## Abstract

Sepsis is a life-threatening condition caused by a dysregulated host response to infection. Recently, researchers have hypothesized that sepsis consists of a heterogeneous spectrum of distinct subtypes, motivating several studies to identify clusters of sepsis patients that correspond to subtypes, with the long-term goal of using these clusters to design subtype-specific treatments. Therefore, clinicians rely on clusters having a concrete medical interpretation, usually corresponding to clinically meaningful regions of the sample space that have a concrete implication to practitioners. In this article, we propose Clustering Around Meaningful Regions (CLAMR), a Bayesian clustering approach that explicitly models the medical interpretation of each cluster center. CLAMR favors clusterings that can be summarized via meaningful feature values, leading to medically significant sepsis patient clusters. We also provide details on measuring the effect of each feature on the clustering using Bayesian hypothesis tests, so one can assess what features are relevant for cluster interpretation. Our focus is on clustering sepsis patients from Moshi, Tanzania, where patients are younger and the prevalence of HIV infection is higher than in previous sepsis subtyping cohorts.

*Keywords:* Clustering, Informative prior, Meta analysis, Prior elicitation, Semi-supervised learning

## 1 INTRODUCTION

For hospitals across the world, the diagnosis and rapid treatment of sepsis is of paramount importance for improving in-hospital outcomes. Broadly, sepsis is defined as organ dysfunction resulting from

an immune response to an infection (Singer et al., 2016) and is the cause of one-third to one-half of in-hospital deaths in the USA (Liu et al., 2014). The catalyst for sepsis is usually a bacterial infection (Bennett et al., 2019), located in the lungs, brain, urinary tract, or digestive system (Tintinalli et al., 2016), but sepsis can also be a generalized systemic infection (e.g., bloodstream infection), and microbes causing sepsis also include fungal, viral, and protozoal pathogens. The clinical manifestations are dynamic, changing over the course of the illness. If not recognized and treated early, a patient is more likely to progress to a state of circulatory collapse, known as septic shock, which significantly increases the risk of mortality (Singer et al., 2016). Sepsis is life-threatening: even minor organ dysfunction in the presence of infection has a mortality rate of at least 10% (Singer et al., 2016), and septic shock is estimated to have as high as 25% mortality (Rowan et al., 2017). Once detected, prompt interventions, such as antibiotics, vasopressors (Rhodes et al., 2017), intravenous fluids (Rowan et al., 2017), or adjunctive corticosteroids (Annane et al., 2018) can improve outcomes.

However, despite its prevalence and risk, therapies specifically targeted towards treatment of sepsis, including early goal-directed therapy (EGDT), have not led to improved outcomes (Opal et al., 2014; Rowan et al., 2017; van der Poll et al., 2017). This phenomenon has been attributed to the hypothesis that the general condition of sepsis is comprised of heterogeneous and distinct subtypes which may respond better to treatment plans specifically oriented to the pathophysiology of these respective subtypes. For example, randomized trials of adjunctive corticosteroids in adults with sepsis had mixed results, and in pediatric patients adjunctive corticosteroids were associated with increased mortality in one subtype of septic shock (Wong et al., 2017). Sepsis subtypes have been derived by several studies which clustered in-hospital cohorts and found distinct patient groups, or *phenotypes*, using comparative mRNA transcriptional analysis of the patient’s immune response (Davenport et al., 2016; Scicluna et al., 2017; Wong et al., 2017; Sweeney et al., 2018). Given that these descriptions of sepsis subtypes were primarily based upon immunologic characteristics, the Sepsis Endotyping in Emergency Care (SENECA) project hypothesized that subtypes could also be derived from routine clinical information that is readily extractable from patient electronic health record sources (Seymour et al., 2019). They described four distinct phenotypes characterized by age and renal dysfunction ( $\beta$ ), inflammation and pulmonary dysfunction ( $\gamma$ ), liver dysfunction and septic shock ( $\delta$ ), and the absence of these characteristics ( $\alpha$ ). Moreover, they found evidence that EGDT was beneficial for patients in the  $\alpha$  subtype, whereas the  $\delta$  subtype responded negatively to the treatment.

Our interest is in inferring phenotypes present within a patient population not adequately represented by previous studies. The Investigating Febrile Deaths in Tanzania (INDITe) study sought to describe the etiologies of fatal febrile illness in sub-Saharan Africa (sSA) with the over-arching goal of identifying priorities for the prevention and treatment of severe infectious diseases (Snavely et al., 2018). From September 2016 to May 2019, the study collected detailed transcriptome and clinical information from 599 febrile patients across two hospitals in Moshi, Tanzania, the administrative seat of the Kilimanjaro Region. Studies have estimated that the in-hospital mortality rate of severe sepsis in sSA is between 20 and 60% (Jacob et al., 2009; Andrews et al., 2014, 2017), and the region has the highest health-related burden of sepsis in the world (Rudd et al., 2020). In contrast to the primarily European and North American populations in previous phenotype classifications such as SENECA, the INDITe cohort had markedly different immunological profiles and sepsis etiologies. For one, the average age of the INDITe cohort was 41.3, whereas for SENECA the average age was 64 (Seymour et al., 2019). Secondly, the prevalence of HIV infection among the INDITe participants was 38.2%, and of the persons living with HIV, 69.0% had CD4 T-cell lymphocyte percentage indicative of advanced HIV; this prevalence of HIV and advanced HIV is much higher than the HIV prevalence in the sepsis subtyping populations from Europe and North America. In terms of etiologies, febrile patients in Kilimanjaro exhibit pathogens not common in Europe and North America, including cryptococcosis, chikungunya, and histoplasmosis (Crump et al., 2013; Rubach et al., 2015). Due to these substantial differences, it is possible that there were endotypes present in the INDITe cohort that have not been previously cataloged.

Clustering methods utilized by the aforementioned phenotype analyses include agglomerative hierarchical clustering (Jain and Dubes, 1988), consensus k-means (Wilkerson and Hayes, 2010), and a combined mapping of clustering algorithms (Sweeney et al., 2015). Such methods can be categorized as being *algorithmic* in using an iterative mechanism to minimize a clustering loss function or meet a clustering criterion. Algorithmic clustering methods can work well in certain cases but need the number of clusters to be pre-specified and typically lack a characterization of uncertainty in clustering. These points are addressed by *model-based* methods which compute clusters using tools from statistical inference. Model-based clustering methods rely on *mixture models* to simultaneously sort individuals into groups while inferring the probability distribution of data within each group. The Gaussian mixture model (GMM) results when one assumes that the features of individuals in each cluster follow a multivariate Gaussian distribution. A wide range of approaches are used to estimate the clustering of

the data under a GMM using either frequentist or Bayesian inference, see [MacLachlan and Peel \(2000\)](#), [Frühwirth-Schnatter et al. \(2019\)](#), and [Wade \(2023\)](#) for an overview.

This article will take a Bayesian approach to clustering. We observe data  $\mathbf{y} = (\mathbf{y}_1, \dots, \mathbf{y}_n)$ , where for each individual  $i$ , we have features  $\mathbf{y}_i = (y_{i1}, \dots, y_{ip})$ . Our goal is to group patients into  $L$  phenotype clusters, denoted by  $\mathbf{c} = (c_1, \dots, c_n)$ , where  $c_i \in \{1, \dots, L\}$ . To express uncertainty in  $\mathbf{c}$  before observing  $\mathbf{y}$ , we assign a prior  $\pi(\mathbf{c})$ , which is a probability distribution over the space of all clusterings. Incorporating information in the data, the prior is updated to obtain the posterior  $\pi(\mathbf{c} \mid \mathbf{y})$ . Since this posterior tends to be analytically intractable, Bayesian inference typically relies on Markov chain Monte Carlo (MCMC) algorithms that produce samples  $\mathbf{c}^{(t)}$  from  $\pi(\mathbf{c} \mid \mathbf{y})$  ([MacLachlan and Peel, 2000](#); [Wade, 2023](#)). From the samples  $\mathbf{c}^{(t)}$ , one obtains standard quantities in statistical inference, including a point estimate  $\mathbf{c}^*$  of  $\mathbf{c}$  ([Binder, 1978](#); [Lau and Green, 2007](#)) and uncertainty quantification using a credible ball ([Wade and Ghahramani, 2018](#)) or posterior similarity matrix (PSM), the latter of which quantifies  $\Pr(c_i = c_j \mid \mathbf{y})$ . Endotypes have been derived using Bayesian clustering for illnesses such as cancer ([Savage et al., 2010](#); [Yuan et al., 2011](#); [Lock and Dunson, 2013](#); [Wang et al., 2023](#)), Alzheimer’s ([Poulakis et al., 2022](#)), emphysema ([Ross et al., 2016](#)), and type 2 diabetes ([Udler et al., 2018](#)). The Bayesian paradigm can allow a broad variety of feature types including time-to-event ([Bair and Tibshirani, 2004](#); [Raman et al., 2010](#); [Ahmad and Fröhlich, 2017](#)) and longitudinal data ([Poulakis et al., 2020, 2022](#); [Lu and Lou, 2022](#)).

A key step in Bayesian clustering is modeling the distribution of observations within each cluster. Within cluster  $l$ , data are assumed to be distributed as  $f(\cdot; \boldsymbol{\theta}^{(l)})$ , where  $f$  is some parametric probability kernel and  $\boldsymbol{\theta}^{(l)}$  is the cluster-specific parameter. In a GMM,  $f$  is the Gaussian kernel and  $\boldsymbol{\theta}^{(l)} = (\boldsymbol{\mu}^{(l)}, \Sigma^{(l)})$  is the mean and covariance of the  $l$ th cluster. An often under-discussed aspect of Bayesian clustering is the prior specification for  $\boldsymbol{\theta}^{(l)}$ . The general consensus is to assume that  $\pi(\boldsymbol{\theta}^{(l)})$  is conjugate to  $f$  because  $\pi(\mathbf{c} \mid \mathbf{y})$  can then be sampled using a Gibbs sampler. For GMMs, the conjugate family is the Gaussian-inverse-Wishart prior. It is a well-known fact that improper priors for the cluster-specific parameters lead to improper posteriors ([Wasserman, 2000](#)), so the cluster-specific priors can be weakly-informative on likely feature ranges for each cluster ([Richardson and Green, 1997](#)) or data-based ([Raftery, 1995](#); [Bensmail et al., 1997](#)). Cluster-specific priors are inappropriate for our application because we expect to observe new phenotypes explained by the immunoprofiles of the INDITe cohort, and label-switching is still likely to occur even if substantial prior information on the phenotypes were

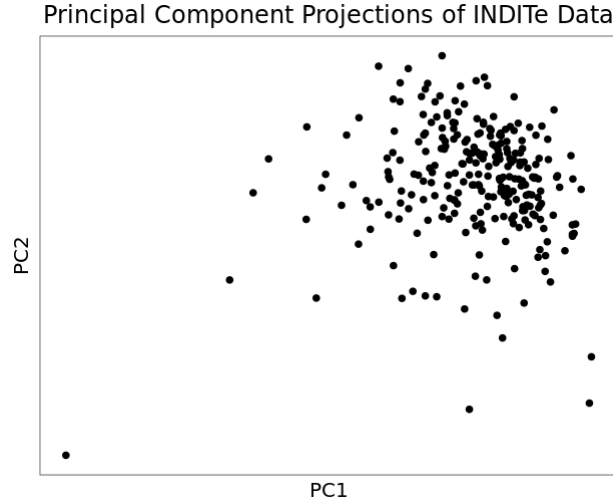

Figure 1: Projections onto the first two principal components for a subset of the numeric features from the original INDITe dataset.

available. Additionally, data-based priors forfeit the probabilistic updating of information that occurs in subjectivist Bayesian inference and can potentially lead to underestimation of uncertainty.

