

LEARNING THE LOCAL DENSITY OF STATES OF A BILAYER MOIRÉ MATERIAL IN ONE DIMENSION*

DIYI LIU[†], ALEXANDER B. WATSON[‡], STEPHEN CARR[§], AND MITCHELL LUSKIN[¶]

Abstract. Recent work of three of the authors showed that the operator which maps the local density of states of a one-dimensional untwisted bilayer material to the local density of states of the same bilayer material at non-zero twist, known as the twist operator, can be learned by a neural network. In this work, we first provide a mathematical formulation of that work, making the relevant models and operator learning problem precise. We then prove that the operator learning problem is well-posed for a family of one-dimensional models. To do this, we first prove existence and regularity of the twist operator by solving an inverse problem. We then invoke the universal approximation theorem for operators to prove existence of a neural network capable of approximating the twist operator.

Key words. Electronic Structure, Tight Binding Model, Numerical Analysis, Operator Learning

MSC codes. 68U10, 65J22, 68Q32

1. Motivation and summary. Since the discovery of correlated insulating phases and superconductivity in twisted bilayer graphene in 2018 [8, 9], it has become clear that stackings of 2D materials with a relative interlayer twist provide an excellent platform for investigating quantum many-body electronic phases. The huge number of novel materials which can be realized in this way motivates the development of computational tools for efficiently predicting which 2D materials stackings, and which twist angles, are likely to support such phases.

The stacking-dependent local density of states (SD-LDOS), the local density of states defined on the space of stackings (configurations) rather than in real space, provides a useful probe of whether a given twisted bilayer is likely to support interesting quantum many-body electronic phases. This is because, although the SD-LDOS is computed entirely from a single-particle model, peaks in the SD-LDOS correspond to energies and stackings where electron-electron interactions are likely to be enhanced. Peaks in the SD-LDOS can be viewed as the generalization of flat Bloch bands of effective moiré-scale continuum models to materials where no moiré-scale continuum model is available [11].

The basic challenge in predicting electronic properties such as the SD-LDOS of a twisted bilayer material is their lack of periodicity at generic (irrational) twist angles. Although powerful computational methods which leverage ergodicity of the twisted bilayer have been developed [7, 10, 36, 37], it remains much easier to compute the properties of untwisted stackings, which retain the periodicity of the monolayer. This is especially true for density functional theory approaches, to which approaches based

on ergodicity have not yet been generalized (although see [45, 52, 53]).

These considerations lead to a natural question: is it possible to predict electronic properties such as the SD-LDOS of a twisted bilayer material directly from the electronic properties of the same material at zero twist? If this were possible, it would allow for the discovery of new twisted bilayer materials likely to support interesting many-body phases relying only on relatively simple computations on untwisted bilayers. The same question can be posed more mathematically: do there exist operators which map properties of models of untwisted bilayer materials to those of the same bilayer materials at non-zero twist? Could these operators be numerically computed? In what follows, we will refer to such operators as twist operators.

Recent work of three of the authors [33] has provided considerable evidence that the answer to these questions may be yes. They considered a dataset consisting of pairs of images: on one hand, an image showing the numerically computed SD-LDOS for an untwisted one-dimensional bilayer material, and on the other, the numerically computed SD-LDOS for the same one-dimensional bilayer material, but twisted. Here, “twisting” a one-dimensional bilayer material refers to slightly shortening the lattice constant of one of the layers to create a lattice mismatch analogous to twisting a 2D bilayer. They then showed that it is possible to train a neural network on such a dataset so that the network accurately predicts the twisted SD-LDOS image corresponding to untwisted SD-LDOS images not in the training dataset. In other words, not only does a twist operator for the SD-LDOS exist, it is possible for a neural network to effectively learn it. Our model and analysis can also be applied to 2D untwisted heterostructures [49] directly where the lattice shortening models lattice mismatch.

The present work has two main goals. The first is to provide a mathematical formulation of [33], where we describe the one-dimensional models considered in [33] in detail, introduce the twist operator for the SD-LDOS in a general setting, and then make the specific operator learning problem considered in [33] precise. The second goal is to provide insight into the results of [33] by initiating the rigorous theory of the twist operator for the SD-LDOS. More specifically, for a specific family of one-dimensional bilayer models, and when the SD-LDOS is approximated by a polynomial, we are able to prove existence of the twist operator relating untwisted SD-LDOS images to their twisted counterparts. The key step is to prove that the coefficients of the untwisted bilayer Hamiltonian can be recovered from untwisted SD-LDOS data. Moreover, we are able to show that the twist operator is continuous, and hence can be approximated by a neural network up to arbitrary accuracy by invoking the universal approximation theorem.

1.1. Related work. The learning problem considered here and in [33] is an operator learning problem. Other operator learning problems have been considered in the mathematical literature; see, for example, [4, 6, 31, 32, 35]. Note that the task of learning the solution u of a differential equation $\mathcal{L}u = f$ can be interpreted as learning the action of the operator \mathcal{L}^{-1} [23, 26].

The problem of learning the unknown Hamiltonian operator for a given quantum system from data has been considered in the physics literature, although we emphasize that these works do not develop rigorous mathematical theory justifying their methods. For example, using band structure data or other kinds of electronic observable data [18, 20, 27, 41, 46], or atomistic local environment data [17, 19, 30, 50]. The problem of predicting atomic reconstruction in materials using machine learning was considered in [1]. The problem of identifying materials likely to host flat bands

using machine learning has also been considered in the physics literature; for example, see [5, 44].

Some related mathematical work has been done in the setting of quantum information science, where the works [24, 29, 38, 39] have introduced rigorously efficient algorithms for learning unknown parameters of many-body Hamiltonians from dynamics data. It would be interesting to try to apply similar ideas to the inverse problem we consider here, but note that the problem is quite different, since here we consider spectral (density of states) data.

1.2. Structure of this work. The structure of this work is as follows. In Section 2, we introduce the class of discrete tight-binding models of one-dimensional bilayer materials from which the dataset of [33] was constructed. In Section 3, we define the stacking-dependent local density of states (SD-LDOS) and the concept of SD-LDOS images. In Section 4, we introduce the concept of the twist operator for SD-LDOS images considered in [33] and present our results proving existence and regularity of the twist operator under specific conditions. In Section 5, we apply the universal approximation theorem for operators to prove existence of a neural network approximating the twist operator. In Section 6, we discuss computing SD-LDOS images for commensurate twists, which is how the data in [33] were generated. We provide our Conclusion in Section 7.

2. Mathematical formulation of the coupled chain model. Consider two periodic atomic chains in parallel within a certain plane. For the coupled chain, the Bravais lattice for each of the two chains can be defined as

$$\mathcal{R}_i = \{na_i : n \in \mathbb{Z}\}, \quad i \in \{1, 2\},$$

where a_i is the lattice parameter for the i th chain. We assume $a_1 = 1$ and $a_2 = 1 - \theta$ in the paper where $\theta < 1$ is the lattice mismatch for the coupled chain. The atomic orbitals attached to the two chains are labelled by the indices,

$$\Omega = (\mathcal{R}_1 \times \mathcal{A}_1) \cup (\mathcal{R}_2 \times \mathcal{A}_2),$$

where \mathcal{A}_i denotes the set of indices of atomic positions within each unit cell of chain i and $m_i := |\mathcal{A}_i|$. Each atomic orbital is attached to an atom, and each atom is indexed by a unit cell and the shift in the unit cell. We define the unit cell for i -th chain as

$$\Gamma_i = \{\beta a_i : \beta \in [0, 1)\}, \quad i \in \{1, 2\},$$

where each atomic orbital labeled by $R_i \alpha_i \in \Omega$ for $R_i \in \mathcal{R}_i$ and $\alpha_i \in \mathcal{A}_i$ is located at $R_i + \tau_{\alpha_i}$ for shifts $\tau_{\alpha_1} \in [0, 1]$ and $\tau_{\alpha_2} \in [0, 1 - \theta]$.

The general coupled chain system is aperiodic when θ is irrational, but the emergence of a new scale called the *moiré scale* can be observed, whose length is given by

$$a_M := \left(\frac{1}{a_1} - \frac{1}{a_2} \right)^{-1} = \frac{1 - \theta}{\theta}.$$

The disregistry function is defined by

$$b_{1 \rightarrow 2}(x) := (1 - a_2 a_1^{-1})x \pmod{\mathcal{R}_2},$$

where for any $x \in \mathbb{R}$, $x \pmod{\mathcal{R}_2} = \{x - na_2 \mid n \in \mathbb{Z} \text{ such that } 0 \leq x - na_2 < a_2\}$. The disregistry function describes the local environment for an atomic orbital located at x . The moiré period is defined to be the period of the disregistry function, i.e., $b_{1 \rightarrow 2}(a_M) = 0$ [12–14, 36, 37, 47].

FIG. 1. Schematic of the coupled chain system described in Section 2 with two orbitals per cell ($m_1 = m_2 = 2$), with a positive lattice mismatch $\theta > 0$ without interlayer shift ($d = 0$). When θ is irrational, the system has no exact periodic cell.

2.1. The tight binding model. In the tight-binding model [25, 36, 37], we model the wave function of an electron as an element ψ of the Hilbert space

$$\ell^2(\Omega) = \left\{ (\psi(R_i\alpha))_{R_i\alpha \in \Omega} : \sum_{R_i\alpha \in \Omega} |\psi(R_i\alpha)|^2 < \infty \right\}.$$

The tight binding Hamiltonian H is defined as the linear operator on $\ell^2(\Omega)$ acting as

$$(2.1) \quad (H\psi)(R\alpha) = \sum_{R'\alpha' \in \Omega} H(R\alpha, R'\alpha')\psi(R'\alpha'),$$

where $H(R\alpha, R'\alpha')$ is referred as the ‘‘hopping energy,’’ which models the interaction of the orbital associated with each atom. When $R\alpha, R'\alpha' \in \mathcal{R}_i \times \mathcal{A}_i$, $H(R\alpha, R'\alpha')$ is referred as an intralayer hopping energy. Moreover, when $R\alpha \in \mathcal{R}_i \times \mathcal{A}_i$ and $R'\alpha' \in \mathcal{R}_j \times \mathcal{A}_j$ but $i \neq j$, $H(R\alpha, R'\alpha')$ is referred as an interlayer hopping energy.

