#### Abstract

Multi-Target Multi-Camera Tracking (MTMCT) has broad applications and forms the basis for numerous future city-wide systems (e.g. traffic management, crash detection, etc.). However, the challenge of matching vehicle trajectories across different cameras based solely on feature extraction poses significant difficulties. This article introduces an innovative multi-camera vehicle tracking system that utilizes a selfsupervised camera link model. In contrast to related works that rely on manual spatial-temporal annotations, our model automatically extracts crucial multi-camera relationships for vehicle matching. The camera link is established through a pre-matching process that evaluates feature similarities, pair numbers, and time variance for high-quality tracks. This process calculates the probability of spatial linkage for all camera combinations, selecting the highest scoring pairs to create camera links. Then, a transition time is estimated by kernel density estimation that provides temporal information on created camera link. Our approach significantly improves deployment times by eliminating the need for human annotation, offering substantial improvements in efficiency and cost-effectiveness when it comes to real-world application. This pairing process supports cross camera matching by setting spatial-temporal constraints, reducing the searching space for potential vehicle matches. According to our experimental results, the proposed method achieves a new state-of-the-art among automatic camera-link based methods in CityFlow V2 benchmarks with $61.07 \%$ IDF1 Score.

Keywords: multi-camera tracking, camera link model
CCS Concepts: Camera Networks and Vision

## 1. Introduction

With the continuous expansion of urbanisation, the city traffic management is becoming more and more challenging, which is calling for the development of intelligent transportation systems within the broader concept of smart cities. One of the key enabling elements of those systems is the MultiTarget Multi-Camera Tracking (MTMCT), which aims to track the vehicles over large areas in networks comprised of multiple traffic cameras. The MTMCT can usually be divided into two main computational stages: single camera tracking (SCT) and inter-camera tracking (ICT). Over the past decades, many researchers have looked into the SCT problem and have created many robust tracking algorithms [1, 2, 3]. Building on the foundations of SCT algorithms, we focus on the ICT problem in this study.

Despite some promising results have been achieved for MTMCT [18], there are still several challenges making multi-target tracking a difficult task [4]. The first challenge is the Dramatic Appearance Variabilities: The most popular methodology for matching tracklets across different cameras is by comparing the features of different tracklets / objects. Features such as the edges, centroid, stereo disparity, texture, motion field, and gradients are often retrieved for association [5]. However, variabilities caused by factors like occlusion, changes in illumination, shadows, and non-rigid deformation can significantly alter the appearance of the same object. In addition to the appearance variabilities, the different Camera Overlapping Ratios (FOV) can also make it difficult to create robust algorithms adaptable to various scenes. There are three different scenes, the overlapping FOV, mixed FOV and non-overlapping FOV. Both overlapping FOV and mixed FOV would face the problem of

Figure 1. The pipeline diagram of our MCVT system.
the different overlapping ratios. The level of FOVs overlap affects the formulation of tracking problems in multi-camera systems thereby affecting the algorithm performance. Furthermore, the Unknown Number of Targets and Cameras also complicates the matching process, as the total number of targets is indeterminate, adding complexity to establishing the complete trajectory of each target [6]. This issue becomes even more complex when a tracker erroneously produces multiple local tracklets for a single target within a single camera [7]. In addition to the above three challenges, there are some other challenges includes Camera Motion [8], Varying Object Motion [5] also contribute to the difficulties faced in MTMCT.

It is difficult for multi-camera trajectory matching to deal with these problems in a systematic way, therefore there are many works focused on using various techniques [9, 10]. By implementing constraints, the searching space for potential tracklet matches is reduced, thereby decreasing the likelihood of mismatches among visually similar vehicles. Among these constraints, spatial-temporal factors are often prioritized for improving the overall performance of our MTMCT algorithm, since they have the greatest impact on the searching space. Previous work has manually segmented traffic camera scenes into entry and exit zones, and defined to transition time between cameras [11, 12]. The effectiveness of these constraints has been proven [11], however, these methods require manual input. This may work in the research phases with limited camera number and simple camera network settings but such human-labeled approaches are impractical for real-world applications. Often involve more complex camera networks, variable transition times or temporal road topology changes which requires regular updating, real-world application would thus pose a significant challenge in terms of human resources. To mitigate the demand for manual labor, an automated method known as the camera link model (CLM) has been developed [15] (initially for multi-camera tracking on people). Later, with the rising popularity of the multi camera vehicle tracking (MCVT) problem, CLM was adapted to MCVT as well $[14,16,17]$; however, these adaptations still necessitated some human labeling and focused primarily on overlapping and mixed FOV. To the best of our knowledge, [18] is the only work that applies a self-supervised CLM capable of handling non-overlapping FOV camera networks, but this self-supervised CLM still has a focus on overlapping and mixed FOV. Thus, an improved selfsupervised CLM focusing on Non-overlapping FOV capable of automatically generating and updating spatial-temporal constraints for MCVT is proposed in this paper.

