

Highlights

Early and elongated epochs of planetesimal dynamo generation

Hannah R. Sanderson, James F.J. Bryson, Claire I.O. Nichols

- Planetesimal thermal dynamos can begin before the dissipation of the nebula field.
- Core solidification is not required to trigger a second epoch of dynamo generation.
- Planetesimal dynamos can last several 100 Ma longer than previously thought.
- Planetesimal radius and reference viscosity have a strong effect on dynamo duration.

Early and elongated epochs of planetesimal dynamo generation

ABSTRACT

Accreting in the first few million years (Ma) of the Solar System, planetesimals record conditions in the protoplanetary disc and are the remnants of planetary formation processes. The meteorite paleomagnetic record carries key insights into the thermal history of planetesimals and their extent of differentiation. The current paradigm splits the meteorite paleomagnetic record into three magnetic field generation epochs: an early nebula field ($\lesssim 5$ Ma after CAI formation), followed by thermal dynamos (~ 5 – 34 Ma after CAI formation), then a gap in dynamo generation, before the onset of core solidification and compositional dynamos. These epochs have been defined using current thermal evolution and dynamo generation models of planetesimals. Here, we demonstrate these epochs are not as distinct as previously thought based on refined thermal evolution models that include more realistic parametrisations for mantle convection, non-eutectic core solidification, and radiogenic ^{60}Fe in the core. We find thermal dynamos can start earlier and last longer. Inclusion of appreciable ^{60}Fe in the core brings forward the onset of dynamo generation to ~ 1 – 2 Ma after CAI formation, which overlaps with the existence of the nebula field. The second epoch of dynamo generation begins prior to the onset of core solidification, suggesting this epoch is not purely compositionally driven. Planetesimal radius is the dominant control on the strength and duration of dynamo generation, and the choice of reference viscosity can widen the gap between epochs of dynamo generation from 0–200 Ma. Overall, variations in planetesimal properties lead to more variable timings of different planetesimal magnetic field generation mechanisms than previously thought. This alters the information we can glean from the meteorite paleomagnetic record about the early Solar System. Evidence for the nebula field requires more careful interpretation, and late paleomagnetic remanences, for example in the pallasites, may not be evidence for planetesimal core solidification.

1. Introduction

The strength and duration of magnetic fields generated within planetesimals can provide unique insight into the differentiation and thermal histories of rocky bodies in the early Solar System. For a rocky body to internally generate a magnetic field (a dynamo), it must have a partially molten metallic core in which flow is being driven, for example by convection. Magnetic remanences recorded by meteorites indicate that some planetesimals met these criteria during their thermal history, providing evidence for planetesimal differentiation and vigorous core convection.

Three strands of investigation can be combined to allow observations of magnetic field generation in planetesimals to constrain planetesimal behaviour. Firstly, magnetic remanences measured from meteorites have provided evidence for dynamos on specific parent bodies and radiometric dating of these meteorites provide estimates for the age of dynamo activity (e.g. Maurel et al., 2020). Secondly, thermal evolution models can be used to explore parent body properties, such as radius and accretion time, for which the requirements for magnetic field generation are met (e.g. Dodds et al., 2021). For undated magnetic remanences, thermal evolution models can provide possible dynamo timing

Early and elongated epochs of planetesimal dynamo generation

Figure 1: The meteorite paleomagnetic record. Blue and red boxes indicate undifferentiated (chondritic) meteorite groups and green, yellow and pink boxes indicate differentiated (achondritic) meteorite groups. Blue and black arrows represent magnetic remanences dated using radiometric methods and thermal evolution models, respectively. Solid arrows with filled caps indicate magnetised samples and dashed arrows with unfilled caps indicate unmagnetised samples. For the angrites, the time range is so short that only the arrowheads are visible. Multiple measurements for the same meteorite group are combined, but measurements of bulk magnetisation vs chondrules are kept separate to distinguish between pre-accretionary and post-accretionary remanences. Unlike the other chondrules, the CV chondrules remanence is not pre-accretionary, because the CV chondrules have experienced aqueous alteration, thermal metamorphism, and possibly brecciation (Fu et al., 2014a; Shah et al., 2017). The data table shown in this plot and references for each measurement can be found in the Supplementary Materials.

constraints, for example based on the timing of core crystallisation (e.g. Tarduno et al., 2012; Bryson et al., 2015; Maurel et al., 2020; Nichols et al., 2021). Finally, thermal evolution models can also predict whether a remanence is likely to have a dynamo or solar nebula origin (e.g. Bryson et al., 2019a; Dodds et al., 2021). Thermal evolution models to-date include incomplete or simplified physical descriptions of planetesimals. Here, we use refined thermal models to re-evaluate the meteorite paleomagnetic record.

1.1. Meteorite paleomagnetic record

Meteorites with similar isotopic compositions are assumed to come from the same parent body and form a group. Paleomagnetic measurements have been recovered from both differentiated (achondritic) and undifferentiated (chondritic) meteorites from both the outer (carbonaceous) and inner (non-carbonaceous) Solar System (Figure 1).

Three possible sources have been proposed for these magnetisations: the nebula field in the protoplanetary disc, which existed prior to $\sim 4\text{--}5$ Ma after calcium-aluminium-rich inclusion (CAI) formation (e.g. Fu et al., 2014a; Wang et al., 2017; Fu et al., 2020; Borlina et al., 2021; Bryson et al., 2023; Maurel and Gattacceca, 2024); internally generated dynamos (e.g. Tarduno et al., 2012; Wang et al., 2017; Bryson et al., 2019b); and the solar wind (Tarduno et al., 2017; O'Brien et al., 2020). Magnetisation from the solar wind has been proposed to be three to four orders of magnitude too weak to explain meteorite paleomagnetic remanences (Oran et al., 2018). Remanences from the nebula field can be identified by randomly oriented chondrule magnetisation directions (e.g. Fu et al., 2020).

Paleomagnetic remanences can be dated radiometrically if the closure temperature of the radiometric system is close to the blocking temperature of the magnetised mineral. Remanences dated to < 4 Ma after CAI formation have been interpreted to have a nebula origin due to the delay in the onset of dynamo generation predicted by previous dynamo models (Dodds et al., 2021). Meanwhile, remanences that were acquired after the dissipation of the nebula field, ~ 4 – 5 Ma after CAI formation (Weiss et al., 2021), are thought to originate from planetesimal dynamos. For systems where radiometric dating is not possible or extrapolation from a dated closure temperature to the Curie temperature is required, thermal evolution models can be used to predict the timing of dynamo generation. For example, this method was used to estimate an age for the Main Group pallasite remanent magnetisation based on the timing of core crystallisation (Tarduno et al., 2012).

1.2. Thermal evolution models

Two mechanisms of dynamo generation are considered by thermal models: thermal dynamos, where temperature-induced density differences drive core convection; and compositional dynamos, where density differences between solidifying pure iron and the liquid core enriched in incompatible light elements drive convection. For thermal dynamos, the superadiabatic portion of the core-mantle boundary (CMB) heat flux determines the timing and strength of magnetic field generation. Modelling compositional dynamos requires assumptions regarding the mechanism of planetesimal core solidification. The lower pressures at their CMB compared to planets (≤ 0.5 GPa compared to ≥ 8 GPa) mean planetesimal cores solidify inwards rather than nucleation occurring at the centre of the core (Williams, 2009). Several mechanisms for inward core solidification have been proposed, including iron snow where solid iron particles form at the CMB and then fall to the centre of the core triggering convection (Rückriemen et al., 2015; Scheinberg et al., 2016) and delamination of large iron diapirs from the CMB (Neufeld et al., 2019). Due to the complexity of these mechanisms, previous thermal evolution models of mantled planetesimals either ended after the cessation of mantle convection but prior to core solidification (Sternberg and Crowley, 2012; Dodds et al., 2021) or used the duration of eutectic core solidification as a first estimate of the timings of compositional dynamo duration (Bryson et al., 2019a; Nichols et al., 2021). Models of outward non-eutectic core solidification have been attempted but either did not model the full history of the body, or only considered cooling by mantle conduction (Nimmo, 2009; Nichols et al., 2021).

Previous thermal evolution models (e.g. Sternberg and Crowley, 2012; Bryson et al., 2019a; Dodds et al., 2021) that successfully generate dynamos predict several events in the thermal evolution:

- (i) Following instantaneous accretion or during gradual accretion, planetesimals are heated by ^{26}Al decay, causing the body to differentiate into a metallic core and silicate mantle.