To analyze the INDITe data, we propose a simple but novel prior for  $\theta^{(l)}$  that is motivated by phenotype inference. Essential to understanding our prior is the notion of meaningful regions (MRs), areas of the feature domain that have a clear clinical interpretation. For example, MRs of the  $j$ th feature could correspond to intervals in which clinicians can classify an individual as having diminished, neutral, or elevated expression of that feature. MRs are assumed to be known in advance, usually identified by investigators with expert knowledge of the application. We focus on the cluster center, or the mean, in a GMM. We specify the prior for the centers to be itself a mixture model comprised of non-overlapping and informative components which cover the MRs. This prior highly favors cluster centers located inside the meaningful regions, ultimately leading to clinically relevant clusters. For that reason, we call our approach CLustering Around Meaningful Regions (CLAMR). In Section 2, we introduce CLAMR, discuss default prior settings, show how our prior can test the influence of features on the clustering, and provide computational details. In Section 3, CLAMR is evaluated by repeatedly sampling synthetic data. We display all results for applying CLAMR to the INDITe data in Section 4 and provide interpretations of the phenotypes we uncover. Finally, we present concluding remarks, extensions, and generalizations in Section 5.

## 2 CLUSTERING AROUND MEANINGFUL REGIONS

### 2.1 APPLIED CONTEXT AND MOTIVATION

In this article, we aim to catalog sepsis phenotypes in the INDITe data which reflect the subtypes of sepsis present in northern Tanzania. The INDITe study enrolled 599 febrile patients from two Moshi hospitals and measured both detailed RNA sequencing and routine clinical information on each participant. The clinical data are derived from two different sources. The first is a case report form (CRF) that details relevant signs and demographic information on the individual, and the second is comprehensive laboratory testing. From a statistical perspective, the INDITe data presents several challenges for cluster analysis. An integral factor is the lack of any clear separation in the data into isolated clusters, as can be seen in the principal component projections in Figure 1. While there are some noticeable patterns, including a clear outlier and skewness in the density of the data, we expect there to be substantial uncertainty in cluster membership. Moreover, the sample size of the INDITe study is markedly smaller than previous phenotype analyses, particularly SENECA. For these reasons, we use Bayesian methods that can coherently incorporate uncertainty quantification to cluster the INDITe data. Furthermore, despite the lack of separation, we opt to distinguish clusters by accounting for differences in *clinical interpretation*. The intuition here is that clusters should reflect a relevant medical designation that can inform treatment. Accounting for interpretations involves incorporating prior information on the features into our analysis, motivating a semi-supervised approach. Finally, an additional challenge is the selection of clinical variables that explain fundamental differences between the clusters, which can be useful for phenotype assignment of a patient. In the following sections, we discuss an approach that can account for each of these factors while leveraging the mathematical benefits of a Bayesian clustering model.

### 2.2 BAYESIAN PROBABILISTIC CLUSTERING

Let  $y_{ij} \in \mathbb{R}$  denote the value of the  $j$ th feature for the  $i$ th individual,  $j = 1, \dots, p$  and  $i = 1, \dots, n$ , which we collect into the matrix  $\mathbf{y} = (y_{ij})_{i,j}$ . We are primarily interested in inferring the phenotype clustering  $\mathbf{c} = (c_1, \dots, c_n)$ , where  $c_i \in \{1, \dots, L\}$  and  $L > 0$ , with  $C_l = \{i : c_i = l\}$  denoting the  $l$ th cluster. Generally, the likelihood  $\pi(\mathbf{y} \mid \mathbf{c})$  depends on some *kernel family*  $\mathcal{F} = \{f(\boldsymbol{\theta}) : \boldsymbol{\theta} \in \Theta\}$  and *cluster-specific parameters*  $\boldsymbol{\theta} = (\boldsymbol{\theta}^{(1)}, \dots, \boldsymbol{\theta}^{(L)})$ , so that  $\boldsymbol{\theta}^{(l)} \in \Theta$  for all  $l$  and  $(\mathbf{y}_i \mid c_i = l) \sim f(\cdot; \boldsymbol{\theta}^{(l)})$ . In many applications, the cluster-specific parameters are dimension dependent, so we write  $\boldsymbol{\theta}^{(l)} = (\theta_1^{(l)}, \dots, \theta_p^{(l)})$ .

After specifying a prior distribution  $\pi(\boldsymbol{\theta})$  for the cluster-specific parameters, the marginal posterior distribution of  $\mathbf{c}$  is

$$\pi(\mathbf{c} \mid \mathbf{y}) \propto \pi(\mathbf{c}) \prod_{l=1}^L \int_{\boldsymbol{\theta}^{(l)}} \left\{ \prod_{i:c_i=l} f(\mathbf{y}_i; \boldsymbol{\theta}^{(l)}) \right\} \pi(\boldsymbol{\theta}^{(l)}) d\boldsymbol{\theta}^{(l)}. \quad (1)$$

There are many possible choices for the clustering prior, including Dirichlet-Multinomial, Dirichlet process (Ferguson, 1973), and Pitman-Yor process (Pitman and Yor, 1997). Alternatively, when prior information on the clustering  $\mathbf{c}$  is available, one can use informative clustering priors such as constrained clustering (Lu and Leen, 2004) and centered partition processes (Paganin et al., 2021). Also relevant to the posterior of  $\mathbf{c}$  in (1) are the priors for the cluster-specific parameters,  $\pi(\boldsymbol{\theta}^{(l)})$ . One approach is to calibrate  $\pi(\boldsymbol{\theta}^{(l)})$  to be *weakly informative* for each cluster using prior information. For example,  $\pi(\boldsymbol{\theta}^{(l)})$  can be specified to have support on a likely range of spread for cluster  $l$  if such information is available (Richardson and Green, 1997). However, a more common approach is to assume that  $\boldsymbol{\theta}^{(l)}$  are identically distributed for all  $l$  from some *base measure*  $g(\cdot; \boldsymbol{\nu})$  with *hyperparameters*  $\boldsymbol{\nu}$ , i.e.  $\pi(\boldsymbol{\theta}^{(l)}) = g(\boldsymbol{\theta}^{(l)}; \boldsymbol{\nu})$  for all  $l$  (Wade, 2023). The choice of  $\boldsymbol{\nu}$  in such models is a frequent topic of discussion in the literature. If  $\boldsymbol{\nu}$  is chosen so that  $g(\boldsymbol{\theta}^{(l)}; \boldsymbol{\nu})$  is improper, one can show that the posterior distribution is also improper (MacLachlan and Peel, 2000; Wasserman, 2000). For that reason, noninformative or weakly-informative base measures have been implemented with modifications of Jeffrey’s prior (Diebolt and Robert, 1994; Rubio and Steel, 2014), noninformative hierarchical priors (Grazian and Robert, 2018), and global reparameterizations (Robert and Mengersen, 1995; Kamary et al., 2018). Another strategy is to calibrate  $\boldsymbol{\nu}$  via the data itself to create a data-based prior, see Raftery (1995) and Wasserman (2000) for applications of such methodology to the priors in a GMM.

We will focus on the case when the data are modeled as a GMM with diagonal covariance. The cluster specific parameters are  $\boldsymbol{\theta}^{(l)} = (\boldsymbol{\mu}^{(l)}, \Sigma^{(l)})$ , where  $\boldsymbol{\mu}^{(l)} = (\mu_1^{(l)}, \dots, \mu_p^{(l)})$  and  $\Sigma^{(l)} = \text{diag}(\sigma_1^{(l)2}, \dots, \sigma_p^{(l)2})$ , or  $\theta_j^{(l)} = (\mu_j^{(l)}, \sigma_j^{(l)2})$ . The data are generated by

$$(y_{ij} \mid c_i = l, \mu_j^{(l)}, \sigma_j^{(l)2}) \sim \mathcal{N}(\mu_j^{(l)}, \sigma_j^{(l)2}), \text{ for } j = 1, \dots, p; \quad (2)$$

with  $\mu_j^{(l)}$  being the mean, or *center*, and  $\sigma_j^{(l)2}$  being the variance of feature  $j$  in cluster  $l$ , for  $l = 1, \dots, L$ . The natural choice for  $\pi(\mu_j^{(l)}, \sigma_j^{(l)2})$  is the Gaussian-inverse-Gamma base measure because it is conjugate to the normal likelihood, leading to a simple Gibbs sampler for  $\pi(\mathbf{c} \mid \mathbf{y})$ . This choice of base measure has several pitfalls in practice, including the aforementioned ambiguity for the choice of hyperparameters

and degenerate clustering behavior in high dimensional regimes (Chandra et al., 2023). In this article, we present an alternative prior for (2) that is computationally tractable but favors interpretability in clustering. Similar to the approach of Richardson and Green (1997), we use expert prior information to construct the prior for  $(\mu_j^{(l)}, \sigma_j^{(l)2})$ , but rather than setting a different weakly-informative prior for each cluster, we collate the information into a simple base measure.