The intralayer hopping energy for the coupled chain where $R\alpha, R'\alpha' \in \mathcal{R}_i \times \mathcal{A}_i$ can be modeled as

$$(2.2) \quad H(R\alpha, R'\alpha') = \begin{cases} t_{\alpha, \alpha'}, & R - R' = a_i, \\ t_{\alpha', \alpha}, & R - R' = -a_i, \\ \epsilon_{\alpha, \alpha'}, & R = R', \\ 0, & \text{else.} \end{cases}$$

The constants $\epsilon_{\alpha, \alpha'}$ and $t_{\alpha, \alpha'}$ are given in \mathbb{R} for a specific material system and atomical orbital index α, α' . The interlayer hopping energy will be modeled by a smooth interlayer hopping function $h : \mathbb{R} \rightarrow \mathbb{R}$ such that

$$(2.3) \quad H(R\alpha, R'\alpha') = h(|r|), \quad r = R + \tau_\alpha + d(-\delta_{i1} + \delta_{i2}) - R' - \tau_{\alpha'},$$

where $R\alpha \in \mathcal{R}_i \times \mathcal{A}_i$, $R'\alpha' \in \mathcal{R}_j \times \mathcal{A}_j$ and $i \neq j$. The parameter d represents a relative shift between the layers, illustrated in Figure 2. At incommensurate twist angles, averages of physical quantities over R , such as the density of states, can be efficiently represented as averages over local configurations d using ergodicity [7, 37]. We assume that h decays exponentially in the sense that there exist positive constants $h_0, \gamma > 0$ such that

$$(2.4) \quad |h(x)| \leq h_0 e^{-\gamma|x|}.$$

FIG. 2. Schematic of the coupled chain system described in Section 2 with two orbitals per cell ($m_1 = m_2 = 2$), with a positive lattice mismatch $\theta > 0$ with interlayer shift ($d \neq 0$).

Given the assumption on interlayer coupling function and intralayer coupling function, by Young's inequality [16], the tight binding Hamiltonian is a bounded operator on $\ell^2(\Omega)$; see, e.g., [28]. To emphasize the dependence of H on these parameters, we will also use $H_{\theta,d}$ to denote the tight binding Hamiltonian for the coupled chain with mismatch θ and shift d .

3. Stacking-dependent local density of states: analysis and computation. The local density of states (LDOS) measures the density of eigenvectors of the Hamiltonian as a function of energy (eigenvalue) and position. It can be probed experimentally and is important for understanding the electronic properties of solids. The emergence of a singularity in the LDOS of twisted layered material, an indicator of a highly correlated physical system, give rise to the possibility of superconductivity and other interesting electronic properties [33]. The local density of states can also be used for computing the density of states, another important electronic property of materials [7, 37]. Predicting the LDOS of a solid is a crucial task for condensed matter physics, quantum chemistry as well as quantum material science.

3.1. Stacking-dependent local density of states. We introduce notation for one specific unit cell in layer two

$$\Gamma_{2,d} := \{d + (1 - \theta)\beta : \beta \in [0, 1)\},$$

and for the orbitals within that cell

$$R_0 := \{R\alpha \in \mathcal{R}_2 \times \mathcal{A}_2 \mid R + \tau_\alpha + d \in \Gamma_{2,d}\}.$$

We can then introduce the smoothed stacking-dependent local density of states as

$$(3.1) \quad \rho_\theta(d, E) := \sum_{R\alpha \in R_0} g(H_{\theta,d} - E)(R\alpha, R\alpha),$$

where g is a positive even polynomial approximating the Dirac delta function. We can choose g to be an approximation of the normal distribution with variance inversely proportional to the square of the polynomial degree [37, 48]. The use of polynomial approximations to the delta function, constructed using Chebyshev polynomials, to compute the local density of states is known as the kernel polynomial method [48]. Note that we only consider the local density of states in a single cell. This is because

the local density of states in other cells can be obtained by different choices of the shift d [37].

The degree of the polynomial g will play a significant role in what follows and we denote this degree by n_{poly} . Since g is a polynomial and $H_{\theta,d}$ depends smoothly on θ and d , the smoothed stacking-dependent local density of states is smooth as a function of θ, d , and E .

3.2. The local density of states image. In practice, one generally only has access to the local density of states evaluated on a discrete grid of d and E values. This is because one can only perform finitely many experiments or computations. To model this, we introduce the concept of the local density of states image, defined as follows. We first introduce uniform grids of d and E values for $N_d, N_E \geq 2$

$$(3.2) \quad \mathcal{X} := \{d_1, d_2, d_3 \dots d_{N_d}\}, \quad d_i = \frac{(i-1)a_1}{N_d}, \quad 1 \leq i \leq N_d,$$

$$(3.3) \quad \mathcal{Y} := \{E_1, E_2, E_3 \dots E_{N_E}\}, \quad E_j = E_1 + \frac{(j-1)(E_{N_E} - E_1)}{N_E}, \quad 1 \leq j \leq N_E,$$

where $E_1 < E_{N_E}$ are fixed. For example, we could choose E_1 and E_{N_E} such that they bound the whole spectrum of $H_{\theta,d}$ for all values of d , or we could choose them to bound one important subset of the spectrum, such as energies near to the Fermi level [2]. We refer to the set $\mathcal{X} \times \mathcal{Y}$ as the LDOS grid, and we define the local density of states image $\varrho_{\theta, \mathcal{X}, \mathcal{Y}}$ as the smoothed stacking-dependent local density of states restricted to the LDOS grid $\mathcal{X} \times \mathcal{Y}$, i.e.,

$$(3.4) \quad \varrho_{\theta, \mathcal{X}, \mathcal{Y}} := (\varrho_{\theta, i, j})_{1 \leq i \leq N_d, 1 \leq j \leq N_E} \in \mathbb{R}^{N_d \times N_E}, \quad \varrho_{\theta, i, j} := \rho_{\theta}(d_i, E_j), \quad (d_i, E_j) \in \mathcal{X} \times \mathcal{Y}.$$

Note that the LDOS grid is fully specified by the choice of the LDOS grid parameters N_d, E_1, E_{N_E} , and N_E . Typical LDOS images can be seen in Figure 3.

4. Introduction to the twist operator. The stacking-dependent local density of states can be computed efficiently when $\theta = 0$ for all values of d and E , because, in this case, the system is periodic at the scale of the monolayer lattice constant. The computation is more difficult for $\theta \neq 0$ because periodicity at the lattice scale is generally broken.

The central idea of the work [33] is that there may exist an operator, dubbed the *twist operator*, mapping local density of states values calculated at $\theta = 0$ to their associated values at $\theta \neq 0$. In other words, the idea is that there may exist an operator

$$(4.1) \quad \begin{aligned} \mathcal{L}_{\theta} &: C(\Gamma_2 \times \mathbb{R}) \rightarrow C(\Gamma_2 \times \mathbb{R}), \\ \rho_0(d, E) &\mapsto \rho_{\theta}(d, E), \end{aligned}$$

where ρ_{θ} is as in (3.1). More modestly, we may hope that, for a fixed LDOS grid $\mathcal{X} \times \mathcal{Y}$, there exists a discrete twist operator acting on local density of states images

$$(4.2) \quad \begin{aligned} \tilde{\mathcal{L}}_{\theta} &: \mathbb{R}^{N_d \times N_E} \rightarrow \mathbb{R}^{N_d \times N_E}, \\ \varrho_{0, \mathcal{X}, \mathcal{Y}} &\mapsto \varrho_{\theta, \mathcal{X}, \mathcal{Y}}. \end{aligned}$$

The work [33] provided evidence for the existence of such an operator (4.2) by successfully training a neural network to approximate this map. The neural network was trained using a database of LDOS image pairs, each pair consisting of one LDOS image computed at $\theta = 0$, called the input image, and a second LDOS image computed with the same Hamiltonian with $\theta \neq 0$, called the output image.

FIG. 3. Schematic showing relationships between tight-binding models of untwisted and twisted structures and stacking-dependent LDOS images. The twist operator \mathcal{L}_θ learned in [33] maps from untwisted LDOS images to twisted LDOS images. It can be defined via the inverse map from untwisted LDOS images to tight-binding model parameters, composed with the forward map from these tight-binding model parameters to the LDOS image of the twisted bilayer tight-binding model.

4.1. Existence of the twist operator: an inverse problem perspective.

The work [33] also suggested a route to rigorously proving existence of such a map, i.e., to proving well-posedness of the learning problem addressed in [33]. The idea is that the twist operator could be defined as the composition of two maps. First, the inverse map from the LDOS function (image) at $\theta = 0$ to the set of parameters defining the tight-binding model. Then, the forward map from the set of parameters defining the tight-binding model to the LDOS function (image) at $\theta \neq 0$. Since the forward map is well-defined through (3.1), a sufficient condition for the twist operator to exist is existence of the inverse map from LDOS functions (images) to tight-binding parameters. This idea is illustrated in Figure 3. Another important consideration is the regularity of the twist operator map between LDOS functions (images). In particular, for the map to be rigorously learnable by a neural network, it must be continuous. Since the forward map (3.1) is smooth, a sufficient condition for this to hold is continuity of the inverse map from LDOS functions (images) to model parameters.

In the following sections, we will make these ideas more precise (Section 4.2), and then present two theorems establishing sufficient conditions for existence and continuity of the twist operator between LDOS images (4.2) (Section 4.3). We will then discuss theorems guaranteeing that the operator can be learned by a neural network (Section 5).

4.2. Rigorous theory of the twist operator: precise inverse problem.

We will establish existence and continuity of the twist operator for a more specific family of tight-binding models than given in Section 2. We start by assuming that both chains have only one orbital per unit cell. The Hilbert space is then

$$(4.3) \quad \ell^2(\Omega) = \left\{ (\psi(R_i))_{R_i \in \Omega} : \sum_{R_i \in \Omega} |\psi(R_i)|^2 < \infty \right\}, \quad \Omega = \mathcal{R}_1 \cup \mathcal{R}_2.$$

The tight-binding Hamiltonian H is again given by (2.1), where, for $R, R' \in \mathcal{R}_i$, i.e., for the intralayer part of the Hamiltonian, we have

$$(4.4) \quad H(R, R') = \begin{cases} t, & R - R' = a_i, \\ t, & R - R' = -a_i, \\ \epsilon, & R = R', \\ 0, & \text{else.} \end{cases}$$

For $R \in \mathcal{R}_i, R' \in \mathcal{R}_j$ with $i \neq j$, i.e., for the interlayer part of the Hamiltonian, we have

$$(4.5) \quad H(R, R') = h(|r|), \quad r = R + d(-\delta_{i1} + \delta_{i2}) - R',$$

where we assume the interlayer hopping function has the form

$$(4.6) \quad h(|r|) = \nu f\left(\frac{r}{l}\right)$$

for some fixed decaying function $f : \mathbb{R} \rightarrow \mathbb{R}$. Once f is specified, we see that the model depends on precisely five model parameters: ϵ, t, ν, l , and θ (recall that the model depends on θ since the lattice constant of \mathcal{R}_2 is $1 - \theta$, which enters the interlayer hopping through (4.5)). At this point, we will assume that while ϵ is an arbitrary real number, the parameters t, ν , and l are all positive, i.e., we assume $(\epsilon, t, \nu, l) \in \mathbb{R} \times \mathbb{R}_+^3$, where \mathbb{R}_+ denotes the positive real half line. For any choice of model parameters and LDOS grid parameters N_d, E_1, E_{N_E} and N_E , we can define LDOS images through (3.1) and (3.4).

We can now pose the following precise inverse problem regarding the model when $\theta = 0$.