- (ii) Following differentiation, ^{26}Al preferentially partitions into the silicate mantle. After further heating, the melt fraction in the mantle is high enough to initiate mantle convection. The core is heated by the mantle from above and develops a stable thermal stratification that prevents the onset of a dynamo.
- (iii) Once the mantle cools below the temperature at the CMB, the core thermal stratification is removed and the CMB heat flux becomes superadiabatic. Core convection triggers the onset of thermal dynamo generation.
- (iv) As the mantle cools, it becomes more viscous until mantle convection ceases. The cessation of mantle convection leads to a sharp decrease in CMB heat flux and core convection drops below the critical value, terminating the dynamo.
- (v) Eventually the core cools below its solidus temperature and begins to solidify, which can lead to a compositional dynamo and a second epoch of dynamo generation.
- (vi) Once the core has fully solidified, dynamo generation is no longer possible.

These previous models predict two epochs of dynamo generation: an early thermal dynamo, and a second later compositional dynamo during core solidification. This has led to paleomagnetic remanences >65 Ma after CAI formation being interpreted as evidence of a solidifying core (Bryson et al., 2015; Nichols et al., 2016, 2021; Maurel et al., 2021) and remanences <4 Ma after CAI formation being interpreted as a record of a nebula field due to the delay in start time of thermal dynamos caused by core thermal stratification (Bryson et al., 2019a, 2020a; Fu et al., 2021).

The assumptions made in these earlier models are re-explored here. First, previous models neglect heating from ^{60}Fe in the core, because for low values of primordial ^{60}Fe , such that $^{60}\text{Fe}/^{56}\text{Fe}=10^{-8}$ (Tang and Dauphas, 2012), only a very small difference in core temperature (~ 10 K) results over the lifetime of the planetesimal (Henke et al., 2013). However, new measurements suggest $^{60}\text{Fe}/^{56}\text{Fe}$ may have been as high as $6 \pm 2 \times 10^{-7}$ in the formation region of carbonaceous chondrites (Cook et al., 2021). Therefore, the role ^{60}Fe on planetesimal core thermal evolution should be explored for a wider range of values.

Second, previous thermal evolution models do not fully combine thermal and compositional dynamo generation, mantle convection, and non-eutectic core solidification. This limits the ability of existing thermal evolution models to predict the full magnetic history of a body.

Third, the effect of mantle viscosity on magnetic field generation has not been investigated in previous thermal models. CMB heat flux is limited by the cooling rate of the mantle above and the thickness of the CMB boundary layer, which are both governed by the mantle viscosity. Therefore, the parameterisation of mantle viscosity as a function of temperature has a critical role in planetesimal thermal evolution.

Sanderson et al. (2024) present a new, refined model, that accounts for all the points discussed above. Here, we apply this new model across the full range of realistic parameters to reassess the existing meteorite paleomagnetic record.

2. Methods

This study uses the 1D spherically symmetric planetesimal thermal evolution and dynamo generation model from Sanderson et al. (2024) to predict the timings of dynamo generation in planetesimals with a radius up to 500 km. This model builds on the previous planetesimal thermal evolution models of Sterenborg and Crowley (2012), Bryson et al. (2019a) and Dodds et al. (2021) by including radiogenic heating from ^{60}Fe in the core, an adjustable mantle viscosity law, and updated stagnant lid and CMB boundary layer parametrisations that better reflect mantle conditions. The model includes both convection and conduction in the mantle and models magnetic field generation by non-eutectic core solidification. The details and complete mathematical description of this model can be found in Sanderson et al. (2024).

2.1. Thermal evolution model

All model runs begin at 0.8 Ma after CAI formation with instantaneous accretion of the planetesimal at 200 K. The body heats up due to radiogenic heating of ^{26}Al and the Fe-FeS and silicate phases melt until the silicate reaches its critical melt fraction, ϕ_C . At this point, differentiation is assumed to take place instantaneously, as the molten, dense Fe-FeS sinks through the rheologically weak silicates to the centre. The model then consists of two coupled reservoirs: the Fe-FeS core and the silicate mantle. Sulfur is the only light element considered in the core. The surface temperature is held constant at 200 K throughout the simulation.

In the mantle, heat is transported either by conduction or convection. Mantle convection is assumed to occur in the stagnant lid regime with an isothermal, convective layer between conductive boundary layers at the CMB and the surface. These boundary layers thicken as the mantle cools and convection ceases once the combined CMB and surface boundary layer thicknesses reach the total mantle thickness. The temperature at the CMB is calculated by assuming continuity of heat flux across the boundary.

The core also transports heat by conduction or convection. For the core to convect, either the CMB heat flux, F_{CMB} , must be superadiabatic or the core must be undergoing non-eutectic solidification. During inward core solidification, the density difference between the more dense, solidified pure iron and the less dense Fe-FeS liquid drives core convection, as the solidified iron sinks to the centre of the core. When the core is convecting, the combined thermal and compositional buoyancy flux can be used to calculate a magnetic field strength (see Sanderson et al., 2024, for details). Once the eutectic composition is reached, core solidification no longer generates a compositional buoyancy flux. Combining buoyancy flux contributions enables the thermal and compositional drivers of convection to be considered simultaneously. The model ends once the whole core has solidified and dynamo generation is no longer possible.

2.1.1. *Dynamo generation*

The vigour of convection in the liquid part of the core is characterised by the magnetic Reynolds number, Re_m , which must be supercritical for the core flow to be strong enough to generate a magnetic field. The analytical estimate of the critical value is 10, while from empirical simulations this value ranges from 40–100 (Stevenson, 2003; Aubert et al., 2009). We use a critical Re_m of 10 in line with previous work (Bryson et al., 2019a; Dodds et al., 2021). However, the proportions of model runs with $10 \leq Re_m < 40$, $40 \leq Re_m < 100$, and $Re_m \geq 100$ are also investigated.

2.2. *Parameter variation*

Models were run for a range of mantle viscosities, planetesimal radii, initial core sulfur contents, $X_{S,0}$, and $^{60}\text{Fe}/^{56}\text{Fe}$ ratios in the accreted material (Table 1).

The temperature dependence of mantle viscosity is defined piece-wise (Figure 2) by five control parameters. Below the solidus, the viscosity has an Arrhenius temperature dependence with slope β , which is proportional to the activation energy for viscous deformation. At the solidus, the mantle has a reference viscosity, η_0 . Above the solidus, melt weakens the material and the viscosity decreases with a steeper Arrhenius dependence, quantified by the melt weakening exponent, α_n (Hirth and Kohlstedt, 2003). At the critical melt fraction, ϕ_C , there is enough melt to completely surround any remaining solid phases and the material disaggregates with a rapid drop in viscosity. Beyond ϕ_C , the viscosity tends to a constant liquid viscosity, η_l , following the Krieger-Dougherty relation (Sturtz et al., 2022b) as the melt fraction tends to one.

Each parameter was varied independently while the others were held constant at the median value of their range, except ϕ_C where the constant value was the experimental upper bound. The justifications for each parameter range are detailed in the following subsections.

2.2.1. *Reference viscosity, η_0*

The reference viscosity, η_0 , ranges from 10^{14} – 10^{24} Pas. The lower bound is based on experimental measurements (Scott and Kohlstedt, 2006) while the upper bound is set by extrapolating reference viscosities used in models of Ganymede (Rückriemen et al., 2018) to planetesimal mid-mantle pressures (see Appendix A).

2.2.2. *Critical melt fraction, ϕ_C*

Experiments suggest the critical melt fraction, ϕ_C , is between 0.2–0.3 (Scott and Kohlstedt, 2006). However thermal evolution models of planetesimals both for dynamo generation (Stereberg and Crowley, 2012; Bryson et al., 2019a; Dodds et al., 2021) and differentiation (e.g. Lichtenberg et al., 2019; Monnereau et al., 2023) use a value of $\phi_C=0.5$. Although it is unclear if $\phi_C=0.5$ is physically reasonable, we adopted the range $\phi_C=0.2$ – 0.5 to enable comparison with previous models and encapsulate experimental observations.

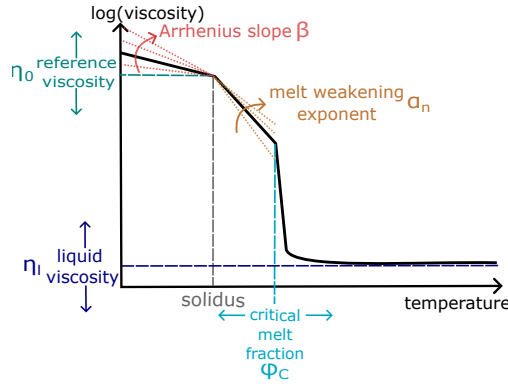

Figure 2: Illustration of parameters varied in the mantle viscosity model. Reference viscosity, $\eta_0=10^{14}\text{--}10^{24}$ Pas, is the viscosity at the mantle solidus. Liquid viscosity, $\eta_l=1\text{--}100$ Pas, is the viscosity when the mantle is fully molten. Critical melt fraction, $\phi_c=0.2\text{--}0.5$, is the melt fraction for which all crystals become surrounded by melt, the material disaggregates and becomes rheologically weak. Arrhenius slope, $\beta=0.01\text{--}0.035\text{ K}^{-1}$, determines the rate of decrease in viscosity with increasing temperature. Melt weakening exponent, $\alpha_n=25\text{--}40$, determines the additional rate of decrease in viscosity with increasing temperature due to melting.