### 2.3 ASSUMPTIONS AND PRIOR ON THE CLUSTER CENTERS

Suppose that for variable  $j$ ,  $y_{ij} \in \chi_j \subset \mathbb{R}$  for all individuals  $i = 1, \dots, n$ . The meaningful regions of  $\chi_j$  are a set of subsets  $\mathcal{M}_j = \{\mathcal{M}_j^{(1)}, \dots, \mathcal{M}_j^{(K_j)}\}$ , so that  $\bigcup_{k=1}^{K_j} \mathcal{M}_j^{(k)} = \chi_j$  and the event that  $y_{ij} \in \mathcal{M}_j^{(k)}$  has a concrete meaning for the investigator. Typically,  $\mathcal{M}_j$  is a set of disjoint intervals that comprise  $\chi_j$ . For instance, in the case where  $\mathcal{M}_j$  reflects diminished, neutral, and elevated levels of variable  $j$ , we have that  $K_j = 3$ ,  $\mathcal{M}_j^{(k)} = [a_j^{(k)}, b_j^{(k)}]$ , and  $a_j^{(1)} < b_j^{(1)} \leq a_j^{(2)} < b_j^{(2)} \leq a_j^{(3)} < b_j^{(3)}$ . In medical applications, knowing that  $y_{ij} \in \mathcal{M}_j^{(k_j)}$  for  $j = 1, \dots, p$  gives the clinician a clear interpretation in terms of individual  $i$ 's overall health, which can then be used to inform decisions such as treatment plans. We discuss alternative examples of MRs that arise in medicine in the Supplement.

We assume that the data are distributed as a GMM with diagonal covariance, such as in (2), with  $0 < L < \infty$  and  $\boldsymbol{\psi} \sim \text{Dir}(\gamma/L, \dots, \gamma/L)$ .  $L$  is set to be a large fixed number, such as  $L = 10$  or  $L = 50$ , so as to capitalize on the theoretic guarantees of such overfitted mixture models for determining the number of clusters (Rousseau and Mengersen, 2011; Van Havre et al., 2015). We set independent prior densities for  $\mu_j^{(l)}$  and  $\sigma_j^{(l)2}$ , i.e.  $\pi(\mu_j^{(l)}, \sigma_j^{(l)2}) = \pi(\mu_j^{(l)})\pi(\sigma_j^{(l)2})$ . For the variance, we opt for the conjugate prior  $1/\sigma_j^{(l)2} \sim G(\lambda_j, \beta_j)$ , where  $G$  is the gamma distribution, with  $\lambda_j$  and  $\beta_j$  chosen so that  $\pi(\sigma_j^{(l)2})$  is weakly-informative, though our approach is compatible with any variance prior, such as the hierarchical model given in Richardson and Green (1997).

We now turn towards specifying a novel prior for  $\mu_j^{(l)}$  based on careful consideration of the MRs. For variable  $j$  in cluster  $l$ , we assume that, a priori,

$$\mu_j^{(l)} \sim \sum_{k=1}^{K_j} \phi_j^{(k)} h_j^{(k)}, \quad (3)$$

where  $0 < \phi_j^{(k)} < 1$ ,  $\sum_{k=1}^{K_j} \phi_j^{(k)} = 1$ , and  $h_j^{(k)}$  are continuous probability distributions with support on  $\mathcal{M}_j^{(k)}$ . The shape of the component distributions in (3) are determined using expert prior knowledge so that  $h_j^{(k)}$  is itself an informative distribution on the  $k$ th MR. The resulting density function  $\pi(\mu_j^{(l)})$

is multimodal, with modes contained inside each meaningful region. Our prior choice is a base measure for the centers, i.e.  $\pi(\mu_j^{(l)}) = g(\mu_j^{(l)}; \boldsymbol{\nu})$  with hyperparameters  $\boldsymbol{\nu} = (\phi_j^{(1)}, \dots, \phi_j^{(K_j)}, h_j^{(1)}, \dots, h_j^{(K_j)})$ . We refer to (3) as the CLAMR prior for cluster centers. Importantly, CLAMR is a prior for the cluster-specific parameters and not an assumption about the distribution of the data. This distinguishes the approach from mixtures of mixtures that model the within-cluster distributions as GMMs (Malsiner-Walli et al., 2017).

The interpretation of (3) with respect to the data generating process can be better understood after the introduction of *labels*  $s_j^{(l)} \in \{1, \dots, K_j\}$ , with the property that the prior for  $\mu_j^{(l)}$  is equivalent to sampling

$$(\mu_j^{(l)} \mid s_j^{(l)} = k) \sim h_j^{(k)}; \quad \pi(s_j^{(l)} = k) = \phi_j^{(k)}; \quad (4)$$

such as in the typical mixture likelihood in (2). The height of each mode in (3) is controlled by  $\boldsymbol{\phi}_j = (\phi_j^{(1)}, \dots, \phi_j^{(K_j)})$ . If  $\phi_j^{(k)} \approx 1$  for some  $k$ , then all cluster centers will concentrate inside the  $k$ th MR. To model uncertainty in  $\boldsymbol{\phi}_j$ , we assume that  $\boldsymbol{\phi}_j \sim \text{Dir}(\rho_j/K_j, \dots, \rho_j/K_j)$  where  $\rho_j > 0$ . The smaller the value of  $\rho_j$ , the more likely it is that the cluster centers in feature  $j$  are all representative of the same MR *a priori*.

The generating process of the centers can be interpreted in terms of a *profile matrix*  $\mathbf{s} = (s_j^{(l)})_{l,j}$ . Sampling (4) associates the  $l$ th cluster center with a  $p$ -dimensional vector of MRs,  $\mathbf{s}^{(l)} = (s_1^{(l)}, \dots, s_p^{(l)})$ , which we refer to as the clinical *profile* of cluster  $l$ . The profiles provide a concise medical description of the cluster centers. If, say,  $p = 3$  and the MRs correspond to expression levels, then  $\mathbf{s}^{(l)} = (2, 1, 3)$  implies that cluster  $l$  is characterized by neutral values of feature one, diminished measurements of feature two, and elevated levels of feature three. Since we expect label-switching to occur,  $\mathbf{s}$  is identifiable up to permutations of the rows. The columns of  $\mathbf{s}$ , denoted  $\mathbf{s}_j = (s_j^{(1)}, \dots, s_j^{(L)})$ , are groupings of the  $L$  clusters into the  $K_j$  MRs, and give an idea on the effect of feature  $j$  on heterogeneity between the clusters. We will expand on this specific property in the following section.

In practice, the component kernels  $h_j^{(k)}$  can be any continuous probability distribution, but a natural choice is the location-scale Gaussian mixture across the MRs,

$$\mu_j^{(l)} \sim \sum_{k=1}^{K_j} \phi_j^{(k)} \mathcal{N}(\xi_j^{(k)}, \tau_j^{(k)2}), \quad (5)$$

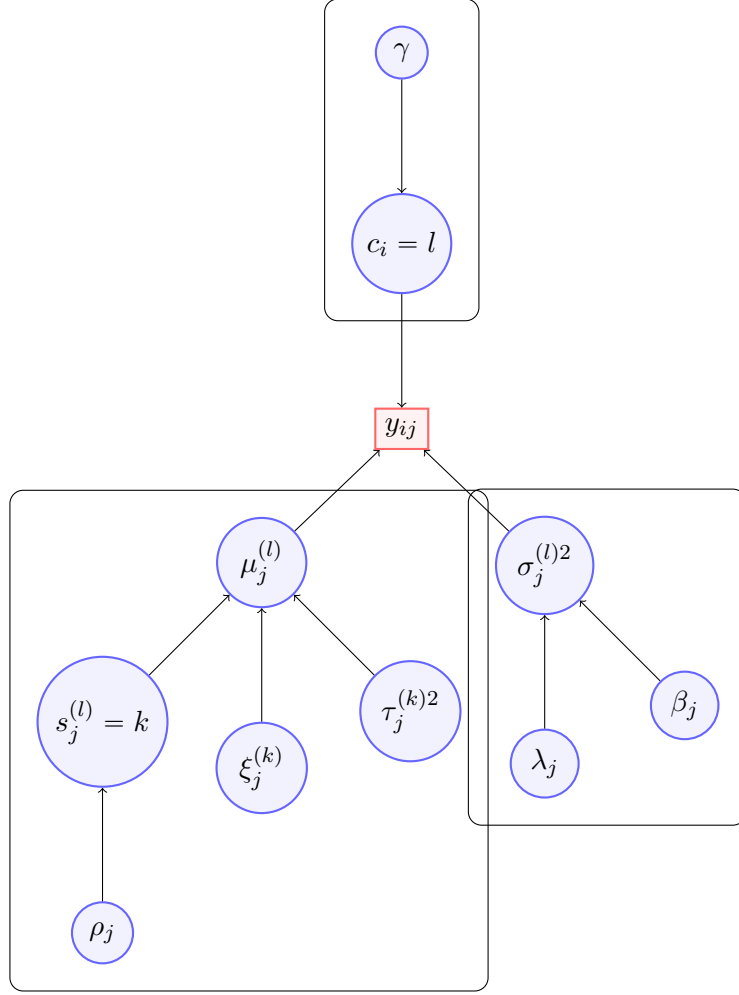

Figure 2: The data generating process according to the CLAMR prior after marginalizing out the prior distributions for  $\psi$  and  $\phi_j$ . The observation  $y_i$  is allocated into cluster  $l$  with probability determined by  $\gamma$ , with mean and variance equal to  $\mu_j^{(l)}$  and  $\sigma_j^{(l)2}$  for variable  $j$ . The cluster center is defined by the cluster's profile  $\mathbf{s}^{(l)}$ , with  $\xi_j^{(k)}$  and  $\tau_j^{(k)2}$  chosen so that the kernels have support on the meaningful regions. The cluster-specific variance is drawn from an inverse-gamma conjugate prior.

where  $\xi_j^{(k)} \in \mathcal{M}_j$  and  $\tau_j^{(k)2} > 0$ . The data generating process of  $\mathbf{y}$  using Gaussian components in the CLAMR prior is visualized with a directed acyclic graph (DAG) in Figure 2. The three main pieces of the generation of  $y_{ij}$  are represented by three boxes, with each box being independent of the other a priori. The box on the bottom left of the DAG details the prior on the cluster center.