INVERSE PROBLEM. *Suppose we are given an LDOS image on the LDOS grid with parameters N_d, E_1, E_{N_E} and N_E generated from the model (4.3)-(4.6) with some (unknown) choice of parameters ϵ, t, ν , and l , with $\theta = 0$, and f fixed (and known). Does the LDOS image uniquely specify the model parameters ϵ, t, ν , and l ? In other words, is the map from parameters ϵ, t, ν , and l to LDOS images one-to-one? When the map is one-to-one so that the inverse map from LDOS images to model parameters exists, is the inverse map continuous?*

In the following section, we will identify assumptions under which this inverse problem can be solved, and hence existence of the twist operator proved.

4.3. Rigorous theory of the twist operator: solving the inverse problem. Our first theorem establishes that the inverse problem can be solved for a specific choice of N_d , sufficiently high resolution in energy N_E , when the interlayer hopping function $f(\cdot) = e^{-|\cdot|}$, assuming that the parameters are drawn from a compact subset of $\mathbb{R} \times \mathbb{R}_+^3$.

THEOREM 4.1. *Assume $N_E > n_{poly}$, where n_{poly} is the degree of the polynomial g in (3.1). Let $E_{N_E} > E_1$ be otherwise arbitrary. Let $N_d \geq 3$, and assume that the points $0, \frac{1}{4}, \frac{1}{2}$ are included in the d grid \mathcal{X} . Thus, the LDOS grid is given by $\mathcal{X} \times \mathcal{Y}$, where*

$$(4.7) \quad \left\{ 0, \frac{1}{4}, \frac{1}{2} \right\} \subset \mathcal{X} \quad \text{and} \quad \mathcal{Y} = \{E_1, \dots, E_{N_E}\}.$$

Assume further that the interlayer coupling function is given by (4.6), with f exponential, so that

$$h(|r|) = \nu e^{-\frac{|r|}{t}}.$$

Finally, we assume that (ϵ, t, ν, l) are constrained to a compact subset $\mathcal{P}_{comp} \subset \mathbb{R} \times \mathbb{R}_+^3$. In particular, we assume t, ν, l are strictly positive. Then, the mapping

$$(4.8) \quad \begin{aligned} \mathcal{K}_1 : \mathcal{P}_{comp} &\rightarrow \mathbb{R}^{N_d \times N_E}, \\ (\epsilon, t, \nu, l) &\mapsto \varrho_{0, \mathcal{X}, \mathcal{Y}}, \end{aligned}$$

from model parameters to LDOS images, defined for each value of the model parameters by (3.1)-(3.4), is one-to-one, and hence a bijection onto its range.

Proof. See proof in [Appendix A.1](#). □

The proof of [Theorem 4.1](#) relies on the fact that the local density of states (3.1) has finite degree with respect to energy E . This means that the coefficient functions of the polynomial in E can be recovered when we have LDOS values for greater than n_{poly} different values of E . The tight binding parameters can then be recovered because of the special form of the interlayer coupling function.

Our second theorem establishes that the inverse problem can be solved under different assumptions. We allow for a quite general class of interlayer coupling functions under the assumption that the parameter space is discretized and finite.

THEOREM 4.2. *Suppose that the parameter space is discrete and finite, i.e., we assume that the model parameters ϵ, t, ν, l are drawn from a known finite subset $\mathcal{P}_{fin} \subset \mathbb{R} \times \mathbb{R}_+^3$. Then, suppose that the interlayer hopping function $h(r) = \nu f(\frac{r}{l}) \chi_{(-r_0-1, r_0+1)}$ for some fixed integer $r_0 > 1$, where f is an entire function, positive when restricted to the real line, satisfying*

$$(4.9) \quad \lim_{r \rightarrow \infty} \frac{f(\frac{r}{l'})}{f(\frac{r}{l})} = 0, \quad \text{for any } 0 < l < l'.$$

Suppose that $N_E > n_{poly}$ and that $E_{N_E} > E_1$ but are otherwise arbitrary. Then, there exists a positive integer N_0 such that for any configuration space resolution $N_d > N_0$, the mapping

$$(4.10) \quad \begin{aligned} \mathcal{K}_2 : \mathcal{P}_{fin} &\rightarrow \mathbb{R}^{N_d \times N_E}, \\ (\epsilon, t, \nu, l) &\mapsto \varrho_{0, \mathcal{X}, \mathcal{Y}}, \end{aligned}$$

is one-to-one and hence a bijection onto its range.

Proof. See proof in [Appendix A.2](#). □

The assumptions of the theorem are satisfied, for example, if $f(\cdot) = e^{-|\cdot|^2}$, and \mathcal{P}_{fin} is a bounded uniform (equally spaced) grid, but uniformity is not necessary.

The proof of Theorem 4.2 is along the same lines as that of Theorem 4.1, except that one-to-oneness is proved by contradiction using the complex-analytic properties of f and (4.9).

With existence of the inverse map established either through Theorem 4.1 or Theorem 4.2, continuity of the inverse map is guaranteed by the following. Note that the result is trivial in the case of \mathcal{K}_2^{-1} because the domain of \mathcal{K}_2 is discrete.

THEOREM 4.3. *Let \mathcal{K}_1 and \mathcal{K}_2 be as in Theorem 4.1 and Theorem 4.2, respectively. Then, the inverse mappings $\mathcal{K}_1^{-1} : \text{range}(\mathcal{K}_1) \rightarrow \mathcal{P}_{\text{comp}}$ and $\mathcal{K}_2^{-1} : \text{range}(\mathcal{K}_2) \rightarrow \mathcal{P}_{\text{fin}}$ are continuous.*

Proof. See proof in Appendix A.3. \square

As discussed above, existence and continuity of the twist operator on LDOS images (4.2) now follows. We summarize this result in the following.

THEOREM 4.4. *Assume the conditions either of Theorem 4.1 or of Theorem 4.2, and let \mathcal{K} be defined by \mathcal{K}_1 or \mathcal{K}_2 depending on the case. Note that we always have $\text{range}(\mathcal{K}) \subset \mathbb{R}^{N_d \times N_E}$. Then, for any fixed $0 \leq \theta < 1$, there exists an operator*

$$(4.11) \quad \begin{aligned} \tilde{\mathcal{L}}_\theta : \text{range}(\mathcal{K}) &\rightarrow \mathbb{R}^{N_d \times N_E}, \\ \varrho_{0,\mathcal{X},\mathcal{Y}} &\mapsto \varrho_{\theta,\mathcal{X},\mathcal{Y}}. \end{aligned}$$

Furthermore, this operator is continuous.

Proof. Theorems 4.1 and 4.2 guarantee that we can define $\tilde{\mathcal{L}}_\theta := \mathcal{T}_\theta \mathcal{K}^{-1}$, where \mathcal{T}_θ is the map from model parameters ϵ, t, ν , and l to LDOS images through (3.1)-(3.4) at twist angle θ . Continuity follows from Theorem 4.3 and continuity of \mathcal{T}_θ . \square

5. Universal approximation with neural network. With existence and continuity of the twist operator established in Theorem 4.4, we now turn to approximability of this operator by a neural network. This will follow easily from the well-known universal approximation theorem [3, 15], which establishes conditions under which neural networks can be used to approximate functions. For the reader's convenience, we state a simple special case of this result for continuous functions and two-layer neural networks [22, 40]. This will suffice to guarantee that the twist operator between SD-LDOS images can be approximated by such a neural network under the assumptions of Theorem 4.4. In passing we remark that versions of this result have been proved for deep neural networks [51], smooth functions [34], and networks with different structures developed for approximating nonlinear continuous functionals and nonlinear operators [15, 35].

THEOREM 5.1. *Universal Approximation Theorem* *Let $C(X, \mathbb{R}^n)$ denote the space of continuous functions from a subset $X \subset \mathbb{R}^n$ to \mathbb{R}^n . Let $\sigma \in C(\mathbb{R}, \mathbb{R})$ be a non-polynomial function, and let $\sigma \circ x$ denote σ applied to each component of x , so that $(\sigma \circ x)_i = \sigma(x_i)$. Then, for any $f(x) \in C(X, \mathbb{R}^n)$ and $\epsilon > 0$, there exist $k \in \mathbb{N}_{>0}$, $A \in \mathbb{R}^{k \times n}$, $b \in \mathbb{R}^k$, and $C \in \mathbb{R}^{n \times k}$ such that*

$$(5.1) \quad \sup_{x \in X} \|f(x) - g(x)\| < \epsilon,$$

where

$$(5.2) \quad g(x) = C \cdot (\sigma \circ (A \cdot x + b)).$$

For the proof of Theorem 5.1, see [40]. When an estimate of the form (5.1) holds, we say that the function f can be approximated by a two-layer neural network. Neural

networks with additional layers are defined recursively from (5.2) by applying additional affine transformations (with associated coefficients A, b) composed with σ to the output of the previous layer, so that the number of layers corresponds to the number of times σ appears in (5.2) plus one [21]. It now follows immediately from Theorem 4.4 that two-layer neural networks can approximate the twist operator if the existence condition for either Theorem 4.1 or Theorem 4.2 is satisfied. We summarize this in the following theorem.

THEOREM 5.2. *Universal Approximation Theorem for Twist Operators (fixed θ)* *Fix $0 \leq \theta < 1$. Assume the conditions either of Theorem 4.1 or of Theorem 4.2, and let \mathcal{K} be defined by \mathcal{K}_1 or \mathcal{K}_2 depending on the case. Let $\tilde{\mathcal{L}}_\theta : \text{range}(\mathcal{K}) \subset \mathbb{R}^{N_d \times N_E} \rightarrow \mathbb{R}^{N_d \times N_E}$ denote the twist operator defined in Theorem 4.4. Then, for any $\epsilon > 0$, there exist $k \in \mathbb{N}_{>0}$, $A \in \mathbb{R}^{k \times N_d N_E}$, $b \in \mathbb{R}^k$, and $C \in \mathbb{R}^{N_d N_E \times k}$ such that*

$$(5.3) \quad \sup_{x \in \text{range } \mathcal{K}} \|\tilde{\mathcal{L}}_\theta(x) - g(x)\| < \epsilon,$$

where

$$(5.4) \quad g(x) = C \cdot (\sigma \circ (A \cdot x + b)).$$

Theorem 5.2 guarantees that it is possible to use a two-layer neural network to approximate the local density of states for a fixed lattice mismatch (twist angle) θ . Training the neural network refers to choosing C, A , and b appearing in (5.4) to minimize the cost function defined by

$$(5.5) \quad \frac{1}{N} \sum_{i=1}^N \|\tilde{\mathcal{L}}_\theta(x_i) - g(x_i)\|,$$

where $(x_i, \tilde{\mathcal{L}}_\theta(x_i))$ for $i = 1, \dots, N$ denotes N sample pairs consisting of untwisted and twisted SD-LDOS images computed with the same tight-binding parameters (see Section 6 for details of how the twisted SD-LDOS images are computed).