2.2.3. Arrhenius slope, β

The Arrhenius slope in the viscosity law, β , is typically defined as $\frac{E}{RT_{\text{ref}}^2}$, where E is the activation energy, $R = 8.31\text{ Jmol}^{-1}\text{K}^{-1}$ is the gas constant, and T_{ref} is a reference temperature - often taken to be the temperature at which the reference viscosity is measured. Experimentally measured activation energies for a range of silicate mantle compositions and strain rates range from $240\text{--}570\text{ kJ mol}^{-1}$ (Karato and Wu, 1993; Hirth and Kohlstedt, 2003). For a reference temperature of the mantle solidus (1400 K), this corresponds to $\beta=0.015\text{--}0.035\text{ K}^{-1}$. Dodds et al. (2021) used $\beta = 0.01\text{ K}^{-1}$, so to enable comparison with previous thermal evolution models, we explore $\beta = 0.01\text{--}0.035\text{ K}^{-1}$.

2.2.4. Melt weakening exponent, α_n

The melt weakening exponent, α_n , depends on whether deformation occurs by diffusion creep ($\alpha_n = 25\text{--}30$) or dislocation creep ($\alpha_n = 30\text{--}45$) (Hirth and Kohlstedt, 2003). To cover both deformation modes we consider values from $25\text{--}45$.

2.2.5. Liquid viscosity, η_l

The liquid viscosity, η_l , is determined by mantle composition and can range from $1\text{--}100$ Pas across the compositions of all volcanic rocks commonly encountered on Earth (Giordano et al., 2008). Increasing silica content increases viscosity and increasing volatile content decreases viscosity (Leshner and Spera, 2015).

Symbol	Meaning	Range of values	Constant value	Reference
η_0	Reference viscosity	10^{14} – 10^{24} Pas	10^{19} Pas	a, b
ϕ_C	Critical melt fraction	0.2–0.5	0.3	a, c
β	Arrhenius slope	0.01 – $0.035 K^{-1}$	$0.0225 K^{-1}$	a, d, e
α_n	Melt weakening exponent	25–45	30	f
η_l	Liquid viscosity	1, 10, 100 Pas	10 Pas	g
$X_{S,0}$	Initial core sulfur content	26.7–33 wt%	29.85 wt%	h, i, j, k
${}^{60}\text{Fe}/{}^{56}\text{Fe}$	${}^{60}\text{Fe}/{}^{56}\text{Fe}$ in accreting material	0, 10^{-9} , 10^{-8} , 10^{-7} , 6×10^{-7}	10^{-8}	
r	Planetesimal Radius	100–500 km	300 km	

Table 1

Values for variable and constant parameters in simulations as described in Section 2.2. The upper five parameters occur in the viscosity law. The range on $X_{S,0}$ is for a 300 km radius planetesimal. For [500, 400, 200, 100] km radius planetesimals the minimum and median $X_{S,0}$ were [25.9, 26.3, 27.1, 27.1] wt% and [29.45, 29.65, 30.05, 30.05] wt% respectively. The constant values are median values in their range, except ϕ_C where the constant value was the experimental upper bound. η_l and ${}^{60}\text{Fe}/{}^{56}\text{Fe}$ vary over several orders of magnitude, so the explored input values are stated explicitly and the constant value was the median from this list of values. (a) Scott and Kohlstedt (2006), (b) Rückriemen et al. (2018), (c) Bryson et al. (2019a), (d) Karato and Wu (1993), (e) Dodds et al. (2021), (f) Hirth and Kohlstedt (2003), (g) Giordano et al. (2008), (h) Tang and Dauphas (2012), (i) Cook et al. (2021), (j) Kodolányi et al. (2022a), (k) Kodolányi et al. (2022b).

2.2.6. Initial core sulfur content, $X_{S,0}$

The initial core sulfur content, $X_{S,0}$, ranges from the minimum Fe-FeS sulfur content for which the metal phase will be fully molten before differentiation to the eutectic composition (33 wt% for $T_{s,Fe} = 1260$ K for $R=300$ km). The Fe-FeS liquidus temperature is pressure dependent so the minimum Fe-FeS changes with planetesimal radius.

2.2.7. Primordial ${}^{60}\text{Fe}/{}^{56}\text{Fe}$

Estimates on the primordial ${}^{60}\text{Fe}/{}^{56}\text{Fe}$ vary by almost two orders of magnitude from 10^{-8} (e.g. Tang and Dauphas, 2012) to 6×10^{-7} (e.g. Cook et al., 2021). However, previous thermal evolution and dynamo models neglected the presence of ${}^{60}\text{Fe}$ in the core. Therefore, the model was run for five values of ${}^{60}\text{Fe}/{}^{56}\text{Fe} = [0, 1 \times 10^{-9}, 1 \times 10^{-8}, 1 \times 10^{-7}, 6 \times 10^{-7}]$ to cover the full range of possible values and to compare with previous models.

2.2.8. Planetesimal radius, r

Models were run for planetesimal radii between 100–500 km. The lower limit is set by previous estimates for the minimum radius for compositional dynamo generation (Nimmo, 2009). The upper limit corresponds approximately to the radius of Ceres, the largest known asteroid today.

3. Results

3.1. Constant radius

Firstly, we ran models with a constant radius of 300 km to identify the impact of other parameters on thermal evolution and dynamo generation. The lowest mantle reference viscosity, η_0 , and lowest initial core sulfur content, $X_{S,0}$, result in a single epoch of dynamo generation, and a single value in each of η_0 , ϕ_C , and α_n result in three epochs of

Early and elongated epochs of planetesimal dynamo generation

Figure 3: Dynamo timings for a 300 km planetesimal for a range of initial $^{60}\text{Fe}/^{56}\text{Fe}$, mantle viscosities, and core compositions. Filled bars indicate periods when a dynamo is active and the colour of the bar indicates dipole magnetic field strength at the surface. The small, vertical, black line on each bar indicates the onset of core solidification in each model run. Magnetic field strengths between the onset of core solidification and the end of dynamo generation are averages for this time interval to remove oscillations in field strength due to the discretisation of the model (Sanderson et al., 2024). The thin, vertical, white lines in some runs are < 0.5 Ma breaks in dynamo generation due to a rapid increase in viscosity at ϕ_c . These lines are artefacts of our viscosity and stagnant lid parameterisation and should not be interpreted. For each parameter, the model was run across the range of values in Table 1, while all other parameters are held at a constant median value (except ϕ_c where the constant value was the experimental upper bound). The constant parameter values were: $\eta_0 = 10^{19}$ Pas, $\beta = 0.0225 \text{ K}^{-1}$, $\alpha_n = 30$, $\phi_c = 0.3$, $\eta_l = 10$ Pas, $^{60}\text{Fe}/^{56}\text{Fe} = 10^{-8}$, $X_{S,0} = 29.85$ wt%. Magnetic field strengths as a function of time for each combination of parameters shown in this plot are provided in the Supplementary Materials.

dynamo generation (see Supplementary Materials). Otherwise, all other parameter combinations produce two periods of dynamo generation (Figure 3). Across these two dynamo generation periods, we observe two distinctive trends in magnetic field strength: (i) the first dynamo generation period can have two peaks in magnetic field strength (ii) in the second dynamo generation period, magnetic field strength increases with time towards a peak value during core solidification. The first peak in the first epoch of dynamo generation corresponds to the onset of dynamo generation and the second peak occurs when the base of the mantle first cools below the critical melt fraction (Sanderson et al., 2024). The peak in field strength at the beginning of the first epoch of dynamo generation is always the strongest because radiogenic heating by ^{60}Fe increases CMB heat flux (F_{CMB}). For all runs with multiple field generation periods, the final dynamo generation period begins before the onset of core solidification. Reference viscosity has the strongest