The pipeline diagram of our proposed system is shown in Figure 1. Initially, each video frame is processed using a YOLO [19]-based one-stage object detector. The detection outputs are then utilized for extracting deep appearance features. These deep embeddings, combined with the object detection results, are used for a DeepSort [1] based SCT. The tracks obtained from the single camera tracking
phase are then used to train the self-supervised CLM. Finally, by utilizing the spatial-temporal constraints generated by the CLM along with the results from single camera tracking, we identify the minimal distances pair among cross-camera track pairs. These paired tracks are then assigned the same track ID, ensuring consistent identification across multiple cameras.

The rest of this article is structured as follow: an overview for related works is discussed on section 2, followed by the methodology part on section 3 . The experiments and results are present on section 4 . Finally, we discuss the conclusion in section 5.

## 2. Related Works

With the aim of linking the same objects captured by different cameras, object re-identification (Re-ID) attracts growing attention recent years. In general, the Re-ID algorithm calculates the similarity between each query-gallery pair and finds the best potential matched targets. Based on the input data formats, the object Re-ID methodologies can be divided into two types: the image-based approaches and the video-based approaches. Technically, video-based Re-ID should achieve better performance compare with the image-based one because video-based RE-ID contains more information. Except for the features extracted from every single frame, the time-related correlations, i.e., spatial-temporal information, trajectory features, vehicle transition order, are also useful in the cross-camera Re-ID comparison [20]. Early research [21, 22, 23, 24] focus more on imaged-based object Re-ID due to the limitation of SCT algorithm performance and the limitation of computational resources. With the mature of SCT algorithms [1,2,3] and better hard-ware development, the researchers see the light at the end of the tunnel. This rises the tide for video-based Re-ID, which refers to our MTMCT problem.

The MCVT problem has garnered increased attention following the release of the open-source dataset -- CityFlow [25] on AICITY challenge [26]. To the best of the our knowledge, CityFlow is the only real-world open-source dataset specifically for MCVT problem. There are some other open-source MCVT synthetic dataset e.g. Synthehicle [27] as well, but most MCVT research is conducted on the real-world dataset. Our review narrows the focus to studies using the CityFlow dataset. Following the research development from 2020 to 2021, there is a significant performance improvement shown up with the involvement of human-labelled spatial-temporal constraints. According to [11], the use of spatial-temporal constraints has contributed to a 0.2346 increase in the IDF1 score, highlighting the effectiveness of this approach. However, while human labelling proves beneficial for datasets like CityFlow, it is still not applicable for real-world MCVT due to the much more complex and variable parameters need to be considered in real-world. Thus, some researchers have looked into CLM to automatically generate spatial-temporal constraints. Initially, CLM was applied to non-overlapping FOV scenarios for multi-camera people tracking [31, 32]. Later then, [14] brings CLM to MCVT field; however, this CLM still relies on human trajectory annotation which doesn't address the issue. Later, $[16,17]$ introduced an improved version of CLM that can autonomously segment entry/exit zones, yet it continued to rely on human-annotated trajectory data to establish zone connections. Finally, [18] first try to solve out this human-label demands problem that propose a self-supervised CLM model that provides the spatial-temporal constraints without the demand for human annotation. The selfsupervised CLM shows great potential in real-world application and achieves the state-of-art performance on overlapped and mix FOV on CityFlow V1 test scenes [16, 17]. However, due to data and algorithm limitation of CLM itself, methods based on CLM could not compete with human annotated approaches on non-overlapping FOV CityFlow V2 test scenes [18].

## 3. Methodology

The general architecture of our proposed Multi-Camera Vehicle Tracking (MCVT) algorithm is depicted in Figure 1. The whole process involves five steps: object detection, feature extraction, SCT,

CLM and multi-camera matching. The steps and dataflow are as follows: 1) The object detector obtains the bounding box (BBox) location for each detected object in every frames; 2) The cropped images of these detected objects are then used as inputs for three different ResNets to extract deep appearance features; 3) The SCT utilizes the BBox and Re-ID features to create tracklets for each target within a single camera's view; 4) Utilizing the results from single camera tracking and the deep features, we train our CLM; 5) The results from single camera tracking and the deep features are used to form a cost-matrix, which is constrained by the spatial-temporal information generated by our CLM. This matrix is then solved to match track IDs across cameras. More detailed processes are described below.