In practice, the neural network trained in [33] had more layers, and was trained using a multi-layer convolutional neural network (CNN) with the alternating direction method of multipliers (ADMM). Moreover, the data used in [33] is slightly more general than what we discussed here. In [33], there are ten types of materials and the data of both input and output data was allowed to correspond to different energy windows (i.e., different choices of E_1 and E_{N_E} in (3.3)) for each different material. We ignore these subtleties in the present work in order to clearly present the most important ideas. However, we expect that the existence of a more general twist operator and its approximation theorem can be established. We leave this to future work.

An interesting generalization of the method described in the present paper would be to learning the twist operator over a range of lattice mismatches θ . This could be done by training the neural network on tensor data consisting of multiple LDOS images corresponding to multiple lattice mismatches. We hope to address this problem in future work.

It remains to discuss how to accurately numerically compute LDOS images for use as training data. We discuss this in the following section.

6. Numerical details of computing LDOS images. In this section, we discuss the methods used in [33] to numerically compute the LDOS defined by (3.1)

and prove error estimates guaranteeing convergence of the methods. The key idea is to restrict attention to rational lattice mismatches θ and use a Bloch decomposition. Note that error estimates have already been proved for irrational θ 's; see [36, 37].

6.1. The commensurate coupled chain. We start by reviewing again the lattice structure and tight-binding model in the case of a rational lattice mismatch. The model we introduce here will be the same as the model introduced in Section 2 (after restricting to rational θ and relabeling sites), but the notation we introduce will be more convenient for the numerical convergence analysis. If lattice mismatch θ is a rational number, let p, q be the integers satisfying $q(1 - \theta) = p$ where $p, q \in \mathbb{N}$ and $\gcd(p, q) = 1$. The moiré scale is $\frac{p}{q-p}$. The coupled chain $\mathcal{R}_1 \cup \mathcal{R}_2$ is periodic on a supercell lattice,

$$\mathcal{R}_1^s = \mathcal{R}_2^s = \mathcal{R}^s = \{(1 - \theta)qn : n \in \mathbb{Z}\} = \{pn : n \in \mathbb{Z}\}.$$

Equivalently, atomic orbitals can also be labeled by

$$\Omega^s = (\mathcal{R}_1^s \times \mathcal{A}_1^s) \cup (\mathcal{R}_2^s \times \mathcal{A}_2^s) = \mathcal{R}^s \times (\mathcal{A}_1^s \cup \mathcal{A}_2^s).$$

The unit cell for the coupled chain can then be defined as

$$\Gamma = \{(1 - \theta)q\beta : \beta \in [0, 1)\} = \{p\beta : \beta \in [0, 1)\},$$

where the reciprocal lattice unit cell is defined as

$$\Gamma^* = \left\{ \frac{2\pi}{p}\beta : \beta \in [0, 1) \right\}.$$

The length of each supercell is p which is identical to the moiré scale when $q = p + 1$. We can equivalently describe the multilattices \mathcal{R}_1 and \mathcal{R}_2 by lattices with shifts

$$\begin{aligned} \mathcal{R}_1^s &= \mathcal{R}_2^s = \{(1 - \theta)qn : n \in \mathbb{Z}\}, \\ \mathcal{A}_1^s &:= \{0, 1, \dots, p - 1\} \times \mathcal{A}_1, \\ \mathcal{A}_2^s &:= \{0, 1, \dots, q - 1\} \times \mathcal{A}_2, \\ \tau_{\alpha_1^s} &= n_1 + \tau_{\alpha_1} \quad \text{for } \alpha_1^s = (n_1, \alpha_1) \in \mathcal{A}_1^s, \\ \tau_{\alpha_2^s} &= n_2 + \tau_{\alpha_2} \quad \text{for } \alpha_2^s = (n_2, \alpha_2) \in \mathcal{A}_2^s. \end{aligned}$$

\mathcal{A}_i^s denotes the set of indices of atomic orbitals within each supercell of chain i . The location of each orbital within each supercell is described by the shift τ_α . We note that more complex 1-D coupled chain geometry for the basis atoms in each unit cell can also be described similarly. Detailed construction of the complex coupled chain and more examples are given in Appendix A of [33].

6.2. Tight binding model for commensurate coupled chain. When θ is a rational number, the coupled chain model is periodic and is referred to as a commensurate structure. It can be equivalently described by another set of indices

$$\Omega^s = \mathcal{R}_1^s \times \mathcal{A}_1^s \cup \mathcal{R}_2^s \times \mathcal{A}_2^s = \mathcal{R}^s \times \mathcal{A}^s$$

where $\mathcal{A}^s = \mathcal{A}_1^s \cup \mathcal{A}_2^s$. The space for wave function of electrons can then be defined as

$$(6.1) \quad \ell^2(\Omega^s) = \left\{ (\psi(R_i\sigma))_{R_i\sigma \in \Omega^s} : \sum_{R_i\sigma \in \Omega^s} |\psi(R_i\sigma)|^2 < \infty \right\}.$$

FIG. 4. Schematic of the commensurate coupled chain system described in Section 6.1 with two orbitals per cell ($m_1 = 1, m_2 = 2$), with a rational lattice mismatch $\theta = \frac{1}{3}$ without interlayer shift ($d = 0$). Despite the lattice mismatch, the system is periodic with supercell period 2.

The intralayer hopping energy for the coupled chain where $R\alpha, R'\alpha' \in \mathcal{R}_i^s \times \mathcal{A}_i^s$ can be defined as

$$(6.2) \quad H(R\alpha, R'\alpha') = \begin{cases} T_{\alpha, \alpha'}, & R - R' = p, \\ T_{\alpha', \alpha}, & R - R' = -p, \\ \mathcal{E}_{\alpha, \alpha'}, & R = R', \\ 0, & \text{else,} \end{cases}$$

where $T_{\alpha, \alpha'}$ and $\mathcal{E}_{\alpha, \alpha'}$ are defined through $t_{\alpha, \alpha'}$ and $\epsilon_{\alpha, \alpha'}$ appearing in (2.2) in such a way that the supercell Hamiltonian equals the tight-binding Hamiltonian introduced in Section 2 up to relabeling sites.

The interlayer hopping energy is modeled by the interlayer hopping function h

$$H(R\alpha, R'\alpha') = h_{\alpha, \alpha'}^s(|r^s|), \quad r = R + \tau_\alpha + d(-\delta_{i1} + \delta_{i2}) - R' - \tau_{\alpha'}$$

where $R\alpha \in \mathcal{R}_i^s \times \mathcal{A}_i^s$, $R'\alpha' \in \mathcal{R}_j^s \times \mathcal{A}_j^s$ and $i \neq j$. We again define each component of h^s so that the supercell Hamiltonian equals the tight-binding Hamiltonian introduced in Section 2. In particular, each component is a smooth function that decays exponentially.

6.3. Bloch transform for commensurate coupled chain. The model defined in this section is periodic. Many properties of such models, such as the stacking-dependent local density of states, are most efficiently calculated via the Bloch transform, defined as follows. The Bloch transform $\mathcal{G} : \ell^2(\mathcal{R}^s \times \mathcal{A}^s) \rightarrow C(\Gamma^*) \times \mathcal{A}^s$ can be defined by

$$(6.3) \quad [\mathcal{G}\psi]_\alpha(k) = \check{\psi}_k(\alpha) := \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \sum_{R \in \mathcal{R}^s} \psi(R\alpha) e^{-ik \cdot (R + \tau_\alpha)}, \quad \alpha \in \mathcal{A}^s,$$

and its inverse by

$$(6.4) \quad [\mathcal{G}^{-1}\check{\psi}](R, \alpha) = \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \int_{\Gamma^*} e^{ik \cdot (R + \tau_\alpha)} \check{\psi}_k(\alpha) dk, \quad R \in \mathcal{R}^s \text{ and } \alpha \in \mathcal{A}^s.$$

We can apply the Bloch transform to $H\psi$ for $\psi \in \ell^2(\mathcal{R}^s \times \mathcal{A}^s)$ to derive

$$(6.5) \quad [\mathcal{G}H\psi](k) = H(k)[\mathcal{G}\psi](k)$$

where $H(k) = [\mathcal{G}H\mathcal{G}^{-1}](k)$ is a $|\mathcal{A}^s| \times |\mathcal{A}^s|$ Hermitian matrix. Details of the derivation of $H(k)$, known as the Bloch Hamiltonian, can be found in Appendix D and [36].

6.4. Stacking-dependent local density of states for the commensurate coupled chain. The stacking-dependent local density of states can always be defined by (3.1). When the lattice mismatch θ is rational, this quantity can be efficiently numerically computed using the Bloch transform. Let $H_{\theta,d}$ denote the commensurate coupled chain Hamiltonian introduced in the previous section, where we again use subscripts to emphasize the dependence of the Hamiltonian on θ and d . Since g is a polynomial, we can express the stacking-dependent LDOS (3.1) of $H_{\theta,d}$ using the Bloch transform (6.3) as

$$(6.6) \quad \rho_{\theta}(d, E) = \frac{1}{|\Gamma^*|} \sum_{\alpha: R\alpha \in R_0} \int_0^{\frac{2\pi}{p}} g(H_{\theta,d}(k) - E)_{\alpha,\alpha} dk,$$

where we define $H_{\theta,d}(k) := [\mathcal{G}H_{\theta,d}\mathcal{G}^{-1}](k)$. With a slight abuse of notation, we denote the supercell orbital indices $\alpha \in \mathcal{A}^s$ which correspond to the indices $R\alpha \in R_0$ in (3.1) by $\alpha : R\alpha \in R_0$. We provide the derivation of (6.6) from (3.1) in Appendix B. It is then natural to approximate (6.6) by discretizing the integral over the Brillouin zone and truncating the interlayer hopping in real space (for more details, see Appendix C. We use $H_{k,\text{trunc}}$ to denote the Bloch transformed truncated Hamiltonian at wave-number k (we suppress the subscripts d, θ since they do not play a role here). We thus arrive at the following numerical approximation of the stacking-dependent LDOS

$$(6.7) \quad \varrho_{\theta}(d, E) := \sum_{\alpha: R\alpha \in R_0} \sum_{i=1}^M g_n(H_{k_i,\text{trunc}} - E)_{\alpha,\alpha} \Delta k,$$

where $\Delta k = \frac{2\pi}{pM}$, $k_i = \frac{2\pi i}{pM}$ for $i = 1, 2, \dots, M$, and M and p are positive integers. The numerical scheme is equivalent to (3.1) for a interlayer coupling truncated system with M supercells.

THEOREM 6.1. *Let ρ_{θ} and ϱ_{θ} be as in (6.6) and (6.7), respectively. Then, we have*

$$(6.8) \quad |\rho_{\theta}(d, E) - \varrho_{\theta}(d, E)| \leq \left[\frac{C_1}{pe^{p\gamma M/2} - p} + \frac{C_2 e^{-\gamma cp}}{\gamma p} \right] \cdot \frac{|R_0|}{|\Gamma^*|},$$

where γ is defined same as in (2.4), M is the length of the supercell and $c > 3$ is the number of supercells beyond which interlayer coupling will be truncated. The constant C_1 depends on g, h, E, d and the constant C_2 depends on h, N, E, d .