Figure 4: Magnetic Reynolds number (Re_m) as a function of time for a range of initial $^{60}\text{Fe}/^{56}\text{Fe}$, mantle viscosities, core compositions, and planetesimal radii. Filled bars indicate periods when the dynamo is on and the colour of the bars indicates the magnetic Reynolds number. Subcritical values (< 10) are not shown. Supercritical values are categorised according to the range of possible criticality limits: 10–40, 40–100 and >100 (Christensen and Aubert, 2006; Stevenson, 2003). The small, vertical, black line on each bar indicates the onset of core solidification in each model run. Magnetic Reynolds numbers between the onset of core solidification and the end of dynamo generation are averages for this time interval to remove oscillations in Re_m due to the discretisation of the model (Sanderson et al., 2024). The thin, vertical, white lines in some runs are < 0.5 Ma breaks in dynamo generation due to a rapid increase in viscosity at ϕ_c . These lines are artefacts of our viscosity and stagnant lid parametrisation and should not be interpreted. For each parameter, the model was run across the range of values in Table 1 and shown on Figure 3, while all other parameters were held at a constant median value (except ϕ_c where the constant value was the experimental upper bound). The range of values for radius are shown explicitly. The constant parameters values are: $r = 300$ km, $\eta_0 = 10^{19}$ Pas, $\beta = 0.0225$ K^{-1} , $\alpha_n = 30$, $\phi_c = 0.3$, $\eta_l = 10$ Pas, $^{60}\text{Fe}/^{56}\text{Fe} = 10^{-8}$, $X_{S,0} = 29.85$ wt%.

effect on the duration of the gap in dynamo generation and $^{60}\text{Fe}/^{56}\text{Fe}$ has the strongest influence on the resulting magnetic field strength. Despite the range in dynamo durations and strengths, most Re_m values fall between 10–40 (Figure 4).

3.1.1. Effect of ^{60}Fe

Increasing $^{60}\text{Fe}/^{56}\text{Fe}$ brings forward the onset of the dynamo to 1–2 Ma after CAI formation and increases peak field strength and Re_m in the first epoch of dynamo generation. The onset of the dynamo is earlier for increased ^{60}Fe because increased heating either erodes core thermal stratification more rapidly or prevents its formation altogether,

which brings forward the time that F_{CMB} becomes superadiabatic. Radiogenic heating by ^{60}Fe also increases the temperature of the core and the temperature difference relative to the mantle, which increases F_{CMB} and the strength of the dynamo. Model runs with $^{60}\text{Fe}/^{56}\text{Fe} \geq 10^{-7}$ had peak field strengths in the first period of dynamo generation 2–3 times higher than runs with $^{60}\text{Fe}/^{56}\text{Fe} = 10^{-8}$. This extra heat is removed from the core by an elevated F_{CMB} during the first period of dynamo generation. As such, by the second epoch of dynamo generation the peak field strengths, Re_m and the onset of core solidification are similar across all values of $^{60}\text{Fe}/^{56}\text{Fe}$. There are similar onset times and field strengths for the first dynamo generation period for $^{60}\text{Fe}/^{56}\text{Fe} = 0$ and $^{60}\text{Fe}/^{56}\text{Fe} = 10^{-9}$. This similarity suggests that when $^{60}\text{Fe}/^{56}\text{Fe} \leq 10^{-9}$ the effect of ^{60}Fe can be neglected. The onset times vary little across variations in other parameters indicating $^{60}\text{Fe}/^{56}\text{Fe}$ is the dominant control on onset time for the first period of dynamo generation.

3.1.2. Effect of viscosity

The reference viscosity, η_0 , has the strongest effect on the duration of the first period of dynamo generation and the following gap. Above 10^{21} Pas, the first period of dynamo generation ends after 13–14 Ma and is followed by a gap of >80 Ma in dynamo generation. This results from the rapid thickening of the surface stagnant lid shutting off convection earlier for the highest reference viscosities. In contrast, below 10^{16} Pas, there is only one epoch of dynamo generation, because the mantle viscosity is sufficiently low that mantle convection does not cease before core solidification. The second peak in magnetic field strength in the first epoch of dynamo generation widens and increases in strength with decreasing reference viscosity, because the thinner boundary layer at the CMB raises F_{CMB} . An elevated F_{CMB} increases the rate at which the core cools, which brings forward the onset of core solidification and the end of dynamo generation.

The viscosity parameters have very little effect on the supercriticality of Re_m . Only the lowest η_0 and highest values of ϕ_C increase Re_m in the first 12 Ma (Figure 4). The lowest values of η_0 are less physical, because they are based on the highest values from laboratory experiments, which have not been extrapolated to planetesimal pressure values. As such, this increase in Re_m can be discounted. However, the highest value $\phi_C = 0.5$ has been adopted in previous thermal evolution models, despite not being supported by experimental data. The elevated Re_m for this value may have resulted in overestimates of field strength and dynamo duration in previous work.

3.1.3. Effect of $X_{\text{S},0}$

Initial core sulfur content, $X_{\text{S},0}$, has a strong effect on the timing of core solidification, because increasing $X_{\text{S},0}$ lowers the liquidus temperature of the core and more cooling is required to reach this temperature. The lowest $X_{\text{S},0}$ removes the gap in dynamo generation, because the early onset of core solidification provides additional compositional buoyancy flux to drive the dynamo even when mantle convection ceases.