The component means and variances of (5) must be chosen carefully so that the bulk of the probability mass of each Gaussian kernel are non-overlapping. Clearly,  $\xi_j^{(k)}$  must be some real number contained inside  $\mathcal{M}_j$ . In the case where  $\mathcal{M}_j^{(k)} = [a_j^{(k)}, b_j^{(k)}]$ ,  $\xi_j^{(k)}$  is any point in that interval. A natural default version of (5) is the following specification based on controlling the symmetric tails of the Gaussian kernel,

$$\xi_j^{(k)} = \frac{a_j^{(k)} + b_j^{(k)}}{2} \quad \tau_j^{(k)2} = \left\{ \frac{b_j^{(k)} - a_j^{(k)}}{2\Phi^{-1}\left(\frac{1+\omega}{2}\right)} \right\}^2, \quad (6)$$

where  $0 < \omega < 1$  is a constant. Note that  $\xi_j^{(k)}$  is the midpoint of  $\mathcal{M}_j^{(k)}$ , similar to the prior specification in Richardson and Green (1997). The free parameter  $\omega$  controls the amount of probability mass that overlaps between MR  $k$  and MRs  $k-1$  and  $k+1$ . One can see that  $\pi(\mu_j^{(l)} \in \mathcal{M}_j^{(k)} \mid s_j^{(l)} = k) = \omega$ . Increasing  $\omega$  to 1 will increase the concentration of each kernel towards their midpoint, causing  $\pi(\mu_j^{(l)}) \rightarrow \sum_{k=1}^{K_j} \phi_j^{(k)} \delta_{\xi_j^{(k)}}$ . Hence, a sensible choice is to set  $\omega = 0.95$  so that 95% of the probability density in each kernel is contained within their respective region and centered at the midpoint. If investigators do not wish to place  $\xi_j^{(k)}$  as the midpoint of  $\mathcal{M}_j^{(k)}$ , they can choose  $\tau_j^{(k)2}$  using a similar criteria to (6) to ensure that  $\mathcal{M}_j^{(k)}$  contains 95% of the probability density of component  $k$ . The framework can also be extended to multimodality within MRs by setting  $h_j^{(k)}$  to be mixture of Gaussian kernels, combining CLAMR with mixtures of mixtures (Malsiner-Walli et al., 2017).

An example comparison between the CLAMR prior, the weakly-informative case (as mentioned in Richardson and Green (1997)), and the noninformative case is given in Figure 3 when  $\chi_j = [-3, 1.5]$ ,  $\mathcal{M}_j = \{[-3, -1], [-1, 0], [0, 1.5]\}$ , and the MRs are expression levels. The CLAMR prior favors clusters with centers located at the midpoint of each MR, and the prior probability of the MRs is controlled by  $\phi_j$ . For this visualization,  $\phi_j = (1/3, 1/3, 1/3)$ , but the height of each mode can be lowered or raised by altering these values. In the case where  $\phi_j^{(k)} \rightarrow 1$  for some  $k$ , the CLAMR prior in Figure 3 reduces to an informative prior on the  $k$ th MR. The weakly-informative prior, while leading to a proper posterior, favors neutral levels of feature  $j$ , and the prior probability of each MR is fixed.

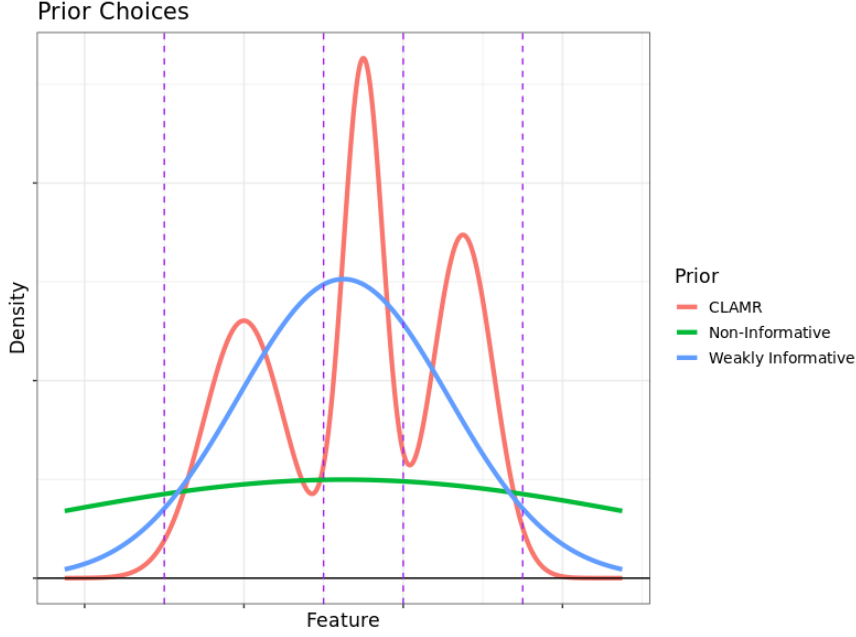

Figure 3: Possible prior choices for the cluster center when the MRs are given by  $\mathcal{M} = \{[-3, -1], [-1, 0], [0, 1.5]\}$  and  $\chi_j = [-3, 1.5]$ . The non-informative prior is flat on  $\chi_j$ , whereas the weakly-informative choice is concentrated at the midpoint of  $\chi_j$ . The CLAMR prior has hyperparameters given by (6), where each component of the mixture is a non-overlapping Gaussian with mean at  $(a_j^{(k)} + b_j^{(k)})/2$ . In this specific example, the prior probability under CLAMR of observing a cluster center in each MR is  $1/3$ , though that need not be the case in general.

## 2.4 TESTING FEATURE INFLUENCE AND PRE-TRAINING

The clinical profiles  $\mathbf{s}$  will be useful for assessing the *influence* of feature  $j$  on  $\mathbf{c}$ . In phenotype analyses, investigators are interested in what features help explain the phenotypes and which variables do not. The intuition here is that some features tend to contribute more than others to meaningful differences between the groups. Suppose then, for example, that for some  $k$ ,  $s_j^{(l)} = k$  for all clusters  $l = 1, \dots, L$ . This would mean that the profiles of each cluster are all identical for the  $j$ th variable. If  $k = 2$  and the MRs are expression levels, this would amount to concluding that individuals in all clusters tend to have neutral values of variable  $j$ . Therefore, variable  $j$  on its own does not explain the heterogeneity between groups.

We can formulate this intuition in terms of a Bayesian hypothesis test. Recall that for each cluster  $l$  and variable  $j$ , there is a label  $s_j^{(l)} \in \{1, \dots, K_j\}$ . In practice, there may be some clusters that are empty, so for the remainder of this section, we only focus on the clusters  $C_l$  that are non-empty, i.e.  $|C_l| \geq 1$ . Without loss of generality and for ease of notation, we will assume that clusters  $l = 1, \dots, L_n \leq L$  are non-empty. The labels induce  $p$  partitions of  $[L_n] = \{1, \dots, L_n\}$ , denoted  $S_j = \{S_j^{(1)}, \dots, S_j^{(K_j)}\}$ ,

where  $S_j^{(k)} = \{l : s_j^{(l)} = k, |C_l| \geq 1\}$ , for  $j = 1, \dots, p$ . That is, each  $S_j^{(k)}$  is the set of cluster indices that are associated with the  $k$ th MR. For example, suppose there are  $L_n = 3$  clusters and  $K_j = 3$  MRs. Then by sampling (4) there are three possibilities for the allocation of clusters to regions: all clusters are in the same MR ( $S_j = \{[3]\}$ ), two clusters are in the same MR while one cluster is in a different MR ( $S_j = \{\{1, 2\}, \{3\}\}$ ,  $S_j = \{\{1\}, \{2, 3\}\}$ , or  $S_j = \{\{1, 3\}, \{2\}\}$ ), or all clusters are in different MRs ( $S_j = \{\{1\}, \{2\}, \{3\}\}$ ).

From our argument above, if  $S_j = \{[L_n]\}$ , then the influence of variable  $j$  on  $\mathbf{c}$  is minimal because each cluster is located in the same MR. This motivates setting the null hypothesis to be  $H_{0j} : S_j = \{[L_n]\}$ . However, in this article, we set the interval null for feature influence to be  $H_{0j} : d(S_j, \{[L_n]\}) < \epsilon_j$ , where  $\epsilon_j > 0$  is a positive constant and  $d$  is a distance metric over the partition space. We implement our approach with  $d$  set to be Binder’s loss (Binder, 1978), but other partition metrics exist that could be used instead, e.g. the Variation of Information (VI) (Meilă, 2007).

In accordance with formal Bayesian hypothesis testing, we focus on the prior and posterior probability of  $H_{0j} : d(S_j, \{[L_n]\}) < \epsilon_j$  versus  $H_{1j} : d(S_j, \{[L_n]\}) \geq \epsilon_j$ .  $H_{0j}$  is tested via computation of the Bayes factor (BF <sub>$j$</sub> ), or the ratio of the marginal likelihoods of  $\mathbf{y}$  given  $H_{1j}$  and  $H_{0j}$  (Jeffreys, 1935, 1961; Kass and Raftery, 1995). When  $\pi(H_{0j}) = \pi(H_{1j}) = 1/2$ , the Bayes factor can be further simplified to  $\text{BF}_j = \pi(H_{1j} | \mathbf{y}) / \pi(H_{0j} | \mathbf{y}) = \{1 - \pi(d(S_j, \{[L_n]\}) < \epsilon_j | \mathbf{y})\} / \pi(d(S_j, \{[L_n]\}) < \epsilon_j | \mathbf{y})$ , which is the ratio of the posterior probabilities of  $H_{1j}$  and  $H_{0j}$ . We can conclude in favor of either  $H_{0j}$  or  $H_{1j}$  using the magnitude of BF <sub>$j$</sub> , e.g. the guidelines given in Kass and Raftery (1995). The smaller BF <sub>$j$</sub>  is, the smaller the influence of feature  $j$  on  $\mathbf{c}$ . Note that  $\pi(H_{0j}) = 1/2$  only occurs for specific values of  $\rho_j$  and  $\gamma$ , so we fix  $\gamma = 1$ , which favors a small number of clusters, then choose  $\rho_j$  using Monte Carlo simulation.

In practice, testing feature influence can be implemented as a pre-training step in order to reduce dimension in  $\mathbf{y}$  and identify relevant features for clustering. This involves first fitting the model, computing the Bayes factors, and removing the non-influential features. We then run the CLAMR model on the reduced set of variables and infer the clustering  $\mathbf{c}$ . In Section 4 we implement our hypothesis testing scheme as a pre-training procedure to remove noisy features in the INDITe data.

