilon$ where we can safely cross. Using the bounds $|X(1-s)| \ll T^{\sigma-1/2}$ and $\zeta(2s+2) \ll T^{-\frac{1}{2}-\sigma}$ we can get the sum of the residues arising from the zeros up to height T together with an error term that tends to 0 as $T \rightarrow \infty$. Thus, assuming the zeros are simple,

$$\frac{f(x)}{\pi} = -\frac{4\pi x^{3/2}}{3\zeta(1/2)} + \sum_{\rho} \frac{X(2-\rho) \zeta(2\rho) x^{2-\rho}}{(2-\rho) \zeta'(\rho)} + \frac{1}{2\pi i} \int_{(c)} \frac{X(1-s) \zeta(2s+2) x^{1-s}}{(1-s) \zeta(s+1)} ds.$$

If the zeros are not simple we modify the sum over zeros appropriately. We make the change of variable $s \rightarrow -s$ in the integral. Using the functional equation for the ζ -function and functional relations for the Γ -function, we see that the new integrand is

$$\frac{X(1+s) \zeta(2-2s) x^{1+s}}{(1+s) \zeta(1-s)} = -\pi^{3/2} 2^{2s} \frac{\Gamma(s-\frac{1}{2}) \zeta(2s-1)}{\Gamma(s+2) \zeta(s)} x^{1+s}.$$

By Lemma 2,

$$\frac{1}{2\pi i} \int_{(c)} \pi^{3/2} 2^{2s} \frac{\Gamma(s-\frac{1}{2}) \zeta(2s-1)}{\Gamma(s+2) \zeta(s)} x^{1+s} = \frac{8\pi}{3} x^{3/2} \sum_{n \leq 4x} \frac{\ell(n)}{\sqrt{n}} \left(1 - \frac{n}{4x}\right)^{3/2}.$$

Then Theorem 2 follows.

Proof of Theorem 4. We denote $\chi_q(n) = \left(\frac{n}{q}\right)$. By Lemma 1,

$$(3) \quad f_q(x) = \frac{\pi}{2\pi i} \int_{(c)} L(s+1, \chi_q) X(1-s)x^{1-s} \frac{ds}{1-s}$$

where $0 < c < 1$. Since χ_q is odd, we find that the integrand has a pole at $s = 0$ and nowhere else in the complex plane. We move the path of integration to (c) where $c < -1$ to see that

$$f_q(x) = 2\pi x L(1, \chi_q) + \frac{\pi}{2\pi i} \int_{(c)} L(s+1, \chi_q) X(1-s)x^{1-s} \frac{ds}{1-s}.$$

Now let $s \rightarrow -s$ in the integral and use the functional equation (see [D], [IK] or [MV1])

$$L(1-s, \chi_q) = 2q^{s-\frac{1}{2}} (2\pi)^{-s} \Gamma(s) \sin \frac{\pi s}{2} L(s, \chi_q).$$

After simplification, the integral above is

$$\frac{-2\pi^2}{2\pi i} \int_{(c)} q^{s-\frac{1}{2}} x^{1+s} L(s, \chi_q) \frac{ds}{s(s+1)}.$$

By Lemma 3, this integral is

$$\frac{-2\pi^2 x}{\sqrt{q}} \sum_{n \leq xq} \chi_q(n) \left(1 - \frac{n}{xq}\right).$$

The proof of Theorem 4 is complete.

Remark 3. *Note that the non-negativity, for $0 < x < 1/4$, of the right-hand side of (3) implies the Riemann Hypothesis. This condition only involves Dirichlet L-functions with quadratic characters. Thus, information solely about Dirichlet L-functions potentially gives the Riemann Hypothesis. This example shows that different L-functions somehow know about each other.*

5. FURTHER REMARKS

Since

$$h(q) \gg_{\epsilon} q^{1/2-\epsilon}$$

we see that

$$f_q(x) \geq 0$$

for $a \ll x \ll q^{-1/2-\epsilon}$. In particular,

$$f_q(a/q) \geq 0$$

for $a \ll q^{1/2-\epsilon}$. But this doesn't give information about $f(x)$.

Also, the Polya-Vinogradov inequality tells us that

$$\max_N \left| \sum_{n=1}^N \chi_q(n) \right| \ll q^{1/2} \log q$$

and the work of Montgomery and Vaughan [MV] shows that the Riemann Hypothesis for $L(s, \chi)$ implies that

$$\max_N \left| \sum_{n=1}^N \chi_q(n) \right| \ll q^{1/2} \log \log q.$$

Moreover, it is known that the right hand side here can not be replaced by any function that goes to infinity slower. It is also known, assuming the Riemann Hypothesis for $L(s, \chi)$, that

$$L(1, \chi) \ll \log \log q.$$

Our desired inequality can be expressed in terms of $L(1, \chi)$ as

$$(4) \quad \max_{N \leq \frac{q}{4}} \sum_{n=1}^N \chi(n) \left(1 - \frac{n}{N}\right) \leq \frac{\sqrt{q}}{\pi} L(1, \chi).$$

It appears that both sides of this inequality can be as big as $\sqrt{q} \log \log q$.