### 3.1 Object Detection

A reliable vehicle detection is a prerequisite for vehicle tracking. Lots of the MCMCT problems use YOLOv5 to be the object detector due to its accuracy and real-time ability. With the development of this one-stage detection algorithm, it already iterated to YOLOv9, currently considered the state-of-the-art in one-stage detectors. For our purposes, we employ the YOLOv9e model, which is pretrained on the COCO dataset, to specifically detect car, motorcycle, bus and truck. To prevent the same target from being recognized multiple times under different categories, we implement non-maximum suppression (NMS) across all detected objects. Additionally, we filter all detection BBoxes within the same video frame based on IOU and confidence scores to minimize redundant detections and mitigate issues caused by occlusions.

### 3.2 Re-ID Feature Extraction

The deep embedding quality contributes a lot for the final matching results. Building on [11], we utilize three distinct ResNet models: ResNet50IBN-a, ResNet101-IBN-a, and ResNeXt101-IBN-a. All weights are pre-trained on the CityFlow dataset with a combination of softmax cross-entropy loss function and triplet loss [11].

$$
\begin{equation*}
L_{r e i d}=L_{c l s}+\alpha L_{t r p} \tag{1}
\end{equation*}
$$

In this function, $L_{\text {reid }}$ refers to the cost function, $L_{c l s}$ and $L_{\text {trp }}$ stands for softmax cross-entropy loss and triplet loss, with $\alpha$ balancing their weights. Each ResNet model outputs a [2048x1] dimension feature, then the final feature of each detected car is the average output of the three models.

### 3.3 Single Camera Tracking

In SCT, we follow the track-by-detection to associate each detection in the video frame with a synchronized track id. Considering the computational load and accuracy, we choose DeepSort [1] as our main framework. DeepSort integrates a Kalman filter, based on a constant velocity model, to predict locations. This prediction is then merged with deep appearance features to formulate tracklets. One of its great advantages is it including the Matching Cascade approach to mitigates the impact of short-term occlusions, which is a pain point for MCVT problem.

### 3.4 Camera Link Model

The Camera Link Model (CLM) leverages temporal and topological information between different cameras to establish spatial-temporal constraints, thereby enhancing the performance of multi-camera matching. This model includes camera link information and the transition time distributions between adjacent cameras. Specifically, our proposed CLM provides the exit/entry zone pair of adjacent cameras with a time-transition kernel estimation window. Basically, if no existing camera need to be passed between two cameras, the two cameras form a camera link. For each link, here should have two zone pairs. One entry/exit pair and one exit/entry, representing the bidirectional flow between two linked cameras. Based on the camera link, high confidence tracklets matching results passing through those zone pair are used to perform the kernel density estimation (KDE), which helps the camera link time transition estimation. The proposed CLM can be divided into three steps: 1) entry/exit zone

Figure 2. CLM illustration
generation in single camera; 2) entry-exit zone pairing across adjacent camera; 3) camera link transition time estimation. An illustration of the CLM for cameras link is shown in Figure 2.
3.4.1 Entry/exit zones generation. Due to road structure and traffic rule, all vehicles follow a certain moving pattern. The generation of entry/exit zones is predicated on these distinct patterns. We select complete tracklets from SCT and extract the entry and exit points of each tracklet along with their vector directions to identify consistent movement patterns. In non-overlapping fields of view (FOV) scene, where typically only one camera located on one intersection, the challenge of visual perspective arises: vehicles that are closer to the camera appear significantly larger than those further away. This will clutter the entry/exit zones, causing a mess for the automatic zone generation. To overcome this, we perform a pre-clustering step based on the direction of travel, before the point distance clustering. The MeanShift algorithm [33] is used for our clustering process. Figure 3 shows an example for autozone generation process that also illustrate the difference between pre-clustering and non preclustering.