## 2.5 COMPUTATIONAL DETAILS

We derive a simple Gibbs sampler for CLAMR, which is detailed in the Supplement. Once the  $T$  samples  $\{\mathbf{c}^{(t)}\}$  and  $\{\mathbf{s}^{(t)}\}$  are obtained, we summarize our findings using MCMC estimation. A key

advantage of the Bayesian framework is the ability to characterize uncertainty in point estimation using the posterior distribution. In Bayesian cluster analysis, the point estimate  $\mathbf{c}^*$  of  $\mathbf{c}$  is a fixed clustering of  $\mathbf{y}$  based on  $\pi(\mathbf{c} \mid \mathbf{y})$ , and is derived by minimizing the posterior expectation of an appropriate clustering loss function. We minimize the Variation of Information (VI) loss (Meilă, 2007), which compares the entropy between  $\mathbf{c}^*$  and  $\mathbf{c}$  as well as their mutual information (Wade and Ghahramani, 2018). For uncertainty quantification, we compute a credible ball or PSM using the MCMC samples. To test the influence of the  $j$ th feature,  $\text{BF}_j$  can be consistently estimated as  $T \rightarrow \infty$  by  $\pi(d(S_j, [L_n]) < \epsilon_j \mid \mathbf{y}) \approx (1/T) \sum_{t=1}^T \mathbf{1}(d(S_j^{(t)}, [L_n^{(t)}]) < \epsilon_j)$ , and is computed using post-processing on the samples  $\{\mathbf{c}^{(t)}\}$  and  $\{\mathbf{s}^{(t)}\}$ .

### 3 SIMULATION STUDY

We now evaluate CLAMR on synthetic data. We focus on the case in which the statistician has obtained expert knowledge on the MRs but the model is *misspecified*. Our simulation scenario explores kernel misspecification, which in our case refers to the regime in which the true data generating process is a mixture model but with non-Gaussian components. Kernel misspecification is a key issue in model-based clustering because statistical methods tend to overestimate the number of clusters when there is a mismatch between the assumed kernels and the true ones. A number of methods have recently been proposed to robustify Bayesian clustering results to model misspecification, such as coarsening (Miller and Dunson, 2019), decision theoretic schemes (Dombowsky and Dunson, 2023; Buch et al., 2024), and hierarchical component merging algorithms (Aragam et al., 2020; Do et al., 2024). However, the effect of the prior distribution on robustifying inference has received little discussion in this nascent literature.

We find that CLAMR can reduce the over-clustering tendency of misspecified models, leading to more accurate estimation and a fewer number of clusters. The synthetic data are comprised of  $p = 6$  features with  $K_j = 3$  true MRs each, which are assumed to be known. The number of true clusters is set to  $\tilde{L} = 3$  and we simulate the true within-cluster center parameters, denoted  $\tilde{\mu}_j^{(l)}$ , from the CLAMR

prior (5), where the true profile matrix  $\tilde{\mathbf{s}}$  is given by

$$\tilde{\mathbf{s}} = \begin{pmatrix} 1 & 3 & 1 & 2 & 1 & 3 \\ 1 & 3 & 2 & 1 & 1 & 3 \\ 1 & 3 & 3 & 3 & 1 & 3 \end{pmatrix}.$$

Observe that this implies that only features 3 and 4 will exhibit meaningful between-cluster variation. To replicate our application to the INDITe data, we make each feature exhibit a different scale. For example, the MRs of feature 1 are  $\{[-1, 1], [1, 2], [2, 4]\}$ , and the MRs for feature 6 are  $\{[0, 10], [10, 30], [30, 200]\}$ . True cluster labels  $\tilde{c}_i$  are simulated uniformly across the integers  $[\tilde{L}]$ . The cluster-specific scales  $\sigma_j^{(l)}$  are chosen so that, for the  $l$ th true cluster, the simulated data are contained within the MR given by the corresponding entry in  $\tilde{\mathbf{s}}$ . This calibration uses the true data generating process, given by  $y_i \mid \tilde{c}_i = l \sim t(\tilde{\nu}, \mu_j^{(l)}, \sigma_j^{(l)})$ , where  $t(\nu, \mu, \sigma)$  denotes the Student's t-distribution with  $\nu$  degrees of freedom, center  $\mu$ , and scale  $\sigma$ . For our simulations, we fix  $\tilde{\nu} = 5$ , meaning that the true kernels have significantly heavier tails than the Gaussian distribution. We vary  $n \in \{100, 500, 750, 1000\}$  and simulate 100 independent replications for each sample size. For a given simulated dataset  $\mathbf{y}$ , we fit a GMM with the CLAMR prior and default hyperparameters (6) with  $\omega = 0.95$ . We compare the results to clusterings yielded by a standard Bayesian GMM with weakly-informative priors (BGMM), an implementation of the EM algorithm, complete linkage hierarchical clustering (HCA), and k-means. Details on hyperparameter choice for all approaches are given in the Supplement. For both CLAMR and the BGMM, a clustering point estimate is selected by minimizing the VI loss.

	$n$	CLAMR	BGMM	EM	k-means	HCA
ARI	100	0.96	0.99	0.99	0.32	0.22
	500	0.98	0.98	0.94	0.35	0.20
	750	0.98	0.97	0.94	0.34	0.17
	1000	0.98	0.97	0.93	0.34	0.17
$\hat{L}$	100	3.17	3.32	3.14	3.00	3.00
	500	4.40	4.59	3.90	3.00	3.00
	750	4.58	4.88	4.10	3.00	3.00
	1000	5.08	5.38	4.27	3.00	3.00

Table 1: Average adjusted Rand index (ARI) with  $\tilde{\mathbf{c}}$  and number of clusters ( $\hat{L}$ ) for CLAMR, the BGMM, EM, k-means, and HCA applied to 100 independent replications for each  $n \in \{100, 500, 750, 1000\}$ . Both k-means and HCA have the number of clusters fixed at  $L = 3$ , the true value.

Results for the simulation study are displayed in Table 1, which shows the average adjusted Rand index (ARI) between each point estimate and the true cluster labels  $\tilde{\mathbf{c}}$ , as well as the number of clusters in the point estimates ( $\hat{L}$ ). For  $n > 100$ , CLAMR achieves the highest ARI across all approaches. In addition, CLAMR consistently reduces the number of clusters on average in comparison to the standard BGMM. The EM algorithm excels at inferring the number of clusters, but is notably less accurate at inferring the true cluster membership, as evidenced by the smaller values of ARI. Despite being fixed at the true number of clusters, k-means and HCA completely fail at recreating the true cluster structure.

## 4 SEPSIS PHENOTYPES IN NORTHERN TANZANIA

### 4.1 DATA AND PRETRAINING

Our main interest is using CLAMR to derive interpretable phenotypes from a cohort of sepsis patients. While the original dataset consists of a vast collection of variables, we opt for features that have been used in SENECA, which we enumerate in Table 2. The clinical variables can be categorized as belonging to four distinct classes: clinical signs, markers of inflammation in the body, markers of organ dysfunction, and additional immunological markers. The original INDITE cohort consisted of febrile patients that are not necessarily sepsis positive, so we only include individuals with systemic inflammatory response syndrome (SIRS) score greater than or equal to 2 in order to derive phenotypes that correspond to sepsis definition, ultimately resulting in  $n = 265$ . The following features have missing observations: bilirubin (0.023%), platelets (0.011%), BUN (0.011%), WBC (0.011%), and bicarbonate (0.008%). Based on our knowledge of the data collection process, we assume that these variables are missing completely at random (MCAR), and we impute these entries using the Gibbs sampler. We also have information on the in-patient outcome (e.g., death), which we do not use for clustering but will refer to in our interpretations.

The MRs correspond to expression levels specified by our clinical science collaborators, who have expert knowledge of the patient population context in northern Tanzania. Thirteen of the features have expression levels written in terms of D, N, and E ( $K_j = 3$ ), whereas the remaining two are expressed in either D and N or N and E ( $K_j = 2$ ). For example, systolic blood pressure, which is measured in mm Hg, has the following MRs: D = [65, 111], N = [111, 220], and E = [220, 300]. Conversely, creatinine, which is measured in ml/dL, has only two MRs: N = [0, 90] and E = [90, 250]. Note that these cut-offs are unique to northern Tanzania. These MRs are used to then define the hyperparameters  $(\xi_j^{(k)}, \tau_j^{(k)2})$

Feature	Type	BF <sub>j</sub>
Temperature	Clinical Signs	6.392
Respiratory Rate		0.024
Pulse Rate		0.402
Systolic Blood Pressure (SBP)		2.765
White Blood Cell Count (WBC)	Inflammation	14.553
C-Reactive Protein (CRP)	Markers	2.636
Aspartate Transaminase (AST)	Organ Dysfunction Markers	<b>250.736</b>
Bilirubin		<b>169.488</b>
Blood Urea Nitrogen (BUN)		<b>12607.696</b>
Creatinine		<b>45.208</b>
Platelets		3.500
Glucose	Additional Markers	0.661
Sodium		1.746
Bicarbonate		6.139
Albumin		4.600

Table 2: The complete 15 variables from the INDITe data with accompanying Bayes factors from the pre-training phase. Features with Bayes factors indicating strong evidence against  $H_0$  are indicated by bolded script.

via (6) with the overlap parameter set to  $\omega = 0.95$ . No other preprocessing is applied to the data, and features are kept in their original units for the analysis.

Before computing the clustering point estimate, we implement a pretraining phase to select influential features for clustering. We set  $\gamma = 1$  and choose  $\rho_j = (1.1)\mathbf{1}_{K_j=2} + (0.7)\mathbf{1}_{K_j=3}$ , which corresponds to  $\pi(d(S_j, [L_n]) < 0.1) = 1/2$ . The resulting Bayes factors for all variables are displayed in the third column of Table 2, with bolded script indicating features that have substantial evidence of clustering influence (Kass and Raftery, 1995). We select  $p = 4$  of the original 15 features for our analysis, corresponding to AST, bilirubin, BUN, and creatinine, all of which are organ dysfunction markers. We then calculate the point estimate using the reduced set of features.