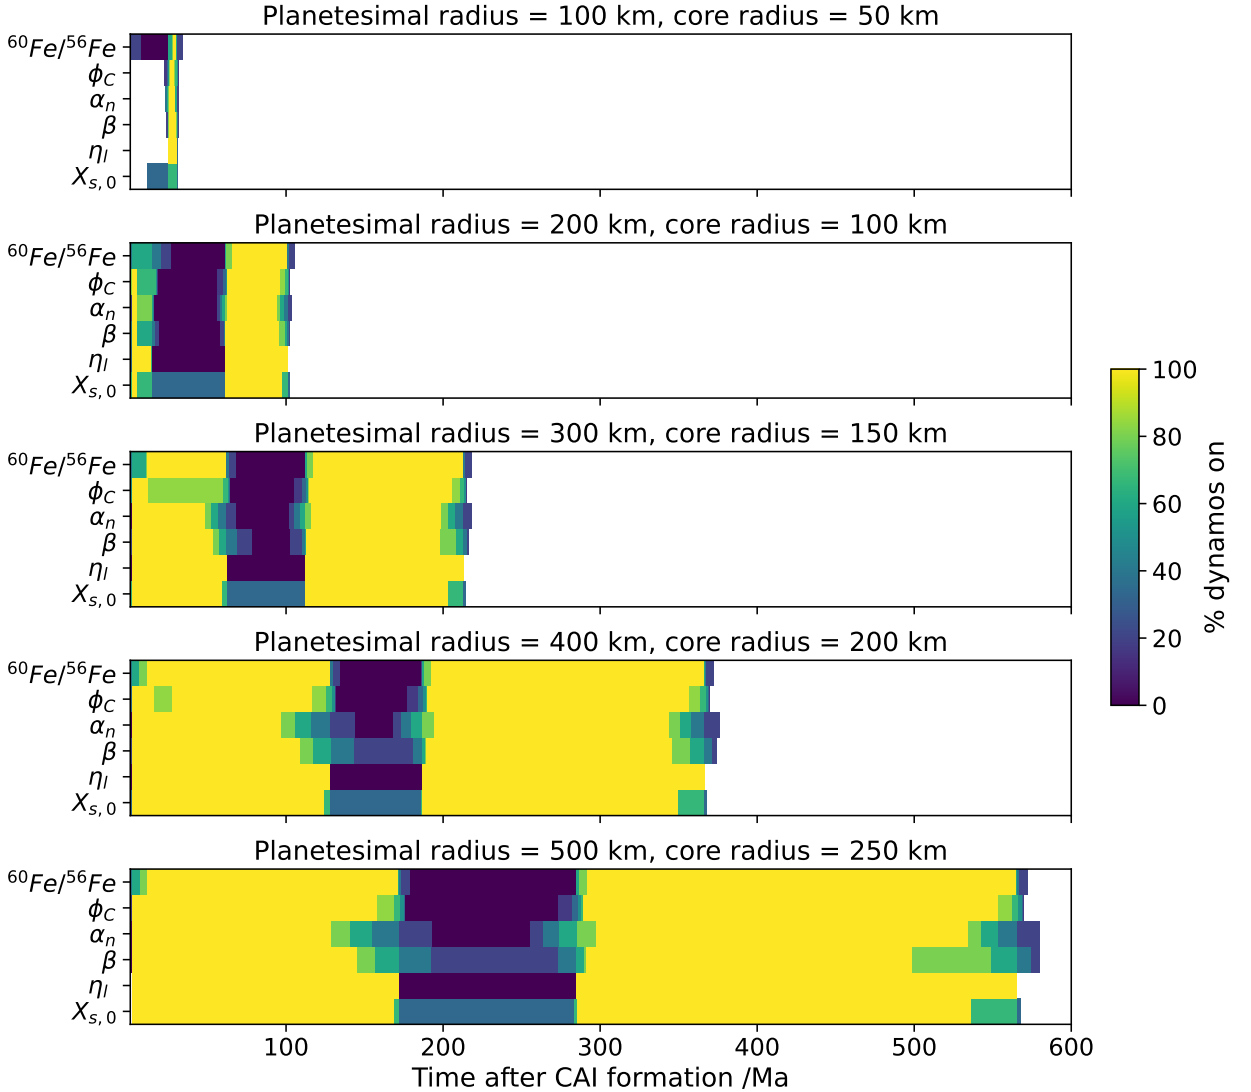

Figure 5: Proportion of active dynamos for variation in initial $^{60}\text{Fe}/^{56}\text{Fe}$, mantle viscosities, and core compositions for planetesimals ranging from 100-500 km in radius. In an individual panel, model runs are grouped in horizontal blocks by parameter. Yellow indicates that all dynamos are on at a given time irrespective of the value of a parameter, dark blue indicates no dynamos are on at a given time irrespective of the value of a parameter. Light blue to green regions indicate a dynamo is on for a subset of values of that parameter. White space indicates times after the last period of dynamo generation and the end of the simulation. The constant parameters values are: $\eta_0 = 10^{19}$ Pas, $\beta = 0.0225 \text{ K}^{-1}$, $\alpha_n = 30$, $\phi_c = 0.3$, $\eta_l = 10$ Pas, $^{60}\text{Fe}/^{56}\text{Fe} = 10^{-8}$ and the range for each parameter is given in Table 1. η_0 causes a wide variation in dynamo timings, so is shown separately in Figure 6.

3.2. Variable radius

To identify the impact of planetesimal radius on thermal evolution and dynamo generation we ran models with varying radii and other variables held constant (Table 1). Core radius was assumed to be half the planetesimal radius. Planetesimal radius has the strongest effect on dynamo timing, duration, and width of the gap in dynamo generation (Figure 5). Larger planetesimals cool more slowly so mantle convection ceases later, which prolongs the first epoch of

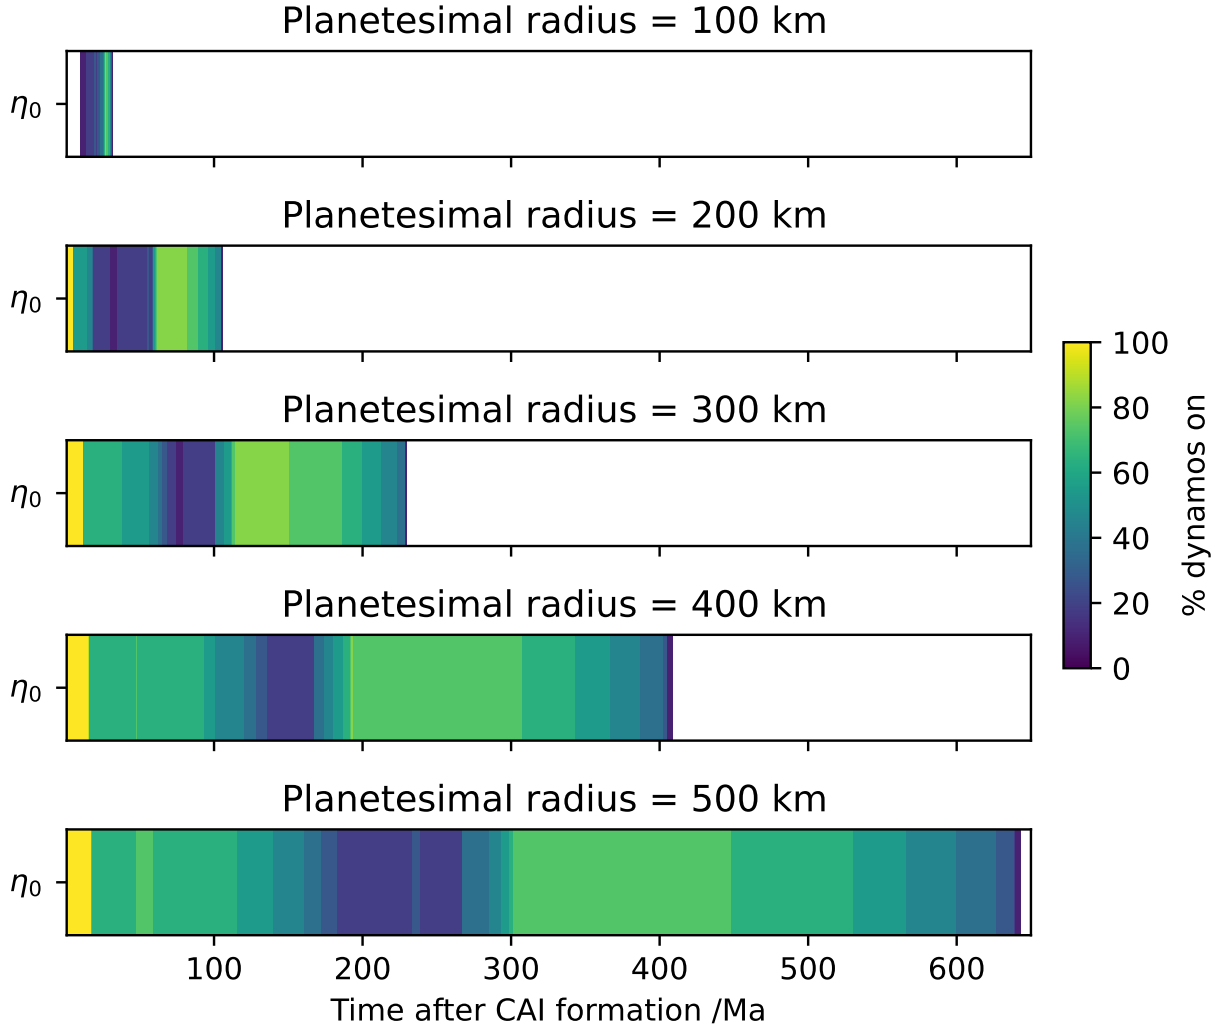

Figure 6: Proportion of active dynamos across a range of reference viscosity, η_0 , for planetesimals ranging from 100–500 km in radius. Core radius is half planetesimal radius. Yellow indicates that all dynamos are on at a given time irrespective of the value of η_0 , dark blue indicates no dynamos are on at a given time irrespective of the value of η_0 . Light blue to green regions indicate a dynamo is on for a subset of values of η_0 . White space indicates times after the last period of dynamo generation and the end of the simulation. The vertical axis is equivalent to one horizontal block in Figure 5 and has no physical meaning. The constant parameter values are: $\beta = 0.0225 K^{-1}$, $\alpha_n = 30$, $\phi_C = 0.3$, $\eta_l = 10 \text{ Pas}$, $^{60}\text{Fe}/^{56}\text{Fe} = 10^{-8}$, $X_{S,0} = [29.45, 29.65, 29.85, 30.05, 30.05] \text{ wt\%}$ for [500, 400, 300, 200, 100] km radius planetesimals. The range for η_0 is given in Table 1.

dynamo generation. Larger core size increases the lengthscale of convection; this raises the Re_m value for a given F_{CMB} , which further prolongs dynamo generation. Larger core size also increases magnetic field strengths (Figure S1–S4). The increase in magnetic field strength is most pronounced at the onset of the first epoch of dynamo generation for when the highest values of $^{60}\text{Fe}/^{56}\text{Fe}$ are considered. Bodies with radius of 100 km only generate magnetic fields after the onset of core solidification (Figure 4) except for the highest values of $^{60}\text{Fe}/^{56}\text{Fe}$. Increasing planetesimal radius from 100 km to 500 km increases the end time of dynamo generation from ~ 30 to ~ 600 Ma. The gap in dynamo generation

moves later ($\sim 20\text{--}200$ Ma) and increases in duration ($\sim 20\text{--}270$ Ma) for increasing planetesimal radius. For each body size, the timings of the dynamo generation periods are consistent across variations in the other parameters (Figure 5). An exception is η_0 (Figure 6), where values $< 10^{16}$ Pas do not produce a gap in dynamo generation. However, there is still a trend of increasing dynamo duration with radius for η_0 .

4. Discussion

4.1. Reevaluating the paleomagnetic record

The purpose of our model is to determine the origins (nebula field, thermal or compositional dynamo) of magnetisations in the meteorite paleomagnetic record. Overall, our model results suggest two key interpretations of the paleomagnetic record should be revisited. First, the earliest recorded magnetisations (< 5 Ma after CAI formation), previously attributed to the nebula field, could have been dynamo generated. This is due to inclusion of ^{60}Fe in our model bringing forward the onset of thermal dynamos to 1–2 Ma after CAI formation, which allows for thermal dynamo generation prior to the dissipation of the nebula field (Figure 7). Second, late magnetic remanences, previously ascribed to the second epoch of dynamo generation during core solidification, may not have been in the second epoch and do not require core solidification, but could instead be produced by a thermal dynamo. Our model predicts an elongated first epoch of dynamo generation lasting until 20–200 Ma after CAI formation (depending on radius) rather than until 9–34 Ma after CAI formation as suggested by previous models (Dodds et al., 2021). Additionally, in our model, the second epoch of dynamo generation begins before the onset of core solidification. The meteorite paleomagnetic record in light of our new model results is reassessed in detail below.