Proof. See proof at Appendix C. □

The first term on the right-hand side of (6.8) corresponds to numerical quadrature errors and the second term corresponds to the interlayer coupling approximation error between $H_{\theta,d}$ and $H_{k,p}$.

We discuss some applications of Theorem 6.1. First, it shows that formula (6.7) can be used to generate accurate input data for training the neural network to approximate the twist operator. Second, combining Theorem 6.1 with continuity of the twist operator established in Theorem 4.4, we see that the difference between the outputs of the twist operator applied to numerically-computed (through (6.7)) LDOS images and to exact LDOS images must be small. Finally, combining this result with the fact that the twist operator can be accurately approximated by a neural network in Theorem 5.2, we have that this property is also shared by the neural network approximation to the twist operator.

To be more precise, if we use \mathcal{L}_{NN} to denote the neural network approximating twist operator, then the error between neural network prediction and exact LDOS image is

$$(6.9) \quad \begin{aligned} |\rho_\theta - \mathcal{L}_{NN}(\varrho_0)| &= |\rho_\theta - \mathcal{L}_{NN}(\rho_0) + \mathcal{L}_{NN}(\rho_0) - \mathcal{L}_{NN}(\varrho_0)| \\ &\leq |\rho_\theta - \mathcal{L}_{NN}(\rho_0)| + |\mathcal{L}_{NN}(\rho_0) - \mathcal{L}_{NN}(\varrho_0)| \\ &\leq I_1 + C_{NN} \cdot I_2, \end{aligned}$$

where C_{NN} is a constant depending on the final trained neural network and I_1, I_2 are errors due to neural network approximation in [Theorem 5.2](#) and numerical error in data generation in [Theorem 6.1](#).

7. Conclusion. In this work, we have studied the twist operator, a map which relates properties of a twisted bilayer material to those of the same bilayer material without twist, focusing in particular on the specific case of the stacking-dependent local density of states (SD-LDOS). We have discussed the relevance of an inverse problem relating SD-LDOS data to the coefficients of the tight-binding model which generated it. We proved that under two types of assumptions, the inverse problem is well-posed and existence of the twist operator can be proved. We then invoked the Universal Approximation Theorem to prove that the twist operator can be approximated by a two-layer neural network and proved smallness of numerical errors in computing SD-LDOS images.

We hope that the present work will stimulate further research into predicting properties of twisted bilayers from data about their untwisted counterparts. We expect this approach to be especially useful when direct numerical computation of properties of the twisted bilayers is intractable; for example, for properties depending delicately on the effects of electron-electron interactions. We expect that this approach could even be used directly on experimental data collected from untwisted bilayers to predict the results of experiments on their twisted counterparts. Although our rigorous results do not apply in these cases, we hope that the fact that similar ideas can be made rigorous in simpler cases provides further impetus to such studies.

We close by noting some interesting potential future directions for further mathematical research. First, it will be interesting to investigate learning the parameters of tight-binding models using spectral data more generally, not only in the context of moiré materials. Then, it would be interesting to further develop the rigorous theory of this learning problem, i.e., to investigate well-posedness of the associated inverse problem. It may be possible to connect to the extensive literature on the inverse spectral problem for 1D Schrödinger operators; see, e.g., [\[42\]](#). It would be especially exciting to try to extend the ideas of [\[33\]](#) and the present work to 2D materials, although we expect proving well-posedness of the analogous inverse problem to be very difficult in this case. It would also be interesting to develop the rigorous theory of aspects of [\[33\]](#) not considered here, such as the generalization to multiple types of materials.

Appendix A. Proof for Existence of Twist Operator.

A.1. Proof of Theorem 4.1.

Proof. Our strategy will be to first prove that LDOS images uniquely specify

moments of the Hamiltonian evaluated in the home cell. We will then prove that these moments uniquely specify model parameters.

The polynomial g used to compute LDOS $\rho_\theta(d, E)$ (3.1) can be represented as

$$(A.1) \quad g(x) = a_{n_{\text{poly}}}x^{n_{\text{poly}}} + a_{n_{\text{poly}}-1}x^{n_{\text{poly}}-1} + \dots + a_0.$$

Then $g(x - E)$ can be expanded as

$$\begin{aligned} g(x - E) &= a_{n_{\text{poly}}}(x - E)^{n_{\text{poly}}} + a_{n_{\text{poly}}-1}(x - E)^{n_{\text{poly}}-1} + \dots + a_0 \\ &= a_{n_l}(x - E)^{n_l} + a_{n_{l-1}}(x - E)^{n_{l-1}} + \dots + a_{n_0}(x - E)^{n_0} \\ &= \sum_{k=0}^{n_{\text{poly}}} f_k(E)x^k, \end{aligned}$$

where $n_{\text{poly}} = n_l > n_{l-1} \dots > n_0 \geq 0$ and for any other $n' \neq n_0 \dots n_l$, $a_{n'} = 0$. Collect the coefficients for term x^k , we derive

$$(A.2) \quad f_k(E) = \sum_{k \leq n_m \leq n_{\text{poly}}} a_{n_m} C_{n_m}^k (-E)^{n_m - k}.$$

The highest degree monomial with respect to E of $f_k(E)$ is $E^{n_{\text{poly}}-k}$. Since the coefficient of the highest degree term is nonzero, the f_k is an $n_{\text{poly}} - k$ degree polynomial with respect to E .

LEMMA A.1. *Assume $f_k(E)$ is an $n_{\text{poly}} - k$ degree polynomial with respect to E and matrix S is defined such that*

$$(S)_{ij} = f_j(E_i),$$

$i = 1 \dots n_{\text{poly}}$ and $j = 1 \dots n_{\text{poly}}$ where n_{poly} is the degree of polynomial, $E_i \in \mathbb{R}$ and $E_i \neq E_j$ for $i \neq j$. Then, matrix S is a non-singular matrix.

Proof. See Proof at [Appendix A.1.1](#) □

Therefore, local density of states for the specific 1-D system $\rho_\theta(d, E)$ can be represented as

$$(A.3) \quad \sum_{k=0}^{n_{\text{poly}}} f_k(E) \sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha),$$

where $f_k(x)$ is a polynomial of degree $n_{\text{poly}} - k$ depending on polynomial g in (3.1). We view $\sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha)$ as unknowns and $f_k(E)$ as coefficients for $n_{\text{poly}} + 1$ different E values. Given a local density of states image, [Lemma A.1](#) shows when $N_E > n_{\text{poly}}$, the linear system below has a unique solution

$$(A.4) \quad \begin{aligned} &\sum_{k=0}^n f_k(E_0) \sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha) = \rho_\theta(d, E_0), \\ &\sum_{k=0}^n f_k(E_1) \sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha) = \rho_\theta(d, E_1), \\ &\dots \dots \\ &\sum_{k=0}^n f_k(E_{N_E}) \sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha) = \rho_\theta(d, E_{N_E}). \end{aligned}$$

That is to say, given an LDOS image we can solve for moments of the Hamiltonian evaluated in the home cell, i.e.,

$$(A.5) \quad \sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha),$$

for any integer $0 \leq k \leq n_{\text{poly}}$. We will next show that when $\theta = 0$, we can recover the tight binding parameters for the 1-D coupled chain model defined in [subsection 4.2](#) from these moments.

The $k = 0$ moment yields $\sum_{R\alpha \in R_0} H_{\theta,d}^0(R\alpha, R\alpha) = |\mathcal{A}| = 1$. Evaluating these moments for $k = 1, 2$, we have

$$(A.6) \quad \begin{aligned} \sum_{R\alpha \in R_0} H^1(R\alpha, R\alpha) &= \epsilon \\ \sum_{R\alpha \in R_0} H^2(R\alpha, R\alpha) &= \epsilon^2 + 2t^2 + \nu^2 \sum_{n=-\infty}^{\infty} e^{-\frac{2|d-n|}{l}} \\ &= \epsilon^2 + 2t^2 + \nu^2 \left(e^{-\frac{2d}{l}} + \sum_{k=1}^{\infty} e^{-\frac{2d+2k}{l}} + \sum_{k=1}^{\infty} e^{-\frac{2k-2d}{l}} \right) \\ &= \epsilon^2 + 2t^2 + \frac{\nu^2 \left(e^{\frac{2d-2}{l}} + e^{-\frac{2d}{l}} \right)}{1 - e^{-\frac{2}{l}}}, \end{aligned}$$

where we used $l > 0$ (by assumption) to sum the geometric series in the last line. We see that the first moment uniquely specifies ϵ . We will now prove that the second moment, evaluated at $d = 0, \frac{1}{4}$, and $\frac{1}{2}$, uniquely specifies t, ν , and l . We define

$$(A.7) \quad S_{t,\nu,l}(d) := 2t^2 + \frac{\nu^2 \left(e^{\frac{2d-2}{l}} + e^{-\frac{2d}{l}} \right)}{1 - e^{-\frac{2}{l}}},$$

and it suffices to prove there exists a one to one mapping between (t, ν, l) and value of S on $d_1 = 0, d_2 = \frac{1}{4}, d_3 = \frac{1}{2}$. From direct calculation of the derivative, we have

$$(A.8) \quad \begin{aligned} 0 < d < \frac{1}{2} &\implies \partial_d S < 0, \\ \frac{1}{2} < d < 1 &\implies \partial_d S > 0. \end{aligned}$$

Moreover, since $l > 0$, $\frac{S_{t,\nu,l}(d_2) - S_{t,\nu,l}(d_1)}{S_{t,\nu,l}(d_3) - S_{t,\nu,l}(d_2)} = e^{-\frac{1}{2l}} + e^{\frac{1}{2l}} + 1$ is a well-defined and strictly monotonic decreasing function with respect to l . We now suppose for a contradiction that there exist $(t, \nu, l) \neq (t', \nu', l')$ such that

$$(A.9) \quad \begin{aligned} S_{t,\nu,l}(d_1) &= S_{t',\nu',l'}(d_1), \\ S_{t,\nu,l}(d_2) &= S_{t',\nu',l'}(d_2), \\ S_{t,\nu,l}(d_3) &= S_{t',\nu',l'}(d_3). \end{aligned}$$

We would then have that

$$(A.10) \quad \frac{S_{t,\nu,l}(d_2) - S_{t,\nu,l}(d_1)}{S_{t,\nu,l}(d_3) - S_{t,\nu,l}(d_2)} = \frac{S_{t',\nu',l'}(d_2) - S_{t',\nu',l'}(d_1)}{S_{t',\nu',l'}(d_3) - S_{t',\nu',l'}(d_2)}.$$

But now we must have that $l = l'$ since the quotient function is a single variable monotonic function. In addition to that, $S_{t,\nu,l}(d_1) = S_{t',\nu',l'}(d_1)$ and $S_{t,\nu,l}(d_2) = S_{t',\nu',l'}(d_2)$ gives $t = t'$ and $\nu = \nu'$ since the parameters are assumed to be positive. A contradiction is derived and the theorem is proved. \square

A.1.1. Proof of Lemma A.1.

