Strong excitation of nuclear resonances, particularly of Mössbauer nuclei, has been a longstanding goal and the advance of novel x-ray sources is promising new options in this regard. Here we map out the necessary experimental conditions for the more general goal of realizing nonlinear optics with nuclei and compare with available technology. In particular, we present a comprehensive theory of nonlinear nuclear excitation in thin-film x-ray cavities by focused x-ray pulses. We thereby identify cavity geometries with broad resonances which allow one to boost the nuclear excitation even at moderately tight focusing.

In this paper, we revisit an old challenge: Is it possible to fully excite an ensemble of atomic nuclei using externally applied electromagnetic fields? This question relates to the goal of building a γ -ray laser (“graser”), with inverted nuclei as a gain medium, which was proposed long ago after the laser-maser principle [1]. The discovery of the Mössbauer effect, which allows for the recoil-less absorption and emission of γ -ray photons from certain nuclei [2, 3], further fueled this research. Despite interim hope to circumvent difficulties by utilizing lasing without inversion [4], most approaches to grasing were deemed unfeasible by the late 1990s [5]. Nevertheless, recent technological and conceptual developments prompt us to reconsider the challenge.

First, advances in x-ray source technology such as x-ray free-electron lasers (XFEL) [6, 7] have promoted the study of high-energy nonlinear effects in atoms, analogous to the revolutionary development at lower photon energies following the invention of conventional laser sources [8, 9]. Various nonlinear x-ray processes have already been observed involving electronic transitions [10–14]. Closely related to the original question, also lasing on an inner-shell electronic transition based on XFEL-generated inversion has been demonstrated [15]. This raises the question if the source advances provide new avenues for the excitation of nuclei.

Second, Mössbauer nuclei by now have evolved into a promising platform for quantum optics at energies of hard x-rays. In a series of experiments, key concepts of quantum optics [16–22] and coherent control [23–30] have been demonstrated with nuclei as the matter part. However, while these experiments exploit coherence and interference effects and demonstrate a surprising level of control, they still operate in the linear optics regime, such that they can be described by (semi-)classical optics calculations [31, 32].

These two developments also motivate a shift in focus away from the goal of reaching full inversion and towards more general nonlinear optics effects, further fueled by recent experiments from the optical domain [33–37] demon-

strating that effects such as photon correlations can already appear far below full excitation. First experiments with Mössbauer nuclei at XFELs [38, 39] explore this direction, e.g. by scattering multiple photons per shot [38]. Still these experiments do not reach beyond linear optics, which remains an open challenge.

On the theoretical side, a number of schemes have been proposed to achieve higher excitation or get close to the inversion threshold. For example, it has been suggested to overcome discouraging first estimates [40] using additional accelerations of the target nuclei [41], non-dipole transitions [42], or collective effects in the light-matter interaction [43, 44]. Furthermore, there are multiple approaches to boost the excitation of the nuclei by a suitable tailoring of their electromagnetic environment. As one option, front-coupling in one-dimensional x-ray waveguides is well-studied for imaging applications [45, 46], has recently been implemented with nuclei [47, 48], and tapered variants have been suggested as a candidate for nuclear inversion [49, 50]. Alternatively, x-ray thin-film planar cavities containing layers of Mössbauer nuclei are well established as a major platform for nuclear quantum optics in the linear regime [51, 52]. The field enhancement inside such structures has been considered [16, 31, 53–55] and optimized [46, 56]. However, the latter works consider the state-of-the-art probing using highly collimated x-rays, which is unfavorable for strong excitation. Focusing to enhance the nuclear excitation has been proposed [57], but so far, rigorous modelling of the excitation dynamics in planar waveguides driven by focused x-ray beams and a corresponding roadmap towards nonlinear excitation are missing.

In this Letter, we utilize a comprehensive theory developed in a companion paper [58] to study the excitation dynamics of Mössbauer nuclei in planar cavities driven by focused x-ray pulses (see Fig. 1). We find that the rigorous modeling of the focusing leads to optimum cavity structures which qualitatively differ from well-established design paradigms for collimated x-ray beams. The latter may even lead to an excitation performance worse

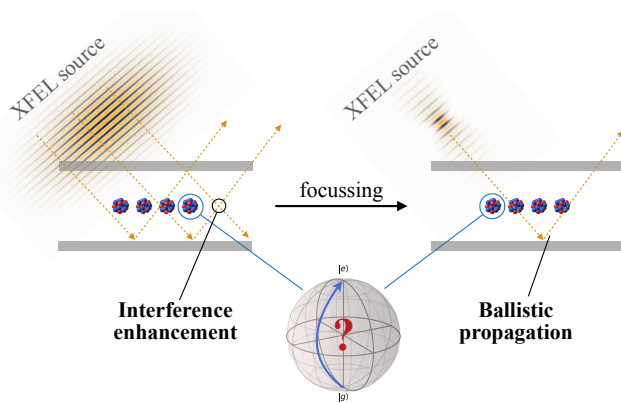

FIG. 1. Sketch of the setup, featuring a focused x-ray pulse (not to scale) incident on a thin-film cavity doped with narrow resonances, such as Mössbauer nuclei. By focusing the incident x-ray pulse, one can concentrate the radiation on fewer nuclei, potentially increasing their excitation towards inversion (illustrated by the Bloch sphere). However, this comes at the cost of reducing the cavity enhancement from interference. We show that using suitably designed cavities, this limitation can be overcome in intermediate focusing regimes and map out which configurations are most advantageous for upcoming experiments.