## 4.2 CLUSTERING POINT ESTIMATE AND INTERPRETATIONS

We compute the point estimate  $\mathbf{c}^*$  by minimizing the VI loss using the MCMC samples from  $\pi(\mathbf{c} \mid \mathbf{y})$ . We also calculate the PSM for the INDITe data to express uncertainty in our point estimate. The point estimate consists of 7 clusters, however, the seventh cluster contains only one individual who has abnormally high levels of bilirubin, so we focus on the 6 clusters derived from the remaining 264 participants. We display a general summary of relevant clinical characteristics among participants, including the proportion of females, persons living with HIV, malaria infection, in-hospital mortality, and age in Table 3 stratified by cluster; we provide a pairs plot of the influential features in Figure

	Overall	$C_1^*$	$C_2^*$	$C_3^*$	$C_4^*$	$C_5^*$	$C_6^*$
Size	264	87	49	44	39	27	18
Pr(Female)	0.485	0.690	0.388	0.409	0.436	0.185	0.500
Pr(HIV+)	0.383	0.414	0.306	0.523	0.359	0.185	0.444
Pr(Advanced HIV)	0.258	0.241	0.224	0.386	0.231	0.148	0.333
Pr(Malaria)	0.098	0.092	0.163	0.045	0.051	0.185	0.056
Pr(Deceased)	0.125	0.057	0.122	0.182	0.179	0.148	0.167
Avg. Age (SD)	42.8 (17)	37 (14.2)	47.5 (17.5)	38.2 (12.1)	48.5 (19)	40.4 (16.8)	60.2 (16.6)
AST	N-E	N	N	E	N	E	N
Bilirubin	D-N	D	N	D	D	N	D-N
BUN	D-E	N	N-E	N	E	N-E	E
Creatinine	N-E	N	N	N	E	N-E	E

Table 3: Basic demographic information consisting of sex, HIV infection, advanced HIV status, malaria status, inpatient outcome, and age measured within each cluster, with the overall numbers included for comparison. In addition, profiles for each cluster estimated using the within-cluster IQR of each feature.

4. For convenience, the clusters are labeled by decreasing size. No cluster contains the majority of participants, and the smallest cluster is cluster 6 which comprises just 18 individuals (or 7%) from the overall cohort.

Participants in cluster 1 are generally female (69%), have the best inpatient outcome (5.7% mortality), and have the lowest average age in comparison to the other clusters (37). These participants tend to have neutral feature expression with the exception of bilirubin, which tends to exhibit diminished values. In comparison, cluster 2 is majority male (61%), has a lower proportion of participants living with HIV (31% in comparison to 41% for cluster 1), and has more than double the mortality (12%). Cluster 2 is also generally associated with neutral feature expression, though it is more inclined towards elevated levels of BUN, bilirubin, and AST than cluster 1. Cluster 3 is the only cluster for which the majority of patients are living with HIV (52%, overall incidence is 38%), and 74% of these patients have CD4 percentage indicative of advanced HIV. It has the lowest proportion of subjects with malaria (4.5%, prevalence among all 264 is 9.8%). Participants in this cluster are generally male and younger (average age of 38.2 years) and have elevated levels of AST. Cluster 4 is characterized by elevated BUN and creatinine levels, but neutral AST levels. Clusters 3 and 4 are similar in size (44 and 39 participants, respectively), and have the joint highest mortality rate (18.2% and 17.9%, respectively). The highest AST levels are observed in cluster 5, which also is associated with relatively high bilirubin and the highest proportion of males (81.5%). Furthermore, this cluster has the lowest proportion of participants living with HIV (18.5%), though 80% of these individuals have advanced HIV. Cluster 6, the smallest cluster, is characterized by having markedly high levels of both BUN and creatinine. In

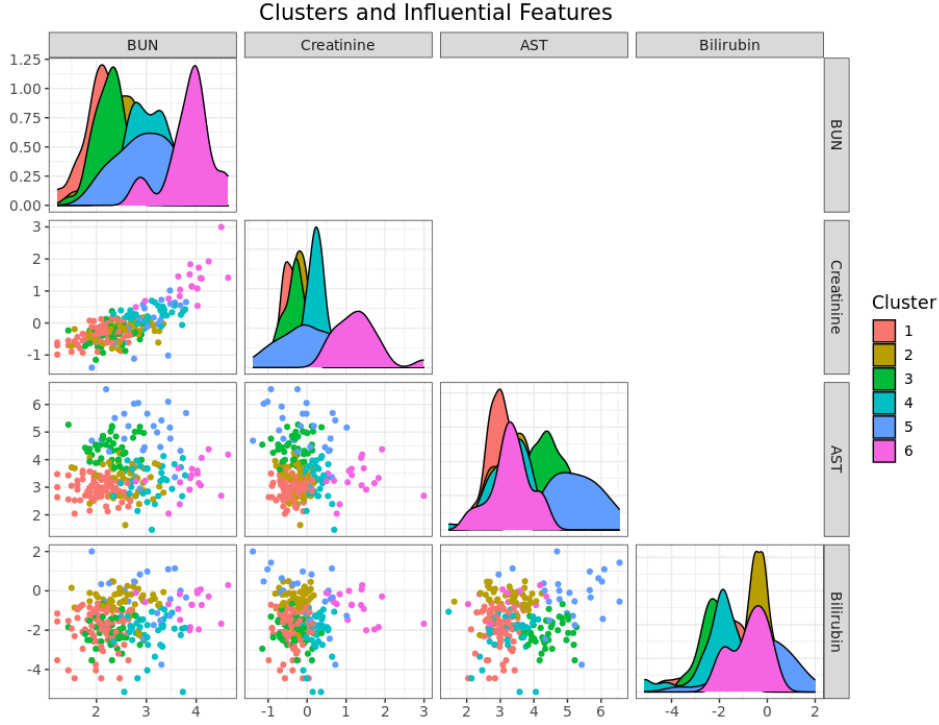

Figure 4: Pairs plots for the influential features BUN, creatinine, AST, and bilirubin, where colors indicate clusters. All features are log-transformed.

addition, patients in this cluster tend to be older (average age of 60.2), and cluster 6 has the second highest proportion of individuals with HIV (44.4%) and, of those individuals, 75% have advanced HIV.

In light of these differential characteristics, we can summarize the interpretation of the clusters as follows. Cluster 1 comprises young female patients with generally neutral markers, low bilirubin (not a clinical concern), and low incidence of mortality; cluster 2 has modestly elevated levels of BUN that suggest possible renal dysfunction and skews older and more towards male sex than cluster 1; cluster 3 is characterized by increased frequency of HIV and elevated AST levels indicative of liver dysfunction; cluster 4 has elevated levels of BUN and creatinine that suggests septic shock or renal dysfunction; cluster 5 is composed of mainly men with low HIV prevalence/frequency and extremely high levels of AST indicative of liver dysfunction; and cluster 6 is composed of older individuals with extremely elevated BUN and creatinine indicative of septic shock or renal dysfunction.

### 4.3 COMPARISON TO SENECA CLUSTERS

Next, we qualitatively compare and contrast the INDITe clusters  $\mathbf{c}^*$  with the four clusters reported in the SENECA study (Seymour et al., 2019), denoted as  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ . Cluster 1 is comparable

Figure 5: Posterior similarity matrix (PSM) for the INDITe data, ordered by point estimate membership.

to their  $\alpha$  cluster due to the lack of organ dysfunction and generally low mortality, and cluster 6 closely resembles their  $\beta$ -cluster as it is characterized by advanced age and renal dysfunction. Their  $\delta$  cluster is associated with liver dysfunction; the elevated levels of AST in clusters 3 and, especially, 5 mean that liver dysfunction is also a defining factor in these INDITe clusters. However, we also find that factors specific to sSA explain heterogeneity between the INDITe clusters. For example, malaria prevalence and low HIV prevalence are key characteristics of cluster 5, whereas cluster 3 is in part driven by low malaria prevalence and high HIV prevalence. While cluster 1 is similar to the  $\alpha$  cluster, there are notable differences in demographics, including average age (37 years for INDITe, 60 years for SENECA) and sex (69% female for INDITe, 49% female for SENECA). These considerations notwithstanding, we may interpret clusters 1 and 6 as being clinical manifestations of the  $\alpha$  and  $\beta$  clusters, respectively, in the northern Tanzanian population. With regards to participant outcomes we observe comparable, but distinct, associations to those from the SENECA study, who found that the  $\delta$  cluster (characterized by liver dysfunction) had the highest mortality rate in their cohort. We find that cluster 3 (characterized by HIV incidence and possible liver dysfunction) has the highest observed mortality at 18.2%, though cluster 4 (characterized by renal dysfunction) has a similar mortality at 17.9%.

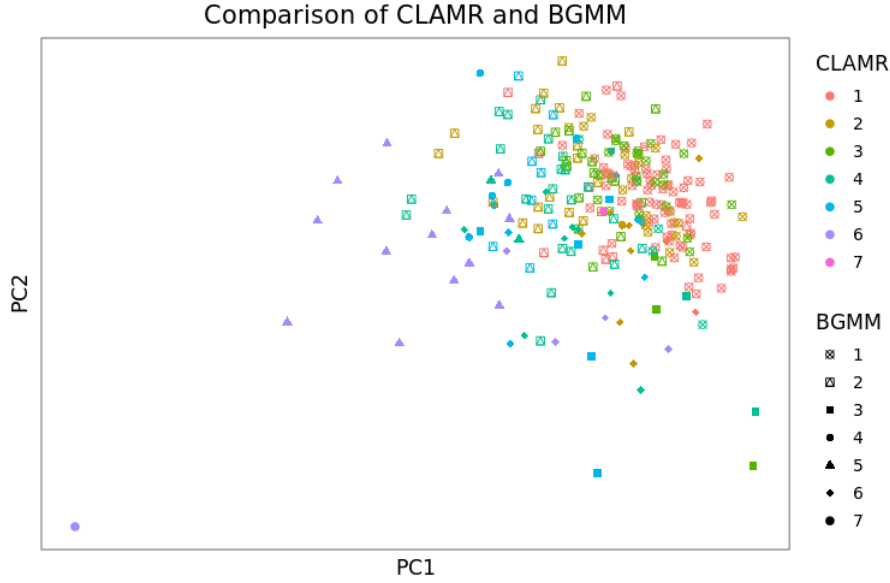

Figure 6: A comparison between the point estimate yielded by CLAMR and that by a standard BGMM. Colors indicate CLAMR, whereas shapes refer to the BGMM. Singleton clusters have been included.