Zone classification result

Figure 3. Example for auto zone generation

After the clustering process, the entry/exit density is calculated to classify different clusters into certain zone type. The definition is as follows:

$$
\begin{gather*}
D_{e}=\frac{N_{e, k}}{N_{e, k}+N_{x, k}}, D_{x}=\frac{N_{\chi, k}}{N_{e, k}+N_{x, k}}  \tag{2}\\
\text { zone class }= \begin{cases}\text { entryzone } & \text { if } D_{e}>\rho_{e} \\
\text { exit zone } & \text { if } D_{x}>\rho_{x,} \\
\text { undefined zone } & \text { else. }\end{cases} \tag{3}
\end{gather*}
$$

In this function, $N_{e, k}$ means the number of entry points in this cluster and $N_{x, k}$ means the number of exit points in this cluster. If the entry/exit density is higher than certain threshold $\rho$, a rectangle window that encompass all points inside this cluster will be defined as the corresponding entry/exit zone.
3.4.2 Entry-exit zone pairing across adjacent camera. Following automatic zone generation, we establish camera links by defining entry-exit zone pairs across adjacent cameras. Each entry-exit zone pair represents the path a vehicle takes when it exits from one camera's zone and enters another camera's zone, without deviating onto side roads. This ensures that the trajectory of the vehicle is continuously tracked across multiple camera views. To find the entry-exit zone pair between adjacent
cameras, some high confidence tracklets across those zones are selected to find the best entry-exit zone pair. To minimize errors from less reliable tracklets, tracklets with time higher than $\rho_{t}$ and the moving distance higher than $\rho_{d}$ are selected as the high confidence tracklets. These tracklets are then compiled into a potential zone matching database. A pre-tracklet matching for each potential zone pair is conducted using the same approach as in multi-camera matching, but without incorporating spatialtemporal constraints. This cost-matrix formation and solving procedure will be detailed explained in the later section.

To assess the confidence of each zone pair, we introduce a zone pair confidence score calculated from the preliminary tracklet matching results. This zone pair confidence score consists three parts 1) the average cosine distance between tracklet pairs, 2) the number of matched high confidence tracklets, and 3) the time variance of these matched tracklet pairs. This zone pair confidence score function is formed as follows:

$$
\begin{equation*}
\text { Score }=-\alpha \text { Distance }_{\text {cosine }}+\beta N_{\text {pair }}-\gamma V \text { ar } \text { time } \tag{4}
\end{equation*}
$$

In this function, $\alpha, \beta, \gamma$ are coefficients that weight the importance of each component in the score evaluation. Distance cosine is the average cosine distance for paired tracklets, $N_{\text {pair }}$ is the number of pair tracklets and Var $_{\text {time }}$ represents the variance for transition time for each pre-matched tracklet pair. Considering our test dataset road topology, each camera connects with 1 adjacent camera, the calculation process follows with the sequence [c041,c042], [c042,c043]...[c045,c046]. And the zone pair corresponding for the highest confidence score are select to be the entry/exit zone pair. This method ensures that the most reliable pathways between cameras are identified based on quantifiable metrics, facilitating accurate vehicle tracking across camera networks.
3.4.3 Camera link transition time estimation. To estimate the transition time of each camera link, the high confidence tracklet pre-matching results for paired zone are used. The transition time for pair tracklets is basically calculated by:

$$
\begin{equation*}
T_{t r a n}=T_{\text {exit }}-T_{\text {entry }} \tag{5}
\end{equation*}
$$

We then filter out any negative transition times $\left(T_{\text {tran }}<0\right)$, as these are not feasible. The remaining $T_{t r a n}$ is used to do a gaussian kernel density estimation (KDE) to find the time transition estimation between two cameras. Comparing with set hard-removal time-window between linked camera, the KDE approach aligned the transition possibility for each transition time that contribute a better way to identify the potential pair across different cameras. This KDE result provides hard temporal removal constraints (if the possibility is too low) while also contributes to build the cost matrix.

### 3.5 Multi-Camera Matching

With the temporal and spatial information provided by our CLM, we can start the matching process. The multi-camera matching is mainly relied on solving cost matrix of tracklets across different cameras. Our cost matrix is consisted of by 1) deep appearance distance; 2) transition time estimation; 3) spatial-temporal information mask. The first step is to calculate distance between each tracklet. This tracklet feature is derived from the object Re-ID feature that is processed by the temporal attention mechanism [34] to generate a 2048x1 dimension feature. The deep appearance distance of tracklets $T_{i}$ and $T_{j}$ can be computed using cosine similarity distance:

$$
\begin{equation*}
\operatorname{Dis}_{c o s}\left(T_{i}, T_{j}\right)=1-\frac{F\left(T_{j}\right) \times F\left(T_{i}\right)}{\left|F\left(T_{j}\right)\right| \times\left|F\left(T_{i}\right)\right|} \tag{6}
\end{equation*}
$$