4.1.1. Paleomagnetic records of the nebula field

Unidirectional magnetisation within chondrules, but non-unidirectional magnetisation between chondrules in a meteorite is only possible if the chondrules acquired their remanence prior to accretion onto the meteorite parent body. The nebula field is the only source of a pre-accretionary magnetisation, therefore non-unidirectional chondrule magnetisations provide conclusive evidence that a paleointensity can be attributed to the nebula field. Non-unidirectional measurements of chondrules from CO (Borlina et al., 2021), LL3 (Fu et al., 2014b) and CR chondrites (Fu et al., 2020) are interpreted as evidence for the nebula field $\sim 1.7\text{--}4$ Ma after CAI formation with paleointensities up to ~ 150 μT (Figure 7). Bulk meteorite magnetisations from parent bodies that were too small to generate a dynamo can also be attributed to the nebula field (e.g. Erg Chech 002, Neumann et al., 2023; Maurel and Gattacceca, 2024).

Null remanences could indicate the dissipation of the nebula field, but there are two other possible interpretations, which must be excluded first. First, a meteorite parent body may have formed in a distal part of the Solar System where the field was weak (e.g. Tagish Lake, Bryson et al., 2020b). Second, the magnetic minerals may not have formed in

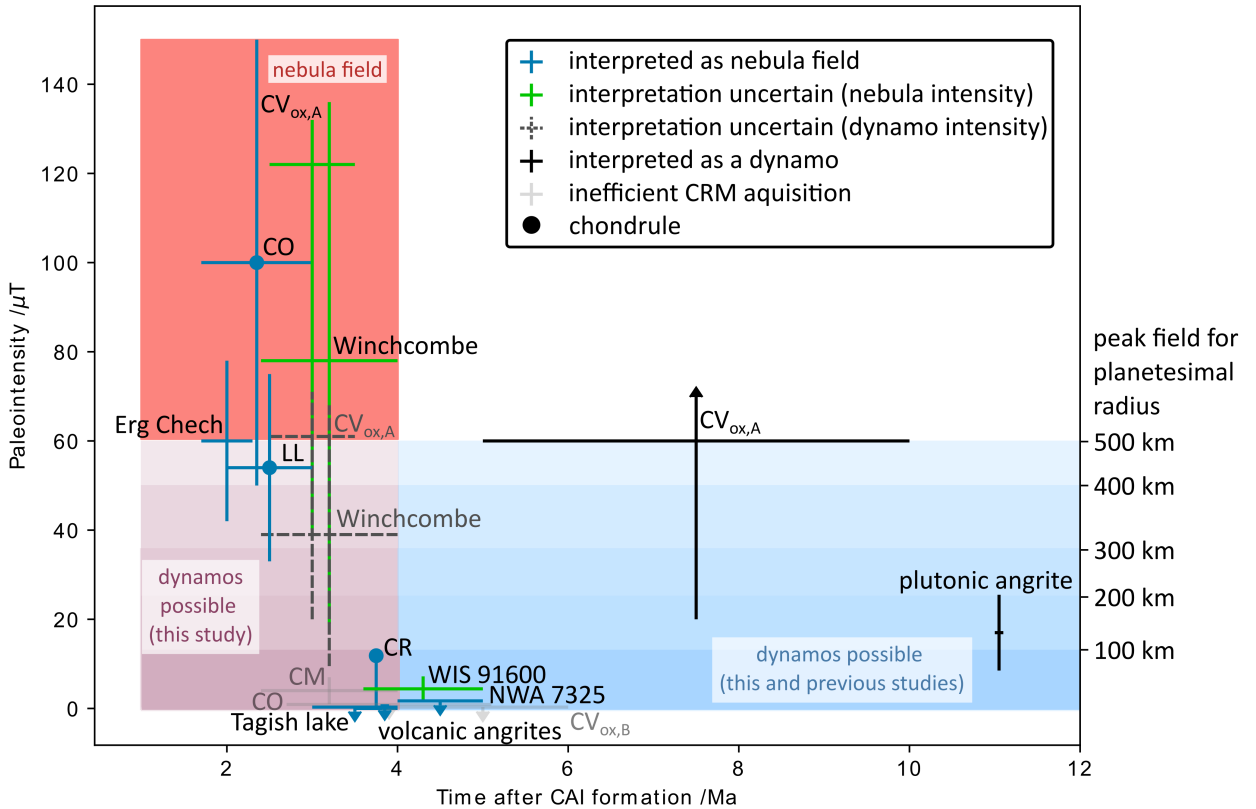

Figure 7: A summary of meteorite paleointensities for the first 12 Ma after CAI formation. Meteorites for which the cause of magnetisation is interpreted as a nebula field (or lack of) are plotted in blue. Meteorites for which the cause of magnetisation has been interpreted as a dynamo field are plotted in black. Meteorites which could have a nebula or dynamo origin are plotted in green for their possible nebula field paleointensities. The dashed grey lines indicate the paleointensities of Winchcombe (Bryson et al., 2023) and Allende (Fu et al., 2021) if the factor of two correction for the nebula field is not applied. Faded grey points correspond to null or low paleointensities, which may be due to formation of magnetite by pseudomorphic replacement which cannot record a chemical remnant magnetisation (CRM) (Bryson et al., 2023). The blue circles indicate pre-accretionary remanences from chondrules. The IVA irons have not been included, because they were generated by a solidifying, unmantled core (Bryson et al., 2017). The R chondrites have too large an age uncertainty and the CV chondrites are too altered to provide useful constraints, so neither are shown (Cournède et al., 2020; Shah et al., 2017). Intensity bars with arrows indicate values with an upper/lower limit (the cap) and for the CV_{ox,A} the best guess is the intersection with the time error bar. Our new model brings forward the onset of dynamo generation (pink box) relative to previous models (blue box). The graduated shading in the blue and pink regions indicates the maximum paleointensity for a given planetesimal radius (shown by ticks on the right hand vertical axis). The orange box indicates the duration of the nebula field, which may be 1 Ma longer than shown here if the angrite age is recalculated based on Piralla et al. (2023). This would further increase the overlap between dynamo and nebula fields. Data and references for this table are given in the Supplementary Materials.

a way that allowed them to record a remanence. Many carbonaceous chondrites record magnetisation in magnetite, which formed during aqueous alteration. If the magnetite formed by pseudomorphic replacement of FeNi metal rather than precipitation, it may not have recorded a new remanence during this process (Bryson et al., 2023). This could explain the null remanence in CV chondrite Kaba (Gattacceca et al., 2016) and the upper limit on paleointensity of 0.9 μT from the matrix of CO chondrites (Borlina et al., 2022). For the volcanic angrites both these interpretations

can be excluded. They formed in the inner Solar System, erupted $\sim 3.8\text{--}3.9$ Ma after CAI formation¹ and cooled quickly forming magnetite that should have recorded any magnetic fields present (Wang et al., 2017). Therefore, a null remanence in the angrites suggests the nebula field in the inner Solar System dissipated 3.8–3.9 Ma after CAI formation (Wang et al., 2017). The recovered paleointensity of $< 0.6 \mu\text{T}$ from ungrouped achondrite NWA 7325 at $\sim 4\text{--}5$ Ma after CAI formation (Weiss et al., 2017) further supports the nebula field in the inner Solar System having dissipated by this time.

4.1.2. Ambiguous paleomagnetic records: nebula or dynamo fields?

Interpretation of bulk chondrite paleomagnetic remanences (i.e. not individual chondrule measurements) from the first 5 Ma after CAI formation is complicated because these meteorites could sample the outer layer of a partially differentiated planetesimal (Carporzen et al., 2011; Elkins-Tanton et al., 2011; Weiss and Elkins-Tanton, 2013). In this case, a chondritic meteorite could record a paleomagnetic remanence from a dynamo generated in the core of their partially differentiated parent body rather than the nebula field. The feasibility of this scenario rests on the timing of planetesimal dynamos and evidence for partially differentiated meteorite parent bodies. Our model demonstrates that a parent body, with $^{60}\text{Fe}/^{56}\text{Fe} \geq 10^{-8}$, would have an early onset of a thermal dynamo before the dissipation of the nebula field. Thermally metamorphosed chondritic meteorites could have been heated purely radiogenically on a parent body that partially differentiated. The interpretation of bulk remanences in the CM and CV chondrites and WIS 91600 (green points in Figure 7) is less clear than previously, in light of the possibility they record an early dynamo. The ages of the R chondrites are too poorly constrained (0–20 Ma after CAI formation, Cournède et al., 2020) for the origin of their remanence to be discussed.