A question is whether the converse of Theorem 1 is true. It might be possible to approach this by showing that the “ $\frac{3}{2}$ ” derivative of $f(x)$ is positive at $x = 0$ so that there is a small interval to the right of 0 for which $f(x) \geq 0$. This method, or trying to prove (2) directly, would involve explicit estimates (assuming RH) for $1/\zeta(s)$ in the critical strip; see [MV1] section 13.2 for a good approach to such explicit estimates.

Finally, we mention that $f(x)$ can be evaluated at a rational number $x = a/q$ as an average involving Dirichlet L-functions $L(s, \chi)$ where χ is a character modulo q .

6. EVALUATION OF $f_q(a/p)$.

Let $p < q$ and $(a, p) = 1$. We explicitly evaluate $f_q(a/p)$ as a sum over characters modulo p as follows. We have

$$\begin{aligned} f_q(a/p) &= \sum_{n=1}^{\infty} \frac{\chi_q(n) \sin \frac{2\pi an}{p}}{n^2} \\ &= \sum_{n=1}^{\infty} \frac{\chi_q(n)}{n^2} \frac{1}{\phi(p)} \Im \left\{ \sum_{\psi \bmod p} \tau(\psi) \bar{\psi}(an) \right\} \\ &= \frac{1}{\phi(p)} \Im \left\{ \sum_{\psi \bmod p} \tau(\psi) \bar{\psi}(a) \sum_{n=1}^{\infty} \frac{\chi_q(n) \psi(n)}{n^2} \right\} \\ &= \frac{1}{\phi(p)} \Im \left\{ \sum_{\psi \bmod p} \tau(\psi) \bar{\psi}(a) L(2, \chi_q \bar{\psi}) \right\}. \end{aligned}$$

Now, if ψ is even, then

$$\begin{aligned}\overline{\tau(\psi)} &= \sum_{n=1}^p \overline{\psi(n)}e(-an/p) = \sum_{n=1}^p \overline{\psi}(-n)e(an/p) \\ &= \sum_{n=1}^p \overline{\psi}(n)e(an/p) = \tau(\overline{\psi})\end{aligned}$$

while if ψ is odd then

$$\overline{\tau(\psi)} = -\tau(\overline{\psi}).$$

Thus, for even ψ

$$\Im \{ \tau(\psi)\overline{\psi}(a)L(2, \chi_q\overline{\psi}) + \tau(\overline{\psi})\psi(a)L(2, \chi_q\psi) \} = 0$$

and for odd ψ

$$\Im \{ \tau(\psi)\overline{\psi}(a)L(2, \chi_q\overline{\psi}) + \tau(\overline{\psi})\psi(a)L(2, \chi_q\psi) \} = 2\Im \{ \tau(\psi)\overline{\psi}(a)L(2, \chi_q\overline{\psi}) \}.$$

Therefore, using the fact that $\tau(\chi_p) = i\sqrt{p}$ when $p \equiv 3 \pmod{4}$, we have

$$f_q(a/p) = \frac{1}{\phi(p)} \sum_{\substack{\psi \pmod{p} \\ \psi(-1)=-1 \\ \psi^2 \neq \psi_0}} \Im \{ \tau(\psi)\overline{\psi}(a)L(2, \chi_q\overline{\psi}) \} + \delta(p \equiv 3 \pmod{4}) \frac{\sqrt{p}}{\phi(p)} \Re \{ \overline{\psi}(a)L(2, \chi_q\overline{\psi}) \}.$$

We use this to prove that

$$f_q(1/3) > 0 \quad \text{and} \quad f_q(1/5) > 0$$

for any q . By the formula above we have

$$f_q(1/3) = \frac{\sqrt{3}}{2}L(2, \chi_q\chi_3) > 0$$

and

$$\begin{aligned}f_q(1/5) &= \frac{2}{\phi(5)}\Im \{ (-1.17557 + 1.90211i)L(2, \chi_q\psi_1) \} \\ &= 1.9\alpha - 1.17\beta\end{aligned}$$

where $\psi_1 = \{1, i, -i, -1, 0\}$ with $\tau(\psi_1) = -1.17557 + 1.90211i$ and

$$\alpha + i\beta = L(2, \chi_q\psi_1) = 1 + \frac{\chi_q(2)i}{2^2} - \frac{\chi_q(3)i}{3^2} - \frac{\chi_q(4)}{4^2} + \dots$$