Where $F\left(T_{j}\right)$ is the feature of tracklet $T_{j}$ and $F\left(T_{i}\right)$ is the feature of tracklet $T_{i}$. Besides the cosine distance, the transition time estimation is a taken into account. Combing those two parameters together, the cost distance is formed:

$$
\begin{equation*}
\operatorname{Cost}\left(T_{i}, T_{j}\right)=\delta D i s_{\cos }\left(T_{i}, T_{j}\right)-\epsilon K D E\left(T_{\operatorname{tran}}\left(T_{i}, T_{j}\right)\right) \tag{7}
\end{equation*}
$$

Here, $\delta$ and $\epsilon$ are coefficient weights for the appearance and transition time factors in the cost function, $K D E$ represents the kernel density score for the transition time. A higher KDE score indicates a more likely transition between the cameras. From all those above we can get the cost matrix C for m tracklets as:

$$
C=\left[\begin{array}{ccc}
\operatorname{Cost}\left(T_{1}, T_{1}\right) & \ldots & \operatorname{Cost}\left(T_{1}, T_{m}\right)  \tag{8}\\
\vdots & \ddots & \vdots \\
\operatorname{Cost}\left(T_{m}, T_{1}\right) & \ldots & \operatorname{Cost}\left(T_{m}, T_{m}\right)
\end{array}\right]
$$

After forming the initial cost matrix, a spatial-temporal mask inspired by [11] is used to filter unlikely matching pairs that reduce the searching space. For tracklet $T_{i}$ and $T_{j}$, we decide whether they conflict with each other by Table 1 .

Table 1. Spatial-temporal confliction rule.

| tracklet in query camera | tracklet in gallery camera | Time | Conflict |
| :---: | :---: | :---: | :---: |
| paired entry zone | paired exit zone | $K D E\left(T_{\text {tran }}\right)<\rho$ | TRUE |
| paired entry zone | paired entry zone | Any $T_{\text {tran }}$ | TRUE |
| paired exit zone | paired entry zone | $K D E\left(T_{\text {tran }}\right)<\rho$ | TRUE |
| paired exit zone | paired exit zone | Any $T_{\text {tran }}$ | TRUE |
| Unpaired entry and exit zone | Any tracklets | Any $T_{\text {tran }}$ | TRUE |
| Any tracklets | Unpaired entry and exit zone | Any $T_{\text {tran }}$ | TRUE |

Table 1 lists all possible situation that two tracklets will conflict with each other. Once a tracklet entry or exit in the entry/exit zone it will be assigned into the entry/exit zone dataset. The paired entry/exit zone in Table 1 represents any tracklets that entry/exit into our camera view through the camera link model generated zone pair. For this spatial-temporal mask, it will form a mask matrix:

$$
\begin{align*}
& \operatorname{Mask}\left(T_{i}, T_{j}\right)=\left\{\begin{array}{ccc}
\text { True } & \text { if Conflict }=\text { True } \\
\text { False } & \text { else }
\end{array}\right.  \tag{9}\\
& M=\left[\begin{array}{ccc}
\operatorname{Mask}\left(T_{1}, T_{1}\right) & \ldots & \operatorname{Mask}\left(T_{1}, T_{m}\right) \\
\vdots & \ddots & \vdots \\
\operatorname{Mask}\left(T_{m}, T_{1}\right) & \ldots & \operatorname{Mask}\left(T_{m}, T_{m}\right)
\end{array}\right] \tag{10}
\end{align*}
$$

Finally, we combine the cost matrix with our spatial-temporal mask:

$$
\begin{equation*}
\hat{C}=C \odot M \tag{11}
\end{equation*}
$$

where, $\odot$ represents the product of the corresponding elements of the matrix. The constrained cost matrix is thus obtained, which is used for subsequent tracklets clustering. After filtering through the spatial-temporal mask, the searching space is significantly narrowed. In this case, we greedily select the smallest pair-wise distance to match the tracked vehicles. For each ordered transition, we further remove the pairs which conflict with previously matched pairs and pairs that have distance higher than threshold SychThresh. We repeat the process until there is no valid transition pair or the minimum distance is larger than a threshold.