Proof. We prove the lemma by contradiction. If the matrix S is singular, there exists a non trivial linear combination of column vectors of S , which equals to zero vector, i.e,

$$\sum_{i=0}^n c_i f_i(E) = 0,$$

where c_i are not all zero and for any $E = E_j$ and $j \in \{0, 1, 2, 3 \dots, n_{\text{poly}}\}$. The linear system can be viewed as a linear system with Vandermonde matrix V as coefficients and linear combination of c as unknowns. To be specific, $(V)_{ij} = E_i^j$ and the matrix is non-singular. For the coefficients of highest degree of E , it only involve c_0 . Therefore via solving the linear system, c_0 must be zero. Through the same argument, we can derive all c are zero and therefore we find the contradiction. \square

A.2. Proof of Theorem 4.2.

Proof. With same argument in the proof of Theorem 4.1, we can show that given a local density of states image we can solve for

$$(A.11) \quad \sum_{R\alpha \in R_0} H_{\theta,d}^k(R\alpha, R\alpha),$$

for any integer $0 \leq k \leq n_{\text{poly}}$. Evaluating these moments we have

$$(A.12) \quad \begin{aligned} \sum_{R\alpha \in R_0} H_{\theta,d}(R\alpha, R\alpha) &= \epsilon \\ \sum_{R\alpha \in R_0} H_{\theta,d}^2(R\alpha, R\alpha) &= \epsilon^2 + 2t^2 + \sum_{n=-r_0}^{r_0} \nu^2 f^2 \left(\frac{d-n}{l} \right). \end{aligned}$$

We define

$$(A.13) \quad S_{t,\nu,l}(d) := 2t^2 + \sum_{n=-r_0}^{r_0} \nu^2 f^2 \left(\frac{d-n}{l} \right).$$

The parameter ϵ can be directly solved from first equation in (A.12). It suffices to prove there exists an integer N_0 such that when $N_d > N_0$,

$$(A.14) \quad \tilde{\mathcal{K}}_2 : (t, \nu, l) \rightarrow (S_{t,\nu,l}(d_1), S_{t,\nu,l}(d_2), \dots, S_{t,\nu,l}(d_{N_d})),$$

is a one-to-one mapping from \mathcal{P}_{fin} to its domain. Since \mathcal{P}_{fin} is finite and S is smooth, there exists a constant $c_1 \geq 0$ such that $|\partial_d^2 S_{t,\nu,l}(d)| \leq c_1$ for all $t, \nu, l \in \mathcal{P}_{fin}$ and all $0 \leq d \leq 1$. We first prove the following lemma.

LEMMA A.2. *If $\max_{0 \leq d \leq 1} |\partial_d S_{t,\nu,l}(d) - \partial_d S_{t',\nu',l'}(d)| = 0$ and there exists $d \in [0, 1]$ such that $S_{t,\nu,l}(d) = S_{t',\nu',l'}(d)$, then $(t, \nu, l) = (t', \nu', l')$.*

Proof. Assume the result is not true, then there exists $(t, \nu, l) \neq (t', \nu', l')$ such that

$$(A.15) \quad \max_{0 \leq d \leq 1} |\partial_d S_{t,\nu,l}(d) - \partial_d S_{t',\nu',l'}(d)| = 0.$$

Since the function $\partial_d S_{t,\nu,l}(d) - \partial_d S_{t',\nu',l'}(d)$ is entire with respect to d , it follows that

$$(A.16) \quad \partial_d S_{t,\nu,l}(d) = \partial_d S_{t',\nu',l'}(d) \text{ for all } 0 \leq d < \infty.$$

We start by showing how the assumption on f in (4.9) implies $t = t'$. First, note that (A.16) together with the fact that the two functions are equal for some $d \in [0, 1]$ implies that

$$(A.17) \quad S_{t,\nu,l}(d) = S_{t',\nu',l'}(d) \text{ for all } 0 \leq d < \infty.$$

That is to say,

$$(A.18) \quad 2t^2 + \sum_{n=-r_0}^{r_0} \nu^2 f^2\left(\frac{d-n}{l}\right) = 2t'^2 + \sum_{n=-r_0}^{r_0} \nu'^2 f^2\left(\frac{d-n}{l'}\right).$$

The exponential decay assumption of interlayer hopping function shows that when d goes to infinity, the equation becomes

$$(A.19) \quad t^2 = t'^2 \implies t = t',$$

as t and t' are positive. We now show how the assumption also implies $l = l'$. If $l < l'$, the assumption (4.9) gives that for each n ,

$$(A.20) \quad \lim_{d \rightarrow \infty} \frac{f^2\left(\frac{d-n}{l}\right)}{f^2\left(\frac{d-n}{l'}\right)} = 0.$$

This leads to the contradiction,

$$(A.21) \quad \lim_{d \rightarrow \infty} \frac{\sum_{n=-r_0}^{r_0} f^2\left(\frac{d-n}{l}\right)}{\sum_{n=-r_0}^{r_0} f^2\left(\frac{d-n}{l'}\right)} = 0 \neq \frac{\nu'^2}{\nu^2}$$

as ν and ν' are nonzero. For the case $l > l'$, similar contradiction can be found. Therefore we prove that $l = l'$. Since f is positive function, we can further derive $\nu = \nu'$, which contradicts with the statement $\nu \neq \nu'$. \square

We now return to the proof that \tilde{K}_2 is one-to-one. Suppose that $(t', \nu', l') \neq (t, \nu, l)$. By Lemma A.2, the following inequality holds

$$(A.22) \quad c_0 := \min_{(\epsilon, t', \nu', l') \neq (\epsilon, t, \nu, l) \in \mathcal{P}_{\text{fin}}} \max_{0 \leq d \leq 1} |\partial_d S_{t,\nu,l}(d) - \partial_d S_{t',\nu',l'}(d)| > 0.$$

We also introduce the following

$$(A.23) \quad c_1 := \max_{(\epsilon, t, \nu, l) \in \mathcal{P}_{\text{fin}}} \max_{0 \leq d \leq 1} |\partial_d^2 S_{t,\nu,l}(d)| \geq 0.$$

We now assume for a contradiction that

$$(A.24) \quad \tilde{\mathcal{K}}_2(t, \nu, l) = \tilde{\mathcal{K}}_2(t', \nu', l')$$

holds with $N_d > \max\{1, \frac{3c_1}{c_0}\}$. First, note that (A.24) gives

$$(A.25) \quad \frac{S_{t,\nu,l}(d_{i+1}) - S_{t,\nu,l}(d_i)}{d_{i+1} - d_i} = \frac{S_{t',\nu',l'}(d_{i+1}) - S_{t',\nu',l'}(d_i)}{d_{i+1} - d_i}.$$

Let $\Delta d := \frac{1}{N_d}$ denote the spacing of d grid (recall (3.2)). Then, by Taylor expansion, we have, for any adjacent grid points d_i, d_{i+1} ,

$$\frac{S_{t,\nu,l}(d_{i+1}) - S_{t,\nu,l}(d_i)}{\Delta d} - \partial_d S_{t,\nu,l}(d_i) \leq \frac{c_1}{2} \Delta d.$$

Using uniform boundedness of $\partial_d^2 S$ again, we can deduce

$$\left| \frac{S_{t,\nu,l}(d_{i+1}) - S_{t,\nu,l}(d_i)}{\Delta d} - \partial_d S_{t,\nu,l}(d) \right| \leq \frac{3c_1}{2} \Delta d$$

for all $d \in [d_i, d_{i+1}]$. With the same argument, the same inequality can be established for $S_{t,\nu',l}$. Using (A.25) and the triangle inequality, these two inequalities give that for any $d \in [d_i, d_{i+1}]$,

$$\begin{aligned} |\partial_d S_{t,\nu,l}(d) - \partial_d S_{t,\nu',l}(d)| &\leq \left| \frac{S_{t,\nu,l}(d_{i+1}) - S_{t,\nu,l}(d_i)}{\Delta d} - \partial_d S_{t,\nu,l}(d) \right| \\ &\quad + \left| \frac{S_{t,\nu',l}(d_{i+1}) - S_{t,\nu',l}(d_i)}{\Delta d} - \partial_d S_{t,\nu',l}(d) \right| \leq 3c_1 \Delta d. \end{aligned}$$

By repeating the argument for d in each interval $[d_i, d_{i+1}]$, the inequality holds for any $d \in [0, 1]$. But now we have a contradiction of (A.22), because, by our choice of N_d , we have, for any $d \in [0, 1]$,

$$(A.26) \quad c_0 \leq |\partial_d S_{t,\nu,l}(d) - \partial_d S_{t,\nu',l}(d)| \leq 3c_1 \Delta d = 3c_1 \frac{1}{N_d} < c_0. \quad \square$$

A.3. Proof of Theorem 4.3.

Proof. The continuity for operator \mathcal{K}_2^{-1} follows directly from the definition as this is a mapping from a discrete set to discrete set.

To prove the operator \mathcal{K}_1^{-1} is continuous, first recall that the mapping \mathcal{K}_1 defined in Theorem 4.1 maps a compact subset $\mathcal{P}_{\text{comp}}$ of \mathbb{R}_+^4 to the LDOS evaluated on a grid,

$$(A.27) \quad \mathcal{K}_1 : \mathcal{P}_{\text{comp}} \rightarrow \text{Range}(\mathcal{K}_1) \subset \mathbb{R}^{N_d \times N_E}. \quad \square$$

Since \mathcal{K}_1 is a bijection between $\mathcal{P}_{\text{comp}}$ and its range by Theorem 4.1, \mathcal{K}_1^{-1} is well defined. We will show continuity by establishing that for any M closed in $\mathcal{P}_{\text{comp}}$, we have that $(\mathcal{K}_1^{-1})^{-1}(M)$ is closed in $\text{Range}(\mathcal{K}_1)$.

Let $M \subset \mathcal{P}_{\text{comp}}$ be a closed set in the subspace topology of $\mathcal{P}_{\text{comp}}$. It follows that the set M can be represented as $\tilde{M} \cap \mathcal{P}_{\text{comp}}$ where \tilde{M} is a closed and bounded set in \mathbb{R}^4 . It follows that $\mathcal{K}_1(\tilde{M})$ is also closed and bounded since \mathcal{K}_1 is continuous. We then have that $\mathcal{K}_1(M) = \mathcal{K}_1(\tilde{M} \cap \mathcal{P}_{\text{comp}}) = \mathcal{K}_1(\tilde{M}) \cap \mathcal{K}_1(\mathcal{P}_{\text{comp}})$, so that $\mathcal{K}_1(M)$ is closed in the subspace topology of $\mathcal{K}_1(\mathcal{P}_{\text{comp}}) = \text{Range}(\mathcal{K}_1)$.

Appendix B. Derivation of momentum space LDOS formula (6.6) from (3.1).

We start by stating the derivation as a theorem.