Now

$$\alpha \geq 1 - \frac{1}{4^2} - \frac{1}{5^2} - \dots = 0.716\dots$$

and

$$|\beta| < \frac{1}{2^2} + \frac{1}{3^2} + \dots = 0.64\dots$$

Thus,

$$f_q(1/5) > 0.6.$$

A couple of formulas may help us move forward here. One is that if θ_1 and θ_2 are characters with coprime moduli m_1 and m_2 respectively, then (see [IK, (3.16)])

$$\tau(\theta_1\theta_2) = \theta_1(m_2)\theta_2(m_1)\tau(\theta_1)\tau(\theta_2).$$

The other is that

$$L(1-r, \theta) = -\frac{m^{r-1}}{r} \sum_{b=1}^m \theta(b)B_r(b/m)$$

for a character θ modulo m and a positive integer r where B_r is the r th Bernoulli polynomial (see [Wa, Theorem 4.2]). Recall the functional equation (see [D]) for a primitive character $\theta \pmod{m}$:

$$L(1-s, \theta) = \left(\frac{m}{2\pi}\right)^s \Gamma(s)(e^{\pi is/2} + \theta(-1)e^{-\pi is/2})L(s, \bar{\theta})/\tau(\bar{\theta})$$

It follows that for an even $\theta = \chi_q\psi$, with $q \equiv 3 \pmod{4}$ and ψ an odd character modulo p ,

$$\begin{aligned} L(2, \chi\bar{\psi}) &= -\pi \left(\frac{pq}{2\pi}\right)^{-1} L(-1, \theta)/\tau(\theta) \\ &= -\pi \left(\frac{pq}{2\pi}\right)^{-1} L(-1, \chi\psi)/(\chi(p)\psi(q)\tau(\psi)i\sqrt{q}) \end{aligned}$$

Therefore,

$$\begin{aligned} \Im\{\tau(\psi)\bar{\psi}(a)L(2, \chi_q\bar{\psi})\} &= \Re\left\{\frac{2\pi^2\chi_q(p)\bar{\psi}(aq)}{pq^{3/2}}L(-1, \chi_q\psi)\right\} \\ &= -\Re\left\{\frac{\pi^2\chi_q(p)\bar{\psi}(aq)}{\sqrt{q}}\sum_{b=1}^{pq}\chi_q(b)\psi(b)B_2(b/(pq))\right\} \end{aligned}$$

We sum this equation over the odd characters modulo p using

$$\begin{aligned} \sum_{\substack{\psi \pmod{p} \\ \psi(-1)=-1}} \psi\left(\frac{b}{aq}\right) &= \frac{1}{2} \sum_{\psi \pmod{p}} (\psi\left(\frac{b}{aq}\right) - \psi\left(-\frac{b}{aq}\right)) \\ &= \frac{\phi(p)}{2} \begin{cases} 1 & \text{if } b \equiv aq \pmod{p} \\ -1 & \text{if } b \equiv -aq \pmod{p} \end{cases} \end{aligned}$$

This gives

$$\begin{aligned} &\sum_{\substack{\psi \pmod{p} \\ \psi(-1)=-1}} \Im\{\tau(\psi)\bar{\psi}(a)L(2, \chi_q\bar{\psi})\} \\ &= -\frac{\phi(p)}{2} \frac{\pi^2\chi_q(p)}{\sqrt{q}} \left(\sum_{\substack{b \leq pq \\ b \equiv aq \pmod{p}}} \chi_q(a)B_2(b/(pq)) - \sum_{\substack{b \leq pq \\ b \equiv -aq \pmod{p}}} \chi_q(a)B_2(b/(pq)) \right) \end{aligned}$$

Note that

$$B_2(x) = x^2 - x + 1/6.$$

Also,

$$\sum_{\substack{b \leq pq \\ b \equiv aq \pmod{p}}} \chi_q(b) - \sum_{\substack{b \leq pq \\ b \equiv -aq \pmod{p}}} \chi_q(b) = 0$$

and

$$\sum_{\substack{b \leq pq \\ b \equiv aq \pmod{p}}} b\chi_q(b) - \sum_{\substack{b \leq pq \\ b \equiv -aq \pmod{p}}} b\chi_q(b) = 0.$$

Thus,

$$\sum_{\substack{\psi \pmod{p} \\ \psi(-1)=-1}} \Im\{\tau(\psi)\bar{\psi}(a)L(2, \chi_q\bar{\psi})\} = -\frac{\pi^2\chi_q(p)}{2p^2q^{5/2}} \left(\sum_{\substack{b \leq pq \\ b \equiv aq \pmod{p}}} b^2\chi_q(b) - \sum_{\substack{b \leq pq \\ b \equiv -aq \pmod{p}}} b^2\chi_q(b) \right).$$