The CM chondrites and WIS 91600 recorded a magnetic field 2–4 Ma after CAI formation (Cournède et al., 2015; Bryson et al., 2023) and likely 3.6–5 Ma after CAI formation (Bryson et al., 2020a), respectively. The timing of these remanences is consistent with either a nebula field or dynamo origin. For example, a 500 km radius planetesimal with $^{60}\text{Fe}/^{56}\text{Fe} = 1\text{--}6 \times 10^{-7}$ and other constant parameters from Table 1 produces intensities that match those recovered from Winchcombe (Figure S10). However, lack of evidence for prolonged thermal metamorphism in the CM chondrites and WIS 91600 (Suttle et al., 2021; Bryson et al., 2020a) argues against partially differentiated parent bodies for these meteorites; unless they sample the topmost, coolest layer of such a body. Further numerical modelling of partially differentiated bodies combining gradual accretion and ^{60}Fe are required to determine whether a dynamo in a partially differentiated body or the nebula field is the source of these remanences.

The CV chondrites are thermally metamorphosed (Carporzen et al., 2011; Elkins-Tanton et al., 2011; Gattacceca et al., 2016) and have a complex paleomagnetic record. CV chondrules have been modified by impacts, heating and

¹These ages were originally reported as absolute Pb-Pb ages and may be shifted to 4.8–4.9 Ma after CAI formation based on reevaluation of the anchor for Pb-Pb (Piralla et al., 2023).

aqueous alteration and have a non-unidirectional magnetisation within an individual chondrule, so their remanence cannot be attributed to the nebula field (Fu et al., 2014a; Shah et al., 2017). Allende records a magnetisation in the iron sulfides in the matrix from 2.5–3.5 Ma after CAI formation (Fu et al., 2021), and has a bulk remanence dated to 5–40 Ma after CAI formation (Carpözen et al., 2011; Elkins-Tanton et al., 2011). The CV chondrite Kaba has a null remanence from aqueous alteration at 4–6 Ma after CAI formation, but a $\sim 3 \mu\text{T}$ remanence from prolonged metamorphism tens of Ma after CAI formation (Gattacceca et al., 2016). The later (> 5 Ma after CAI formation) CV chondrite remanences, combined with evidence for thermal metamorphism, suggest the CV chondrite parent body was partially differentiated and generated a dynamo (Elkins-Tanton et al., 2011; Gattacceca et al., 2016). Previously, Kaba's null remanence, recorded during aqueous alteration, was used as evidence for the dissipation of the nebula field before the onset of the dynamo on the CV chondrite parent body. This supported a nebula origin for the earliest Allende remanence (2.5–3.5 Ma after CAI formation Fu et al., 2021). However, Kaba's magnetite may have been unable to acquire a remanence during formation (Bryson et al., 2023), so this null remanence may not indicate an absence of a magnetic field on the CV parent body at 4–6 Ma after CAI formation. Altogether, the altered interpretation of Kaba's null remanence, thermal metamorphism of the CV chondrite parent body and the early dynamo onset predicted by our models suggests the earliest remanence on Allende could be due to the early onset of a thermal dynamo.

Intensity of remanence Next, we assess whether paleointensity can be used to determine if a remanence has a dynamo or nebula field origin. As shown in Figure 7, the maximum nebula intensities measured are stronger than the maximum intensities predicted by our dynamo model. However, the quoted nebula intensities recorded by Winchcombe (CM chondrite, Bryson et al., 2023) and Allende (CV chondrite, Fu et al., 2021) are a factor of two larger than the measured paleointensities to account for rotation of the parent body during prolonged remanence acquisition. If these paleointensities were produced by dynamo fields this correction would not be required, because the magnetic field is co-rotating with the planetesimal. Removing this correction decreases their paleointensities so they are within the range of field strengths predicted by our dynamo models (dashed lines on Figure 7). Our upper limits on dynamo field strengths ($> 30 \mu\text{T}$) are for the largest planetesimals with highest values of ^{60}Fe at early times (< 3 Ma after CAI formation). Most parameter combinations predict weaker dynamo strengths < 3 Ma after CAI formation (10–30 μT , Figure 3 and S1–S4). A combination of approaches would be required to determine if measured paleointensities, even without the factor of two amplification, are too strong to be dynamo generated. The uncertainty on the paleointensity measurements could be reduced, and parent body size and $^{60}\text{Fe}/^{56}\text{Fe}$ could be independently constrained, e.g. by thermal models and isotopic measurements. Regardless of improved measurements, the difficulty in converting from field strengths acquired by different mechanisms in the laboratory compared to the parent body (factors of 2–5, Weiss and Tikoo, 2014; Maurel and Gattacceca, 2023) and uncertainties in the ratio of dipole field at the CMB to the internal

dynamo field from dynamo scaling laws (0.06–0.1 for Earth, Davies et al., 2022) may mean that the uncertainties of measured and predicted paleointensities overlap. Overall, current recovered paleointensities and modelled field intensities cannot be used to distinguish between a dynamo or nebula field.

The possibility of the earlier onset of a thermal dynamo due to ^{60}Fe reduces the number of meteorite paleomagnetic studies that provide compelling evidence for the nebula field in the outer Solar System, because the bulk remanences in CM and CV chondrites may not record nebula fields. This should be considered when using this data to discuss differences in field strength and protoplanetary disk dispersal time between the inner and outer Solar System (Weiss et al., 2021; Borlina et al., 2022). Paleomagnetic measurements of individual, pristine chondrules are vital to understand the nebula field, because their non-unidirectionality can indicate conclusively if a remanence is preaccretionary.

4.1.3. Paleomagnetic records of planetesimal core crystallisation

Our results argue that late remanences (> 65 Ma after CAI formation based on the current meteorite record) do not require the presence of a solidifying core. The first epoch of dynamo generation can last until 20–200 Ma after CAI formation (depending on radius) rather than until 9–34 Ma after CAI formation suggested by previous models (Dodds et al., 2021). Additionally, our improved core solidification model reveals the second epoch of dynamo generation can begin prior to the onset of core solidification. As a result, the source of buoyancy to drive a dynamo cannot be assumed purely based on timing of a magnetic remanence. For extremes of some parameter values (low η_0 and $X_{S,0}$), onset of solidification is early and most of dynamo generation is powered by a combination of thermal and compositional buoyancy. Previous studies of the Main Group pallasites (Bryson et al., 2015; Nichols et al., 2021) and IIE irons (Maurel et al., 2020) have used the onset of a late-stage dynamo as an indicator for the start of core solidification. This assumption has been used to constrain planetesimal radius, core size, thermal history, and core composition. Our model highlights that the beginning of a second epoch of dynamo is unlikely to be coincident with the beginning of core solidification for any initial core sulfur content, and therefore these studies should be re-evaluated.

4.1.4. Paleomagnetic constraints on primordial $^{60}\text{Fe}/^{56}\text{Fe}$

The null paleointensities in the volcanic angrites and NWA 7325 at 3.8–5 Ma after CAI formation (Wang et al., 2017; Weiss et al., 2017) contradicts the early onset of a dynamo in bodies with $^{60}\text{Fe}/^{56}\text{Fe} \geq 10^{-8}$ predicted by this model. Magnetic remanences in the plutonic angrite, Angra dos Reis at 11 Ma after CAI formation (Wang et al., 2017), indicate the angrite parent body was differentiated and did generate a dynamo later in its history. Explanations, such as parent body size, gradual accretion, or ^{60}Fe fractionation are unlikely to cause this delay in dynamo onset (see Supplementary Materials). Another explanation could be $^{60}\text{Fe}/^{56}\text{Fe} \leq 10^{-9}$ in the formation region of the angrites such that the time taken to erode core thermal stratification led to a delay in dynamo generation (Bryson et al., 2019a; Dodds et al., 2021). Tang and Dauphas (2012) measured values of $^{60}\text{Fe}/^{56}\text{Fe} = 0.9 \pm 0.5 \times 10^{-8}$ in