## 4. Experiments and Results

### 4.1 Dataset

CityFlow [25] is the most representative and the largest MCVT dataset that captured in the actual scene of the city. The dataset includes at least 3.25 hours of traffic video at 960 p resolution from 40 cameras across 10 intersections in a medium-sized US city, covering a total length of approximately 2.5 kilometers. It features a variety of road camera setting topologies, including non-overlapping,
mixed, and overlapping FOV. The test set consists of 6 cameras with non-overlapping FOV, which we use to validate our proposed algorithm.

### 4.2 Evaluation Metric

For MCMOT problem, many evaluation metrics are used including but not limited on: MOTA, IDF1, HOTA and so on. In our task, we choose IDF1 [35] to be the metric to evaluate the performance of our proposed algorithm. IDF1 calculates the ratio of the number of correctly identified detections to the ground truth and the average number of calculated detections.

$$
\begin{equation*}
I D F 1=\frac{2 I D T P}{2 I D T P+I D F P+I D F N} \tag{12}
\end{equation*}
$$

where IDTP, IDFP, and IDFN represent the counts of true positive, false positive, and false negative identifications, respectively.

### 4.3 Implementation Details

The algorithm was implemented using PyTorch 1.7.1 and executed on one Nvidia RTX 4070 Ti GPU. For object detection, the YOLOv9e model pre-trained on coco dataset is applied. The detection confidence score threshold is set to be 0.2 , with NMS-IOU set 0.45 . In the feature extractor training process, we respectively use ResNet50-IBN-a, ResNet101-IBN-a and ResNeXt101-IBN-a as the backbone for training and those trained networks are used to extract $2048 \times 1$ dimension deep feature. In SCT, the DeepSort-based framework was employed, with a minimum confidence score of 0.2 and a minimum IOU of 0.5 between predicted and current BBoxes. For camera link mode, the threshold for entry/exit zone definition $\rho_{e}$ and $\rho_{x}$ is 0.8 ; the high confidence track is filtered by $\rho_{t}=$ $2 s$ and $\rho_{d}=200$ pixels. The zone pair confidence score weights $\alpha, \beta, \gamma$ are set to be $0.7,0.003$ and 0.00001 , respectively, This was found to give the best results. For multi-camera matching, $\delta$ and $\epsilon$ are set to be $1,-0.5$ and the KDE filter $\rho$ is set to be 0.001 . In total 170 tracks across multiple cameras in our test set are detected, and the resulting IDF1 score of 0.6107 surpassed all other camera link-based approaches.

### 4.4 Ablation Study

An ablation study was conducted to determine the individual contributions of different modules within our proposed framework. This study helps to isolate the effects of each component on the overall performance, as detailed in Table 2.

Table 2. Different module influence on final performance.

| Method | IDF1 | IDP | IDR | Precision | Recall |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Baseline | 0.4125 | 0.4807 | 0.3612 | 0.5189 | 0.39 |
| + Parameter Fine Tuning | 0.4462 | 0.4791 | 0.4175 | 0.5197 | 0.4528 |
| + Yolov9 | 0.4524 | 0.4988 | 0.4139 | 0.5396 | 0.4477 |
| + Cosine Similarity | 0.4686 | 0.5063 | 0.4362 | 0.5432 | 0.4679 |
| + Temporal Attention | 0.485 | 0.5273 | 0.449 | 0.5556 | 0.4731 |
| + Spatial Constraint (CLM) | 0.5733 | 0.6248 | 0.5296 | 0.6512 | 0.552 |
| + Temporal Constraint (CLM) | 0.6107 | 0.6471 | 0.5782 | 0.6636 | 0.593 |

According to the ablation study, the result highlights the substantial impact of the proposed CLM, which includes both spatial and temporal constraints, on improving the tracking performance by 0.1257 IDF1 score. However, the limitation of the dataset size and some potential flaws on our algorithm prevent us from leveraging the entire potential of the spatial-temporal constraints compared with human-labelled constraints. A bigger dataset (longer video footage for each camera) might lead a better training on our CLM, which potentially reveal further benefits of our approach.

## 5. Conclusion

In this paper, we present a MCVT framework that incorporates improved CLM. Building on mature methodologies for object detection, feature extraction and SCT, this method introduces novel advancements in spatial-temporal constraints and multi-camera matching modules. The proposed CLM is capable of generating spatial-temporal constraints autonomously, mitigating the need for human intervention. Our ablation study validates the effectiveness of these spatial-temporal constraints within the multi-camera matching process. The innovative approach achieves the 0.6107 IDF1 score, surpassing all other camera link model-based methods. This indicates the potential of our framework to provide accurate and reliable spatial-temporal constraints, which essential for future large-scale MTMCT applications.