THEOREM B.1. *Suppose the Bloch transform \mathcal{G} and its inverse \mathcal{G}^{-1} is defined as in (6.3) and (6.4) respectively. Given a tight binding model Hamiltonian H of a*

periodic system with period p , defined in (6.2), the local density of states of the system defined in (3.1)

$$(B.1) \quad \rho_\theta(d, E) := \sum_{R\alpha \in R_0} g(H - E)(R\alpha, R\alpha),$$

has a integral representation

$$(B.2) \quad \rho_\theta(d, E) = \frac{1}{|\Gamma^*|} \sum_{\alpha: R\alpha \in R_0} \int_0^{\frac{2\pi}{p}} g(H(k) - E)_{\alpha, \alpha} dk,$$

where $H(k) = [\mathcal{G}H\mathcal{G}^{-1}](k)$, $|\Gamma^*| = \frac{2\pi}{p}$ and $\alpha : R\alpha \in R_0$ denotes the set of supercell orbital indices $\alpha \in \mathcal{A}^s$ corresponding to the $R\alpha \in R_0$ in (3.1).

Proof. Since g is a polynomial, it is suffice to prove that for the power function the identity holds. Suppose we use the ψ^\dagger to denote the complex conjugate and transpose of the vector ψ . We use $\psi_{R\alpha}$ to denote a vector such that $\psi_{R\alpha}(R'\alpha') = \delta_{RR'}\delta_{\alpha, \alpha'}$. We then have, for any integer $m > 0$,

$$(B.3) \quad \sum_{R\alpha \in R_0} H^m(R\alpha, R\alpha) = \sum_{R\alpha \in R_0} \psi_{R\alpha}^\dagger H^m \psi_{R\alpha} = \sum_{R\alpha \in R_0} \psi_{R\alpha}^\dagger \mathcal{G}^{-1} (\mathcal{G}H\mathcal{G}^{-1})^m \mathcal{G} \psi_{R\alpha}.$$

The second identity follows from $\mathcal{G}^{-1}\mathcal{G} = I$, derived through definitions of the Bloch transform and its inverse for \mathcal{R}^s .

LEMMA B.2. For any $\psi, \phi \in \ell^2(\Omega)$, if we use $\psi^\dagger \phi$ to denote the inner product of the two vectors, then

$$(B.4) \quad \psi^\dagger \phi = \sum_{\alpha \in \mathcal{A}^s} \int_{\Gamma^*} \check{\psi}_k^\dagger(\alpha) \check{\phi}_k(\alpha) dk,$$

where $\check{\psi}_k = [\mathcal{G}\psi](k)$ and $\check{\phi}_k = [\mathcal{G}\phi](k)$ are defined as in (6.3).

Proof. The inner product and inverse Bloch transform give that

$$(B.5) \quad \begin{aligned} \psi^\dagger \phi &= \sum_{R\alpha} \psi^\dagger(R\alpha) \phi(R\alpha) \\ &= \sum_{R\alpha} \frac{1}{|\Gamma^*|} \int_{\Gamma^*} e^{-ik' \cdot (R + \tau_\alpha)} \check{\psi}_{k'}^\dagger(\alpha) dk' \int_{\Gamma^*} e^{ik \cdot (R + \tau_\alpha)} \check{\phi}_k(\alpha) dk \\ &= \frac{1}{|\Gamma^*|} \sum_{\alpha} \sum_R \int_{\Gamma^*} \int_{\Gamma^*} e^{i(k-k') \cdot R} e^{i(k-k') \cdot \tau_\alpha} \check{\psi}_{k'}^\dagger(\alpha) \check{\phi}_k(\alpha) dk' dk \\ &= \sum_{\alpha} \int_{\Gamma^*} \int_{\Gamma^*} \delta(k - k') e^{i(k-k') \cdot \tau_\alpha} \check{\psi}_{k'}^\dagger(\alpha) \check{\phi}_k(\alpha) dk' dk \\ &= \sum_{\alpha} \int_{\Gamma^*} \check{\psi}_k^\dagger(\alpha) \check{\phi}_k(\alpha) dk. \end{aligned}$$

The fourth identity follows directly from Poisson summation formula and others follows from direct calculation. \square

To continue derivation,

$$\begin{aligned}
\sum_{R\alpha \in R_0} \psi_{R\alpha}^\dagger \mathcal{G}^{-1} (\mathcal{G}H\mathcal{G}^{-1})^m \mathcal{G}\psi_{R\alpha} &= \sum_{R\alpha \in R_0} \int_{\Gamma^*} \check{\psi}_{R\alpha,k}^\dagger (\mathcal{G}H\mathcal{G}^{-1})^m \check{\psi}_{R\alpha,k} dk \\
\text{(B.6)} \qquad \qquad \qquad &= \frac{1}{|\Gamma^*|} \sum_{\alpha: R\alpha \in R_0} \int_{\Gamma^*} H(k)_{\alpha,\alpha}^m dk, \quad \square
\end{aligned}$$

where $\check{\psi}_{R\alpha,k} := \mathcal{G}\psi_{R\alpha}(k)$. The first identity in (B.6) follows from Lemma B.2 and the last identity follows from direct calculation.

Appendix C. Proof of Theorem 6.1.

Proof. We define the truncated Hamiltonian H_{trunc} with same intralayer coupling defined as in (2.2) and interlayer coupling as in (6.1), except that there exists a positive integer $c > 3$ such that

$$(C.1) \qquad H_{\text{trunc}}(R\alpha, R'\alpha') = 0, \quad \text{if } |R - R'| > cp.$$

Then the Bloch transformed truncated Hamiltonian $H_{k,\text{trunc}}$ is defined as $\mathcal{G}H_{\text{trunc}}\mathcal{G}^{-1}$. To estimate the numerical error between (6.6) and (6.7), it suffices to estimate the following two terms,

$$\begin{aligned}
\text{(C.2)} \qquad &|\rho(d, E) - \varrho(d, E)| \\
&\leq \frac{1}{|\Gamma^*|} \left| \sum_{\alpha: R\alpha \in R_0} \int_0^{\frac{2\pi}{p}} g(H_{\theta,d}(k) - E)_{\alpha,\alpha} dk - \sum_{\alpha: R\alpha \in R_0} \sum_{i=1}^M g(H_{\theta,d}(k_i) - E)_{\alpha,\alpha} \Delta k \right| \\
&\quad + \frac{1}{|\Gamma^*|} \left| \sum_{\alpha: R\alpha \in R_0} \sum_{i=1}^M g(H_{\theta,d}(k_i) - E)_{\alpha,\alpha} \Delta k - \sum_{\alpha: R\alpha \in R_0} \sum_{i=1}^M g(H_{k_i,\text{trunc}} - E)_{\alpha,\alpha} \Delta k \right| \\
&=: B_1 + B_2.
\end{aligned}$$

LEMMA C.1. *For any polynomial g and any index $\alpha \in \mathcal{A}^s$, $g(H_{\theta,d}(k))_{\alpha,\alpha}$ is a periodic function in k with period $|\Gamma^*|$.*

Proof. From the derivation of the Bloch transformed Hamiltonian in Appendix D, each component of the Hamiltonian has the format $\sum_{\tilde{R}=R-R'} h(\tilde{R} + \tau_\alpha - \tau_{\alpha'}) e^{-ik[\tilde{R} + \tau_\alpha - \tau_{\alpha}]}$ where h could be interlayer coupling or intralayer coupling. For any m -th power of Bloch transform of $H_{\theta,d}(k)$, the diagonal term $H_{\theta,d}^m(k)_{\alpha,\alpha}$ equals

$$(C.3) \qquad \sum_{\alpha_1, \alpha_2, \dots, \alpha_{m-1}} H_{\theta,d}(k)_{\alpha,\alpha_1} H_{\theta,d}(k)_{\alpha_1,\alpha_2} \dots H_{\theta,d}(k)_{\alpha_{m-1},\alpha},$$

where $\alpha_i \in \mathcal{A}^s$ for $1 \leq i \leq m-1$. The phases depending on k in addition to $e^{-ik\tilde{R}}$ term are

$$(C.4) \qquad e^{-ik[\tau_\alpha - \tau_{\alpha_1}]} e^{-ik[\tau_{\alpha_1} - \tau_{\alpha_2}]} \dots e^{-ik[\tau_{\alpha_{m-1}} - \tau_\alpha]} = 1.$$

Therefore, the diagonal terms of Bloch transformed Hamiltonian are periodic with respect to the commensurate reciprocal lattice, i.e the period of diagonal term for Bloch transformed Hamiltonian is $|\Gamma^*|$. \square

LEMMA C.2. *For any polynomial g and any index $\alpha \in \mathcal{A}^s$, $g(H_{\theta,d}(k))_{\alpha,\alpha}$ extends to an analytic function in k in a non-trivial strip containing the real axis.*

Proof. Since addition, multiplication of complex analytic function is still complex analytic function, it suffice to prove that each component of Bloch transformed Hamiltonian is complex analytic. To be specific, $\sum_{\tilde{R}=R-R'} h_{inter}(\tilde{R}+\tau_\alpha-\tau_{\alpha'}) e^{-ik[\tilde{R}+\tau_\alpha-\tau_{\alpha'}]}$ as a function of k converges uniformly in the strip $|\text{Im}(k)| < \gamma$ due to exponential decay of the coefficient function h_{inter} (2.4). Since similar remarks hold also for h_{intra} , and the uniform limit of analytic functions is analytic, the lemma is proved. \square

We state a theorem on numerical quadrature error estimate as below (See [43] for more details and proofs).

THEOREM C.3 (Trefethen). *Suppose v is T -periodic and analytic and satisfies $|v(k)| \leq C_q$ in the strip $-a < \text{Im}(k) < a$ for some $a > 0$. Then for any $M \geq 1$,*

$$(C.5) \quad |\mathcal{I}_M - \mathcal{I}| \leq \frac{2TC_q}{e^{2\pi aM/T} - 1}$$

where $\mathcal{I} = \int_0^T v(k) dk$ and $\mathcal{I}_M = \frac{T}{M} \sum_{i=1}^M v(\frac{Ti}{M})$.