the angrites. Additionally, values of $^{60}\text{Fe}/^{56}\text{Fe}$ from silicates in non-carbonaceous chondrules are within error of zero ($0.8 \pm 1.0 \times 10^{-7}$, Kodolányi et al., 2022a). For a 300 km body accreted at 0.8 Ma after CAI formation, $^{60}\text{Fe}/^{56}\text{Fe} < 1.75 \times 10^{-9}$ results in a dynamo onset time consistent with the angrite data (see Figure S5). This limit lies within the lower bounds of these non-carbonaceous $^{60}\text{Fe}/^{56}\text{Fe}$ values. Current measurements from the carbonaceous IID and IVB irons ($6 \pm 2 \times 10^{-7}$, Cook et al., 2021) and carbonaceous chondrule silicates ($4 \pm 2 \times 10^{-7}$ Kodolányi et al., 2022a) have large uncertainties, but neither are within error of $^{60}\text{Fe}/^{56}\text{Fe} < 10^{-8}$. This suggests there could be heterogeneity in $^{60}\text{Fe}/^{56}\text{Fe}$ between the carbonaceous and non-carbonaceous reservoirs (Cook et al., 2021; Kodolányi et al., 2022a). Measurement of a paleomagnetic remanence in a carbonaceous achondrite between the age of the volcanic and plutonic angrites could inform this discussion. If such a carbonaceous achondrite has a null paleomagnetic remanence, this could provide evidence for $^{60}\text{Fe}/^{56}\text{Fe} < 10^{-8}$ throughout the Solar System and constrain the timing of the dissipation of the nebula field in the outer Solar System. If this carbonaceous achondrite is found to have acquired a remanence at a similar time to null remanence acquisition in the volcanic angrites (i.e., when the nebula field has dissipated), this could provide evidence for early dynamo onset and heterogeneity in $^{60}\text{Fe}/^{56}\text{Fe}$ in the early Solar System.

4.2. Viscosity parameters in future planetesimal thermal evolution models

Mantle critical melt fraction, ϕ_C , is a crucial parameter in thermal evolution models. It determines planetesimal peak temperature and melt fraction (see Appendix B), and defines the threshold for magma ocean formation and convection in some models (e.g. Sturtz et al., 2022a; Neumann et al., 2023). A lower, more realistic value of ϕ_C should be used in future models. For models of specific parent bodies, this will affect the extent of the magma ocean and the inferred initial location of a meteorite (e.g. Erg Chech 002, Sturtz et al., 2022a). In two-phase flow models for planetesimal differentiation (e.g. Lichtenberg et al., 2019; Monnereau et al., 2023), reducing ϕ_C and planetesimal peak temperature may alter the Fe-FeS compositions that can be molten, which will affect initial core composition. Additionally, reducing the melt threshold for magma ocean onset in differentiation models may decrease the time available for processes such as differentiation via percolation.

The value of mantle reference viscosity, η_0 , has a strong effect planetesimal cooling rate. Future models should test multiple values in the extrapolated range of η_0 when attempting to constrain a parent body thermal history from meteorite isotope data (e.g. Bryson et al., 2019b; Neumann et al., 2023). Future models could attempt to constrain values for planetesimal η_0 (and other viscosity parameters) based on parent body composition, water content, and observed gaps in the paleomagnetic record.

4.3. Validity

This work only explored variations within one parameter at a time, while all other parameters were held at their median values (except ϕ_C where the constant value was the experimental upper bound). Using endmember values

for multiple parameters simultaneously may result in an even wider range of dynamo generation times. Varying a single parameter enables the effect of each parameter to be understood and the dominant factors in dynamo generation timing to be isolated. As demonstrated in Figure 5, even across variations in parameters other than radius, there are large portions of time where the planetesimal dynamo is consistently active. Therefore, even if multiple parameters are varied, the trends in timing with radius predicted here are likely to hold true. The choice of critical Re_m , light elements in the core, $X_{S,0}$, core radius fraction and assumptions about accretion and differentiation are justified for the purposes of this work and do not have a large impact on the results (for further discussion see the Supplementary Materials).

5. Conclusions

Using the refined planetesimal thermal evolution model of Sanderson et al. (2024), we explored the effects of ^{60}Fe , mantle viscosity, initial core sulfur content, and planetesimal radius on planetesimal dynamo generation. Our results suggest there is a wider range in dynamo timings and durations than previously predicted. The meteorite paleomagnetic record therefore cannot be split into three distinct epochs of magnetic field generation (nebula field, thermal dynamos and compositional dynamos) and the implications of some paleomagnetic remanences should be re-evaluated.

- Inclusion of ^{60}Fe in the core can bring forward the onset of thermal dynamos to 1–2 Ma after CAI formation, extending the time at which the first planetesimal dynamos were possible. Therefore, some meteorite remanences recorded prior to 5 Ma after CAI formation could have a thermal dynamo origin rather than a nebula field origin.
- Null paleomagnetic remanences in the angrites contradict the early onset of thermal dynamos caused by ^{60}Fe . This could provide evidence for heterogeneous $^{60}\text{Fe}/^{56}\text{Fe}$ in the early Solar System. Paleomagnetic measurements of an old (<10 Ma after CAI formation) carbonaceous achondrite could help inform this.
- Increasing planetesimal radius (from 100 km to 500 km) greatly increases the start time of the gap in planetesimal dynamo generation (20 to 200 Ma after CAI formation) and final end of dynamo duration (40 to 640 Ma after CAI formation).
- The paleomagnetic record does not reflect early thermal dynamos and later compositional dynamos during core solidification, as previously interpreted. Variation in initial core sulfur content and mantle reference viscosity can produce early thermo-compositional dynamos. For most parameter combinations, there is a second thermal dynamo period prior to the onset of core solidification.
- Late magnetic remanences (>65 Ma post CAI formation based on the current record) do not require a solidifying core. As a result, the planetesimal radii, core sizes, thermal histories, and core compositions of the Main Group pallasites and IIE irons should be re-evaluated.

- A range of planetesimal radii, mantle reference viscosities, and initial $^{60}\text{Fe}/^{56}\text{Fe}$ ratios should be explored when attempting to constrain parent body properties based on a meteorite paleomagnetic remanence.

A. Extrapolation of reference viscosities

Viscosity is temperature and pressure dependent. Planetesimal mid-mantle pressures lie above that of lab experiments and below that of planets, therefore extrapolation is required when estimating planetesimal reference viscosities. Laboratory experiments are also on shorter timescales and lengthscales compared to planetary conditions. Therefore, geophysical observations, such as postglacial uplift (Karato and Wu, 1993) are often used to constrain mantle viscosity on Earth. For this reason, the full range of η_0 in this paper was extrapolated from planetary values and

η_0 /Pas	p_{ref} /MPa	T_{ref} /K	Extrapolated η_0 /Pas
10^{19} – 10^{22}	960	1600	10^{19} – 10^{24}

Table 2

Reference parameters for viscosity extrapolations for Ganymede (Rückriemen et al., 2018). Reference pressure is calculated in the mid-mantle using average values for the Ganymede interior structure model in Rückriemen et al. (2018).

the experimental values were included as a lower bound. Extrapolation can be done using an Arrhenius law

$$\eta = \eta_0 \exp\left(\frac{E + pV}{RT} - \frac{E + p_{\text{ref}}V}{RT_{\text{ref}}}\right) \quad (1)$$

or the Frank-Kamenetskii approximation (Noack and Breuer, 2013)

$$\eta = \eta_0 \exp\left(\frac{E + p_{\text{ref}}V}{RT_{\text{ref}}^2}(T_{\text{ref}} - T) + \frac{V}{RT_{\text{ref}}}(p - p_{\text{ref}})\right). \quad (2)$$

In these equations, E and V are the activation energy and volume, p_{ref} and T_{ref} are the reference pressures and temperatures, R is the gas constant and p and T are the temperatures and pressures being extrapolated to. To estimate planetesimal mid-mantle viscosities extrapolations using both laws were performed on reference viscosity values for Ganymede (Rückriemen et al., 2018) (see Table 2) using a range in activation volumes from 2×10^{-6} – 2×10^{-5} m³mol⁻¹ (Hirth and Kohlstedt, 2003) and activation energies from 240–570 kJmol⁻¹ (Karato and Wu, 1993; Hirth and Kohlstedt, 2003). Assuming constant density core and mantle, planetesimal mid-mantle pressures range from 2 MPa to 50 MPa for 100–500 km bodies. These extrapolations give possible a wide range η_0 from 10^{19} – 10^{24} Pas due to the large uncertainties in activation volume and activation energy. Equation 1 and 2 give values within the same order of magnitude.

B. Effect of ϕ_C on peak temperatures

As shown in Figure 8, peak mantle temperature is close to that of ϕ_C due to the negative feedback loop between mantle temperature and stagnant lid thickness. At ϕ_C , an increase in temperature leads to a rapid drop in viscosity and thinning of the stagnant lid. This increases surface heat flux, which reduces mantle temperature, increases the viscosity and thickens the stagnant lid. This means choice of ϕ_C has direct control on the maximum mantle temperature of a planetesimal.