than without the cavity. With varying size of the x-ray focus, we identify a transition between standing-wave interference and ballistic reflections, with significant field enhancement down to moderately tight focusing. We calculate the necessary source parameters to enter the nonlinear regime of significantly excited nuclei and demonstrate its feasibility by comparing with currently available conditions and planned upgrades.

We start with the nuclear excitation dynamics. Unlike in the low-excitation regime [55, 59], the modeling of dissipative quantum dynamics of many interacting few-level systems at higher excitation remains a challenging problem of much current interest [60–62]. However, x-ray pulses delivered by accelerator-based sources are orders of magnitude shorter (typically ps to fs scale) than any other relevant time scale in the nuclear dynamics (e.g., ns for ^{57}Fe). This allows one to separate the excitation from the subsequent decay dynamics. The former then essentially reduces to a single-particle problem (see [58] for details), since dissipative and coupling processes are ineffective over the short excitation time scales.

The single-nucleus dynamics can straightforwardly be solved numerically for arbitrary input fields. However, to gain analytical insight, we further assume resonant and Fourier-limited x-ray pulses, an idealization of pulses generated via hard x-ray self-seeding [63–65]. Then, the pulse area theorem [66–68] relates the nuclear state after the x-ray pulse to the Fourier transform of the x-ray field at the nuclear resonance frequency $\mathbf{E}_{\text{drive}}(\mathbf{r}_{\text{nuc}}, \omega_{\text{nuc}})$

as [58, 69]

$$\Phi = \frac{4\pi}{\hbar} |\mathbf{d} \cdot \mathbf{E}_{\text{drive}}(\mathbf{r}_{\text{nuc}}, \omega_{\text{nuc}})|. \quad (1)$$

Here, Φ is the so-called pulse area, and \mathbf{d} , \mathbf{r}_{nuc} , and ω_{nuc} are the electric dipole moment (an effective quantity for magnetic transitions), the position and the transition frequency of the nuclei, respectively. The nuclear excitation — which is directly related to the magnitude of many nonlinear processes — is then obtained as $\sigma^z = -\cos(\Phi)$, where σ^z is the expectation value of the transition’s Pauli operator.

An intuitive interpretation is gained by rewriting [58] as

$$\Phi = \frac{\chi_\sigma}{w_0} \cdot \chi_{\text{source}} \cdot \xi_{\mathcal{E}}, \quad (2)$$

where χ_σ is a transition characteristic that solely depends on the nuclear properties such as the dipole moment. w_0 is the beam waist size in the focal plane, characterizing the strength of the focusing. The incident x-ray pulses are characterized by their pulse energy E_{pulse} and relative bandwidth b_r via $\chi_{\text{source}} := \sqrt{E_{\text{pulse}}/b_r}$. Finally, $\xi_{\mathcal{E}}$ is an enhancement factor due to the cavity. Without cavity — that is in free space — it is equal to unity. Therefore, the goal of the cavity environment is to increase $\xi_{\mathcal{E}}$. From the criterion $\Phi = \pi$ for reaching inversion, we define a *necessary* source characteristic for a given nucleus, cavity and focusing as

$$\chi_{\text{source}}^{\text{nec}} = \pi \frac{w_0}{\chi_\sigma \xi_{\mathcal{E}}}. \quad (3)$$

For a given χ_{source} , one can then express the achievable nuclear excitation as $\sigma^z = -\cos\left(\frac{\pi \chi_{\text{source}}}{\chi_{\text{source}}^{\text{nec}}}\right)$.

The crucial position-dependent enhancement factor $\xi_{\mathcal{E}}(\mathbf{r})$ is obtained by calculating the propagation of focused x-ray pulses in the cavity medium using Maxwell’s equations. In the companion paper [58], an efficient semi-analytical algorithm specialized for this purpose is developed, which forms the basis of the results below.

We start with the discussion of a standard cavity design [16, 70]. Results are shown in Fig. 2. Panel (a) depicts the electronic reflectance as a function of grazing incidence angle (rocking curve), featuring two cavity resonances. Following standard design criteria, the first resonance is relatively narrow and critically coupled [16, 46, 56]. The latter condition implies a vanishing of the resonant electronic reflectance, such that the isolated response of the nuclei inside the cavity can experimentally be accessed [71].