Theorem C.3 gives an upper bound for B_1 in (C.2) as Lemma C.1 and Lemma C.2 guarantee that the condition of the theorem holds for B_1 . The period $T = |\Gamma^*| = \frac{2\pi}{p}$ due to Lemma C.1 and the polynomials of Bloch transformed Hamiltonian is analytic due to Lemma C.2. We let constant $a = \gamma/2$ in the case and the constants C_q depend on polynomial g and a . Therefore, we derive that

$$(C.6) \quad B_1 \leq \frac{4\pi C_q}{pe^{p\gamma M/2} - p} \cdot \frac{|R_0|}{|\Gamma^*|}.$$

To estimate B_2 , we bound the perturbation of Bloch transformed Hamiltonian $|H_{\theta,d}(k_i) - H_{k_i,\text{trunc}}|$. The tight binding Hamiltonian with assumption (2.4) can be proved to be bounded operator through standard results (see details in [28] for example) and its Bloch transformed Hamiltonian is bounded as well. With Cauchy integral formulas, we have

$$(C.7) \quad \begin{aligned} g(H_{\theta,d}(k) - E) &= \frac{1}{2\pi i} \int_{\Gamma} g(z - E)(z - H_{\theta,d}(k))^{-1} dz \\ g(H_{k,\text{trunc}} - E) &= \frac{1}{2\pi i} \int_{\Gamma} g(z - E)(z - H_{k,\text{trunc}})^{-1} dz \end{aligned}$$

where $\Gamma = \partial\mathcal{D}$ is a smooth contour and the enclosed domain \mathcal{D} contains the spectrum of Bloch transformed Hamiltonian. The Γ satisfies that for any $z \in \Gamma$, $|z - H| \geq d$ for some $d > 0$. Due to the perturbation theory, the spectrum radius of $H_{\theta,d}(k)$ and $H_{k,\text{trunc}}$ are of similar size when c is large enough. We are able to find one contour $\Gamma = \partial\mathcal{D}$ such that \mathcal{D} contains spectrum of $H_{\theta,k}$ and $H_{k,\text{trunc}}$. To simplify notation,

we use $g_E(x)$ to denote the function $g(x - E)$, and then

$$\begin{aligned}
& |[g_E(H_{\theta,d}(k)) - g_E(H_{k,\text{trunc}})]_{\alpha,\alpha}| \\
& \leq \left| \frac{1}{2\pi i} \int_{\Gamma} g_E(z)(z - H_{\theta,d}(k))^{-1}(H_c - H_{k,\text{trunc}})[(z - H_{k,\text{trunc}})^{-1}]_{\alpha,\alpha} \right| \\
\text{(C.8)} \quad & \leq \frac{C_{\Gamma}}{2\pi} \sup_{z \in \Gamma} |[(z - H_{\theta,d}(k))^{-1}(H_c - H_{k,\text{trunc}})(z - H_{k,\text{trunc}})^{-1}]_{\alpha,\alpha}| \\
& \leq \frac{C_{\Gamma} N^2}{2d^2\pi} \sup_{\beta, \beta' \in \mathcal{A}^s} |[H_{\theta,d}(k) - H_{k,\text{trunc}}]_{\beta, \beta'}|,
\end{aligned}$$

where the last inequality uses the distance between z and spectrum of Hamiltonian is at least d and $N = |\mathcal{A}^s|$.

Recall the definition of Bloch transformed Hamiltonian and assumption of inter-layer coupling (2.4), we can derive that

$$\begin{aligned}
\text{(C.9)} \quad |[H_{\theta,d}(k) - H_{k,\text{trunc}}]_{\beta, \beta'}| & = \left| \sum_{|R| > cp: R \in \mathcal{R}^s} h(R + \tau_{\beta} - \tau_{\beta'}) e^{-ik[\tilde{R} + \tau_{\beta} - \tau_{\beta'}]} \right| \\
& \leq \frac{h_0 e^{\gamma p}}{p} \int_{cp}^{\infty} e^{-\gamma r} dr = \frac{h_0}{\gamma p} e^{\gamma p - \gamma cp}.
\end{aligned}$$

Therefore, we derive

$$\text{(C.10)} \quad B_2 \leq \frac{C_{\Gamma} h_0 N^2 e^{-\gamma(c-1)p}}{2\gamma d^2 p \pi} \cdot \frac{|R_0|}{|\Gamma^*|}. \quad \square$$

Appendix D. Derivation of Bloch Transformed Hamiltonian in coupled chain model. In this section, we derive the Bloch transformed Hamiltonian of commensurate coupled chain. We summarize this result in the following [Theorem D.1](#).

THEOREM D.1. *Suppose \mathcal{G} and \mathcal{G}^{-1} are Bloch transform and its inverse defined in (6.3) and (6.4) for supercell lattice \mathcal{R}^s and indices set \mathcal{A}^s , H is a tight binding Hamiltonian for a commensurate coupled chain defined as in (6.2). Then for any $\psi \in \ell^2(\mathcal{R}^s \times \mathcal{A}^s)$ and $k \in \Gamma^*$, there exists a $|\mathcal{A}^s| \times |\mathcal{A}^s|$ Hermitian matrix $H(k)$ denoted as $[\mathcal{G}H\mathcal{G}^{-1}](k)$ such that*

$$\text{(D.1)} \quad [\mathcal{G}H\psi](k) = H(k)[\mathcal{G}\psi](k).$$

Moreover, for $\alpha, \alpha' \in \mathcal{A}^s$ representing indices in the same layer

$$\text{(D.2)} \quad H(k)_{\alpha, \alpha'} = \check{h}_{\alpha, \alpha'}(k) := \sum_{\tilde{R} \in \mathcal{A}^s} h_{\text{intra}}(\tilde{R} + \tau_{\alpha} - \tau_{\alpha'}) e^{-ik[\tilde{R} + \tau_{\alpha} - \tau_{\alpha'}]},$$

and for $\alpha, \beta \in \mathcal{A}^s$ representing indices in different layers,

$$\text{(D.3)} \quad H(k)_{\alpha, \beta} = \check{h}_{\alpha, \beta}(k) := \sum_{\tilde{R} \in \mathcal{R}^s} h_{\text{inter}}(\tilde{R} + \tau_{\alpha} - \tau_{\beta}) e^{-ik[\tilde{R} + \tau_{\alpha} - \tau_{\beta}]},$$

where h_{intra} and h_{inter} are intralayer and interlayer coupling functions.

Proof. Recall the Bloch transform $\mathcal{G} : l^2(\mathcal{R}^s \times \mathcal{A}^s) \rightarrow C(\Gamma^*) \times \mathcal{A}^s$ is defined by

$$(D.4) \quad [\mathcal{G}\psi]_\alpha(k) = \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \sum_{R \in \mathcal{R}^s} \psi(R\alpha) e^{-ik \cdot (R + \tau_\alpha)},$$

where $\check{\psi}_\alpha(k)$ is used to denote $[\mathcal{G}\psi]_\alpha(k)$. To derive the Bloch transformed Hamiltonian, we are going to calculate

$$(D.5) \quad \mathcal{G}H \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \mathcal{G} \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \begin{bmatrix} \psi_1 \\ \psi_2 \end{bmatrix} = \begin{bmatrix} \mathcal{G}H_{11}\psi_1 + \mathcal{G}H_{12}\psi_2 \\ \mathcal{G}H_{21}\psi_1 + \mathcal{G}H_{22}\psi_2 \end{bmatrix}$$

where ψ_i is used to denote wavefunction in i -th layer and H_{ij} denotes one block of Hamiltonian describing coupling between layer i and layer j . We can derive the exact formula for $\mathcal{G}H_{11}\psi_1 + \mathcal{G}H_{12}\psi_2$ in (D.5). In the derivation, we use h_{intra} to denote intralayer coupling function and it is another representation of the model described in (2.2). Indeed, h_{intra} can be defined as,

$$(D.6) \quad h_{intra}(R + \tau_\alpha - \tau_{\alpha'}) = \begin{cases} t_{\alpha, \alpha'}, & R = a, \\ t_{\alpha', \alpha}, & R = -a, \\ \epsilon_{\alpha, \alpha'}, & R = 0, \\ 0, & \text{else,} \end{cases}$$

where a is the length of one supercell. We start by calculating $\mathcal{G}H_{11}\psi_1(k)$ as

$$\begin{aligned} & [\mathcal{G}H_{11}\psi_1]_\alpha(k) \\ &= \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \sum_{R \in \mathcal{R}^s} [H_{11}\psi_1](R\alpha) e^{-ik \cdot (R + \tau_\alpha)} \\ &= \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \sum_{\substack{R \in \mathcal{R}^s \\ R' \in \mathcal{R}^s, \alpha'}} h_{intra}(R + \tau_\alpha - (R' + \tau_{\alpha'})) e^{-ik(R' + \tau_{\alpha'})} \psi_1(R'\alpha') e^{-ik[R + \tau_\alpha - R' - \tau_{\alpha'}]} \\ &= \sum_{\tilde{R} = R - R', \alpha'} h_{intra}(\tilde{R} + \tau_\alpha - \tau_{\alpha'}) e^{-ik[\tilde{R} + \tau_\alpha - \tau_{\alpha'}]} \widetilde{\psi_{1, \alpha'}}(k) \\ &= \sum_{\alpha'} \left(\sum_{\tilde{R} = R - R'} h_{intra}(\tilde{R} + \tau_\alpha - \tau_{\alpha'}) e^{-ik[\tilde{R} + \tau_\alpha - \tau_{\alpha'}]} \right) \widetilde{\psi_{1, \alpha'}}(k) \\ &=: \sum_{\alpha'} \check{h}_{\alpha, \alpha'} \widetilde{\psi_{1, \alpha'}}(k) \end{aligned}$$

where $\widetilde{\psi_{1, \alpha}}$ is the α component of the Bloch transform of ψ . Here $\check{h}_{\alpha, \alpha'}$ is used to denote $\sum_{\tilde{R} = R - R', \alpha'} h_{intra}(\tilde{R} + \tau_\alpha - \tau_{\alpha'})$. The third identity holds due to the fact that the $\sum_{R \in \mathcal{R}^s, \alpha'} h_{intra}(R + \tau_\alpha - (R' + \tau_{\alpha'})) e^{-ik[R + \tau_\alpha - R' - \tau_{\alpha'}]}$ does not depend on R' .

For the off-diagonal block, we use h_{inter} to denote the interlayer coupling function

and can similarly derive that,

$$\begin{aligned}
\mathcal{G}H_{12}\psi_2 &= \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \sum_{R \in \mathcal{R}^s} [H_{12}\psi_2](R\alpha) e^{-ik \cdot (R + \tau_\alpha)} \\
&= \frac{1}{|\Gamma^*|^{\frac{1}{2}}} \sum_{\substack{R \in \mathcal{R}^s \\ R' \in \mathcal{R}^s, \beta}} h_{inter}(R + \tau_\alpha - (R' + \tau_\beta)) e^{-ik(R' + \tau_\beta)} \psi_2(R'\beta) e^{-ik[R + \tau_\alpha - R' - \tau_\beta]} \\
&= \sum_{\tilde{R} = R - R' \in \mathcal{R}^s, \beta} h_{inter}(\tilde{R} + \tau_\alpha - \tau_\beta) e^{-ik[\tilde{R} + \tau_\alpha - \tau_\beta]} \widetilde{\psi_{2,\beta}}(k) \\
&= \sum_{\beta} \left(\sum_{\tilde{R} = R - R' \in \mathcal{R}^s} h_{inter}(\tilde{R} + \tau_\alpha - \tau_\beta) e^{-ik[\tilde{R} + \tau_\alpha - \tau_\beta]} \right) \widetilde{\psi_{2,\beta}}(k) \\
&=: \sum_{\beta} \check{h}_{\alpha,\beta} \widetilde{\psi_{2,\beta}}(k). \quad \square
\end{aligned}$$