#### 4.4 COMPARISON TO A BAYESIAN GAUSSIAN MIXTURE

We compare our results with the clustering point estimate obtained after fitting a Bayesian GMM (BGMM), as in (2), with weakly-informative Gaussian and inverse-Gamma priors. Explicit details on hyperparameters are given in the Supplement. The adjusted Rand index between  $\mathbf{c}^*$ , the CLAMR point estimate, and  $\mathbf{c}'$ , the BGMM point estimate, is 0.273, indicating a modest resemblance between the two clusterings. Both  $\mathbf{c}^*$  and  $\mathbf{c}'$  have 7 clusters, and create singleton clusters (though not of the same participant). In contrast to the cluster sizes displayed in Table 3, the sizes of the BGMM clusters are 125, 77, 26, 15, 11, 10, and 1. An explicit comparison between the two point estimates is given in Figure 6, where it can be seen that CLAMR clusters are split and subsequently merged to create those from the BGMM. For example, cluster 1 in CLAMR is spread across three clusters in the BGMM, and cluster 1 of the BGMM is comprised of participants from clusters 1, 2, 3, and 4 in CLAMR. The clusterings differ in interpretation as well. Clusters 3 and 4 of the BGMM, for instance, have an extremely small HIV incidence (10% and 9.1%), whereas the HIV incidence for all CLAMR clusters are larger than these proportions. Malaria incidences are generally higher in the BGMM clustering, with three of the seven clusters observed to have more than 20% malaria incidence. All clusters derived by CLAMR have lower malaria incidence. Finally, the BGMM places 202 of the individuals in just two clusters (76% of the cohort), whereas the CLAMR clusters more evenly split the dataset, making it

easier to provide definitive interpretations. For these reasons, we find the results from CLAMR to be preferable from a clinical perspective.

#### 4.5 UNCERTAINTY QUANTIFICATION

The PSM for the INDITe data is displayed in Figure 5, where each box along the diagonal indicates a cluster. Observe that both clusters 5 and 6 are notably distinct from cluster 1, i.e.  $\Pr(c_i = c_j \mid \mathbf{y})$  is very close to 0 for  $i \in C_1^*$  and  $j \in (C_5^* \cup C_6^*)$ . Indeed, these clusters seem to be well-separated amongst the influential variables in Figure 4, suggesting differing underlying subtypes and possibly differing treatment regimes. The PSM also indicates similarity between clusters 1, 2, 3, and 4 via the off-diagonal boxes in Figure 5. Comparing again to the within-cluster distributions in Figure 4, we can see that these clusters have similar distributions for the septic shock and renal dysfunction markers (BUN and creatinine). Hence, one would expect that the underlying subtypes manifest themselves similarly in the patient population, though differences in key immunologic factors such as HIV status and age, as well as AST and bilirubin levels, still distinguish these clusters in a clinical sense. Instead, it may be the case that individuals can embody characteristics from multiple subtypes.

### 5 DISCUSSION

In this article, we present CLAMR, a novel augmentation to the Bayesian Gaussian mixture model motivated by disease subtype analysis. The main idea behind our approach is to incorporate commonly used cut-offs in feature values, or meaningful regions, into the prior for the cluster centers, with the ultimate goal being to distinguish clusters via their medical interpretations. We accomplish this mathematically by assuming that the prior on the cluster centers is a mixture model over the MRs. When the CLAMR prior is a Gaussian mixture, a simple Gibbs sampler can be derived for posterior computation. The algorithm performs excellently on synthetic data in which the Gaussian model is misspecified. In addition to clustering, our prior can be used for a pre-training procedure to select relevant clustering features using the results of Bayesian hypothesis tests.

CLAMR is primarily motivated by the clustering challenges presented by the INDITe sepsis data from northern Tanzania, such as the lack of separation in the data and the small sample size. We find that the influential features are all organ dysfunction markers, and using these we derive 6 clusters of varying size and interpretation. These clusters are related to clinical factors and signs, including HIV

prevalence, malaria status, age, sex, and kidney and liver dysfunction, and we also observe varying mortality rates across the clusters. In addition, several of our clusters are similar in interpretation to the clusters from the SENECA study, despite the sepsis patient population in sSA having markedly different distributions of age, comorbidities, and etiologies than those in North America.

There are multiple possible extensions to CLAMR that can generalize our approach. The cluster profiles  $S_j$  can be estimated after applying label-switching algorithms to the samples  $\mathbf{c}^{(t)}$  and  $\mathbf{s}^{(t)}$ , then minimizing a clustering loss such as Binder’s or the VI. The CLAMR prior is presented here as a GMM, but any continuous probability distributions can be used to model the prior density within the MRs. If investigators require the distribution within MRs be multimodal, for instance, one can set the component kernels of  $\pi(\mu_j^{(l)})$  to be themselves GMMs, and posterior computation can be carried out using a similar Gibbs sampler to the one we utilize. Finally, we assume that the cluster-specific variances follow weakly-informative inverse-gamma priors, but this can be simply augmented to a mixture of inverse-gamma kernels over the MRs in order to model varying shapes, not just centers, between profiles.

## SUPPLEMENTARY MATERIAL

In this section, we expand on our concept of meaningful regions, implement our analysis using the SENECA study to calibrate the CLAMR prior, discuss an extension to mixed data, and give extensive technical details on both the simulations and application. Code to implement CLAMR and reproduce our simulation results can be found at <https://github.com/adombowsky/CLAMR>.

## A GIBBS SAMPLER

Posterior computation with the CLAMR prior requires only a few modifications to existing Gibbs samplers for finite GMMs, e.g. the algorithm in [MacLachlan and Peel \(2000\)](#). We must sample from the full conditional distributions of the clustering  $\mathbf{c}$ , the cluster-specific parameters  $\{(\mu_j^{(l)}, \sigma_j^{(l)2})\}_{l=1}^L$ , and the profiles  $\mathbf{s}$ . Note that we have omitted the random probability vectors  $\boldsymbol{\psi}$  and  $\{\boldsymbol{\phi}_j\}_{j=1}^p$  so as to improve MCMC mixing, especially when sampling the multinomial groupings  $\mathbf{c}$  and  $\mathbf{s}_j$ . We update the cluster allocations via  $\pi(c_i = l \mid -) \propto \left\{ \prod_{j=1}^p \mathcal{N}(y_{ij}; \mu_j^{(l)}, \sigma_j^{(l)2}) \right\} \left\{ n_l^{(-i)} + \gamma/L \right\}$ ; for  $l = 1, \dots, L$ , where  $n_l^{(-i)} = \sum_{i' \neq i} \mathbf{1}(c_{i'} = l)$ . A similar identity holds for reallocation of the  $l$ th label in feature  $j$ , i.e.  $\pi(s_j^{(l)} = k \mid -) \propto \mathcal{N}(\mu_j^{(l)}; \xi_j^{(k)}, \tau_j^{(k)2}) \left\{ m_k^{(-l)} + \rho_j/K_j \right\}$ , with  $m_k^{(-l)} = \sum_{l' \neq l} \mathbf{1}(s_j^{(l')} = k)$ . For the cluster centers  $\mu_j^{(l)}$ , we sample from an updated Gaussian distribution, which depends on the data allocated to cluster  $l$  and the hyperparameters of meaningful region  $s_j^{(l)}$ ,

$$\pi(\mu_j^{(l)} \mid s_j^{(l)} = k, -) \propto \mathcal{N} \left( \mu_j^{(l)}; \frac{\xi_j^{(k)} + \frac{\sum_{c_i=l} y_{ij}}{\sigma_j^{(l)2}}}{\frac{1}{\tau_j^{(k)2}} + \frac{n_l}{\sigma_j^{(l)2}}}, \left( \frac{1}{\tau_j^{(k)2}} + \frac{n_l}{\sigma_j^{(l)2}} \right)^{-1} \right),$$

where  $n_l = \sum_{i=1}^n \mathbf{1}(c_i = l)$ . The full conditional distribution of  $1/\sigma_j^{(l)2}$  is the standard updated Gamma distribution,  $G(\lambda_j + n_l/2, \beta_j + \sum_{i:c_i=l} (y_{ij} - \mu_j^{(l)})^2/2)$ . Any missing values are imputed each step of the Gibbs sampler by simulating a draw from the Gaussian likelihood using the current values of  $c_i$ ,  $\mu_j^{(l)}$ , and  $\sigma_j^{(l)2}$ .

## B ALTERNATE NOTIONS OF MEANINGFUL REGIONS

Level of expression may not be the only way in which MRs arise in applications. If a previous study has clustered a similar cohort into  $K$  groups using the same  $p$  variables, then  $\mathcal{M}_j^{(k)}$  can represent the support of variable  $j$  in previously observed cluster  $k$ . In our application, the Sepsis Endotyping in Emergency Care (SENECA) study clustered sepsis patients from 12 hospitals in Pennsylvania, USA using the same clinical variables and provides summaries of the distribution of data within each cluster ([Seymour et al., 2019](#)). The event  $y_{ij} \in \mathcal{M}_j^{(k)}$  can be interpreted as individual  $i$  exhibiting characteristics emblematic of previously observed cluster  $k$ . Alternatively, MRs may correspond to risk scores that predict mortality. Examples from our population of interest include the modified early warnings score (MEWS) ([Subbe et al., 2001](#)) and the universal vital assessment (UVA) score ([Moore](#)

et al., 2017). Both the MEWS and UVA score are calculated by determining the total “points” an individual receives based on cut-offs of the features. We can then set  $\mathcal{M}_j^{(k)}$  to be the set cut-offs for variable  $j$  that correspond to different point values. In the main article we focus on the case of expression level MRs, but alternate strategies for other kinds of MRs may be useful in other settings.

## C ADDITIONAL DETAILS ON SIMULATIONS

The true MRs, which are assumed to be known, are given in Table 4. We simulate the true means  $\tilde{\mu}_j^{(l)}$  from the CLAMR prior with our default hyperparameters and  $\omega = 0.99$ , encouraging cluster centers that are near the midpoint of each interval. The scales  $\sigma_j^{(l)}$  are selected so that simulated data tends to concentrate in each true MR. In each replication, we run the CLAMR and BGMM Gibbs samplers for 15,000 iterations each, with the first 5,000 discarded as burn-in. For CLAMR, the variance priors are  $1/\sigma_j^{(l)2} \sim G(10/R_j, 10)$ , where  $R_j = b_j^{K_j} - a_j^{(1)}$  is the general range of feature  $j$ . For the BGMM, we center and scale the synthetic data to have mean 0 and standard deviation 1. The priors for the BGMM are  $\mu_j^{(l)} \sim \mathcal{N}(0, 1)$  and  $1/\sigma_j^{(l)2} \sim G(1, 1)$ . The point estimates for both Bayesian methods are computed by minimizing the VI loss. The EM algorithm is implemented in the package `mclust` (Scrucca et al., 2016), where the number of clusters is selected by minimizing the Bayesian information criterion over a set of candidate models. We fix the maximum number of clusters in the EM algorithm to be 5. For both k-means and HCA, the number of clusters is fixed at the truth (i.e., 3).