Thus, we have

Theorem 5. *For primes p and q both congruent to 3 modulo 4 and $1 \leq a < p/2$ we have*

$$f_q(a/p) = -\frac{\pi^2\chi_q(p)}{2p^2q^{5/2}} \left(\sum_{\substack{b \leq pq \\ b \equiv aq \pmod{p}}} b^2\chi_q(b) - \sum_{\substack{b \leq pq \\ b \equiv -aq \pmod{p}}} b^2\chi_q(b) \right).$$

and

Corollary 3. *If*

$$(5) \quad \text{test}_a(p, q) := -\chi_q(p) \left(\sum_{\substack{b \leq pq \\ b \equiv aq \pmod{p}}} b^2\chi_q(b) - \sum_{\substack{b \leq pq \\ b \equiv -aq \pmod{p}}} b^2\chi_q(b) \right) > 0$$

for all $p < q$ which are primes congruent to 3 modulo 8 and all $0 < a < p/2$, then the Riemann Hypothesis follows.

We note that by these techniques one can show

Theorem 6.

$$f_q(a/q) = \frac{\pi^2}{2\sqrt{q}} \left(\chi_q(a) - \frac{1}{q^2} \sum_{c=1}^{q-1} c^2(\chi_q(c-a) - \chi_q(c+a)) \right).$$

When this formula is compared with our earlier formula

$$f_q\left(\frac{a}{q}\right) = \frac{2\pi^2}{q^{3/2}} \left(\frac{a}{3} \sum_{n \leq \frac{q-1}{2}} \chi_q(n) - \sum_{n=1}^a (a-n)\chi_q(n) \right)$$

we deduce the identity

$$\frac{a}{3} \sum_{n \leq \frac{a-1}{2}} \chi_q(n) - \sum_{n=1}^a (a-n) \chi_q(n) = \frac{q}{4} \left(\chi_q(a) - \frac{1}{q^2} \sum_{c=1}^{q-1} c^2 (\chi_q(c-a) - \chi_q(c+a)) \right)$$

for $q \equiv 3 \pmod{4}$.

Now we indicate another possible direction.

Proposition 1. *If*

$$f_q(x) = 0$$

then x is a rational number.

Proof. By Corollary 1, $f_q(x) = 0$ implies that $S_q(q/2) - S_q(qx) = 0$. But $S_q(q/2) = h(q)$ is an integer. So $f_q(x) = 0$ implies that $S_q(qx)$ is a rational number. Now

$$S_q(qx) = \sum_{n \leq [qx]} \chi_q(n) \left(1 - \frac{n}{qx}\right) = \sum_{n \leq [qx]} \chi_q(n) - \frac{\sum_{n \leq [qx]} n \chi_q(n)}{qx}.$$

This has the shape integer $- \frac{\text{integer}}{qx}$ which can only be rational if x is a rational number. \square

So, it suffices to show that $f_q(x)$ has no rational zeros; perhaps a congruence argument could work. However, Theorem 5 is not much use here because the hypothetical x for which $f_q(x) = 0$ would likely have a denominator that is divisible by q , so the conditions of Theorem 5 don't hold.

We remark that there are rational values of x for which the numerator of $f_q(x)$ is congruent to 0 modulo q ; for example

$$f_{19}(25/76) = \frac{19}{25} \quad f_{19}(29/190) = \frac{19}{29} \quad f_{19}(30/209) = \frac{19}{30}.$$

These examples, which all seem to have an x with denominator divisible by q , might be worth studying further.

Here is one final formula that may or may not be useful. Suppose that $f_q(x) = 0$. Let $y = xq$. Then either

$$\sum_{n \leq y} \chi_q(n) = h(q) \quad \text{and} \quad \sum_{n \leq y} n \chi_q(n) = 0$$

or else y satisfies

$$y = \frac{\sum_{n \leq [y]} n \chi_q(n)}{\sum_{n \leq [y]} \chi_q(n) - h(q)}.$$

The first alternative seems unlikely as in that case there would be an interval on which $f_q(x)$ would be identically 0.

7. CONCLUSION

Conjecture 1 has been checked for primes up to 10^9 and it holds for those primes. However, probabilistic grounds call into question its truth for all primes $q \equiv 3 \pmod{8}$. Of course, one only needs its truth for a set of characters χ_q for which $\chi_q(n) = \lambda(n)$ for all $n \leq N_q$ where $N_q \rightarrow \infty$ with q . Presumably something like this is correct (and should be equivalent to RH), but it is not clear how to proceed. But the results of section 6, suggest a slightly alternative way forward which may have a more arithmetic flavor.