Feature	1	2	3	4	5	6
D	[-1,1]	[0,2]	[-10,2]	[-0.1,0.1]	[0,100]	[0,10]
N	[1,2]	[2,5]	[2,4]	[0.1,0.3]	[100,250]	[10,30]
E	[2,4]	[5,10]	[4,8]	[0.3,0.5]	[250,400]	[30,200]

Table 4: The true MRs for the simulation study, ordered by their level of expression (D, N, and E).

## D ADDITIONAL DETAILS ON APPLICATION TO INDITE DATA

### D.1 HYPERPARAMETERS AND MCMC DIAGNOSTICS

In this section, we expand on the technical aspects of our main application. Our priors for the cluster-specific variances are  $1/\sigma_j^{(l)2} \sim G(2, 1/R_j)$ , where  $R_j = b_j^{K_j} - a_j^{(1)}$  is the general range of feature  $j$ . This prior is essentially a limiting case of the hierarchical variance prior used in Richardson and Green (1997) for Gaussian mixtures. Both the initial pre-training phase and final clustering phase

were fit using the same hyperparameters and number of iterations and chains. We fit the CLAMR model using 9 independent chains in parallel, where each chain has 300,000 iterations, with the initial 10,000 removed as burn-in. We then thin the MCMC output by only using every 10th iteration to compute the Bayes factors and clustering point estimate. We evaluate MCMC convergence using both the log-likelihood

$$\log \mathcal{L}(\mathbf{y}; \mathbf{c}, \boldsymbol{\mu}, \boldsymbol{\sigma}) = \sum_{i=1}^n \sum_{j=1}^p \log \mathcal{N}(y_{ij}, \mu_j^{(c_i)}, \sigma_j^{(c_i)}).$$

and the maximum cluster size, i.e.  $n^{\max} = \max(|C_1|, \dots, |C_L|)$ , the latter of which we interpret as a diagnostic for the latent partition  $\mathbf{c}$ . The traceplots of both quantities using expression level MRs are displayed in Figure 7.  $\hat{R}$  (Gelman and Rubin, 1992) values for the log-likelihood and  $n^{\max}$  are 1.738 and 1.070, respectively, and we find that  $n^{\max}$ , and therefore, the partition, mixes better than the log-likelihood. To further evaluate convergence in terms of the latent partition, we compute separate clustering point estimates for each chain, then calculate the Rand index Rand (1971) between each pair of point estimates. The lowest pairwise Rand index is 0.88, the highest is 1.00, and the average across all chains is 0.95, indicating substantial similarity between the point estimates.

The BGMM is implemented by first centering and scaling the original  $p = 15$  variables to have mean 0 and unit variance. A priori, we assume  $\mu_j^{(l)} \sim \mathcal{N}(0, 1)$  and  $1/\sigma_j^{(l)2} \sim \text{G}(1, 1)$ . The number of components is set to  $L = 10$ , and the cluster probabilities  $\boldsymbol{\psi} \sim \text{Dir}(1/L, \dots, 1/L)$ . We run a Gibbs sampler with 200,000 iterations with the first 10,000 discarded as burn-in. The point estimates is computed by minimizing the VI loss.

## D.2 ADDITIONAL FIGURES

We display boxplots for the within-cluster distributions across the influential features in Figure 8. Here, we can see that increased values in BUN and creatinine distinguish cluster 6 from the other groups, whereas the same holds for cluster 5 and increased values of both AST and bilirubin. We also see relatively high values of AST in cluster 3 and relatively high values of bilirubin in cluster 2. Boxplots for all 15 original features are displayed in Figure 9.

## E CLUSTERING THE INDITE DATA WITH SENECA CENTERED MRs

We now present an alternative implementation of CLAMR to the INDITE data using a different notion of MR based on the sepsis patient clusters derived by the SENECA study. Recall that the SENECA

Table 6: Basic demographic information for the clusters derived using SENECA centered MRs.

study obtained 4 clusters— $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ —from a cohort spread across twelve hospitals in Pennsylvania (Seymour et al., 2019). Our expert clinical collaborators translated the medical characteristics described in Seymour et al. (2019) to the northern Tanzania population, adjusting for key demographic differences including age and etiologies. Ultimately, our collaborators were able to provide information on the expression levels characteristic of each SENECA cluster, were they to manifest themselves in sSA. For example, BUN would be neutral (N) in the  $\alpha$  cluster, elevated (E) in the  $\beta$  cluster, neutral in the  $\gamma$  cluster, and elevated in the  $\delta$  cluster. Therefore, for BUN, we set the four MRs to be {N, E, N, E}. Note that unlike our application in the main article, the MRs are *not* disjoint, and we exclude any expression levels not represented by the SENECA clusters. For BUN, for instance, it is not possible for a cluster to have a profile that implies diminished (D) expression level, meaning that the prior support has been constrained.

We run 10 MCMC chains in parallel for 200,000 iterations (with the first 10,000 discarded as burn-in, then thinned to every tenth iteration) and all hyperparameters are identical to those for the INDITe application in the main article, with the exception that  $K_j = 4$  for all features, and we set  $\rho_j = 0.69$ . Table 5 shows the Bayes factors for all features from the original dataset. Interestingly, the model selects a less sparse feature set, and includes all inflammation and organ dysfunction markers, as well as the additional marker albumin. After pre-training, the clustering point estimate is obtained, which we summarize in Table 6. We find four clusters, with sizes 107, 105, 35, and 18.

There are some similarities between the clusters in Table 6 and those derived using expression level MRs. In both analyses, there are clusters driven by increased values of BUN and creatinine as well as increased values of bilirubin and AST. In addition, one of the clusters is associated with older age (cluster 6 using expression level MRs, and cluster 4 using SENECA MRs). In terms of differences, the adjusted Rand index between the two point estimates is 0.260, and we visualize the comparison between the two clusterings using the contingency table in Table 7. Note the disparity in cluster sizes between

	SENECA	1	2	3	4
Expression Levels	1	31	56	0	0
	2	37	11	1	0
	3	5	33	6	0
	4	32	5	0	2
	5	0	0	27	0
	6	2	0	0	16
	7	0	0	1	0

Table 7: Contingency table between the clustering derived using expression level MRs (rows) and that using SENECA centered MRs (columns).

the two analyses; the model using SENECA MRs prefers to allocate most of the data into two large clusters. Perhaps the biggest difference is that cluster 1 using expression level MRs is split between two clusters using SENECA MRs. In addition, the SENECA MR analysis does not include a singleton cluster, and it allocates that participant into cluster 3. However, we can see that there is significant overlap between clusters 4, 5, and 6 using expression level MRs and clusters 1, 3, and 4 using SENECA MRs. To compare the two analyses more concretely, we compute the Watanabe–Akaike information criterion (WAIC) (Watanabe and Opper, 2010) for both models. The WAIC under expression level MRs is 7.826, whereas for SENECA MRs, it is 37.615.

## F EXTENSION TO CATEGORICAL AND MIXED DATA

We now discuss a generalization of our approach for categorical and binary features. In medical applications, it is common for a study to gather information related to comorbidities, etiologies, and presence-absence. These features are generally taken to be categorical, i.e.  $y_{ij} \in \{1, \dots, M_j\}$ , where  $1 < M_j < \infty$  is the number of categories for the  $j$ th feature. We model the feature using a mixture of multinomial distributions,

$$y_{ij} \mid c_i = l, \mathbf{p}_j^{(l)} \sim \text{Multinomial}(\mathbf{p}_j^{(l)}),$$

where  $\mathbf{p}_j^{(l)} = (p_{j1}^{(l)}, \dots, p_{jM_j}^{(l)})$ ,  $0 < p_{jm}^{(l)} < 1$  and  $\sum_{m=1}^{M_j} p_{jm}^{(l)} = 1$ . Here, we assume that each category in the  $j$ th feature has a medical interpretation, meaning that the categories  $\{1, \dots, M_j\}$  are the MRs. Similar to our original formulation for a Gaussian mixture, we specify a prior that is a mixture of

informative distributions for each MR,

$$\mathbf{p}_j^{(l)} \sim \sum_{m=1}^{M_j} \phi_j^{(m)} \text{Dir}(\nu_j \mathbf{q}_j^{(m)}), \text{ with } q_{jm'}^m = \begin{cases} \delta_j : & m' = m \\ 1 - \delta_j : & m' \neq m \end{cases} \quad (7)$$

where  $1/2 \leq \delta_j \leq 1$  and  $\nu_j > 0$  is a fixed constant, such as  $\nu_j = 1$ . At one extreme, when  $\delta_j = 1/2$ , we have that  $\mathbf{p}_j^{(l)} \sim \text{Dir}(\nu_j/2, \dots, \nu_j/2)$ , i.e. the MRs of feature  $j$  have no impact on the clustering. Hence, the parameter  $\nu_j$  controls the distribution of the null model. On the other extreme, as  $\delta_j \rightarrow 1$ ,  $\mathbf{p}_j^{(l)} \sim \sum_{m=1}^{M_j} \phi_j^{(m)} \delta_{\mathbf{e}_m}$ , where  $\mathbf{e}_1, \dots, \mathbf{e}_{M_j}$  are the standard basis vectors, meaning that clusters correspond exactly to the categories. In the special case in which  $y_{ij}$  is binary, we focus on modeling  $0 < p_j^{(l)} < 1$ , or the probability that feature  $j$  is equal to 1, via a mixture of Beta distributions. That is, (7) translates to

$$p_j^{(l)} \sim \phi_j \text{Beta}(\nu_j \delta_j, \nu_j (1 - \delta_j)) + (1 - \phi_j) \text{Beta}(\nu_j (1 - \delta_j), \nu_j \delta_j), \quad (8)$$

where each component is an informative Beta distribution concentrated at the endpoints of the unit interval. Clearly, when  $\delta_j = 1/2$ , then  $p_j^{(l)} \sim \text{Beta}(\nu_j/2, \nu_j/2)$ , indicating no clustering heterogeneity. For both the categorical and binary cases, we construct a Bayesian hypothesis test by focusing on  $H_0 : \delta_j < 1/2 + \epsilon_j$ , where  $\epsilon_j > 0$  is a small positive constant. Observe that, since we assume independence between features, we can combine (7) and (8) with the Gaussian CLAMR model we discuss in the main article in order to apply our approach to data of mixed types.