Panel (b) shows the spatially-resolved cavity enhancement factor inside and outside the cavity for three different x-ray input fields (top to bottom). Their incidence angles are all on resonance with the first cavity mode, but they feature different focusing strengths. The corresponding beam divergences $\theta_{\text{div}} = 0.3, 0.685$ and 2.0 mrad are

FIG. 2. Results for an example cavity following standard design criteria. (a) Electronic reflection as a function of incidence angle (rocking curve). The shaded areas indicate three different input beam divergence ranges considered in panel (b), see legend. (b) Spatially resolved cavity enhancement factor $\xi_{\mathcal{E}}$ in and around the example cavity (cladding boundary at $z = 0$) for the beam divergences $\theta_{\text{div}} = 0.3, 0.685$ and 2.0 mrad (top to bottom), where the middle value corresponds to 40 nm spot size. The incident beam propagates from the top left to the bottom right and encounters the cavity starting from $z = 0$. The colored areas and white horizontal lines indicate the location of the cavity layers (see legend). The red dot indicates the free-space beam focus, which is placed at the depth of the nuclear ensemble. Intensities are normalized to corresponding free-space intensity maxima.

indicated as shaded regions in (a). x is the projection of the pulse propagation direction onto the waveguide surface, and z the surface normal.

At low focusing (panel b, top), the field enhancement inside the cavity is clearly visible, arising from the constructive interference of multiple x-ray reflections. As desired, the intensity maximum is at the position of the nuclei. Above the cavity surface, a standing wave pattern appears from the interference of in- and outgoing x-ray fields.

Towards higher focusing [panel (b), top to bottom] the intensity enhancement reduces. On the one hand, with increasing beam divergence, a growing part of the incident wave vector components is off-resonant and cannot contribute to the standing wave enhancement. Also,

FIG. 3. Analogous to Fig. 2, but for a cavity optimized for a focal spot size of 40 nm. The resonance structure in this case is rather different from the standard cavity, with a broad resonance far from critical coupling. However, such a cavity allows to obtain field enhancement at the resonant ensemble location (magenta) even for tight focusing. Note that the free-space focus is located above the plot limits at 33.2 nm as a result of the optimization.

however, the focused wave packets become smaller such that the spatial overlap of the different reflections diminishes, again impeding the constructive interference leading to the intensity enhancement. The latter effect is visible in the highly focused case (b, bottom), and implies a practical lower spot-size limit for the focusing. In addition to the enhancement reduction, most of the wave packet is reflected already at the outer cladding, such that the maximum field intensity is shifted to the outside of the cavity structure. Thus, the intensity at the nuclei's positions is in fact lower than it would be in the absence of the cavity.

From these results, we conclude that standard cavity designs are unsuitable in combination with focusing. However, these limitations can be overcome using alternative cavity designs. To this end, we choose a moderately strong focusing spot size of 40 nm and optimized the cavity layer structure for maximum intensity enhancement at the position of the nuclei [70]. The results in this case are shown in Fig. 3. In comparison to the standard cavity in Fig. 2, we observe two qualitative differences.

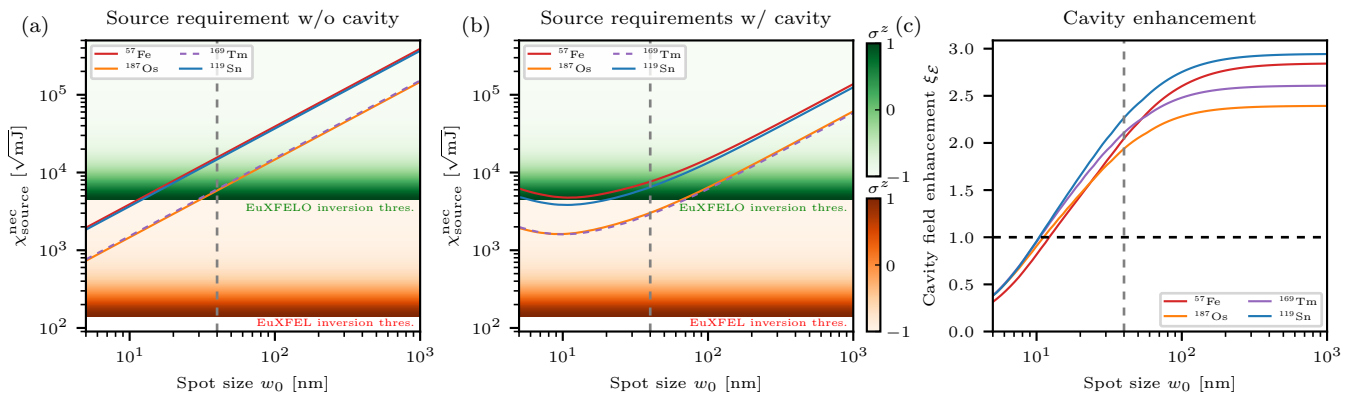

FIG. 4. Source requirements necessary for inversion as a function of the beam spot size, expressed as the necessary source characteristic $\chi_{\text{source}}^{\text{nec}} = \sqrt{E_{\text{pulse}}^{\text{nec}}/b_r^{\text{nec}}}$. Panel (a) shows results for nuclei in free space, panel (b) with a cavity environment optimized for enhancement at 40 nm focusing (vertical dashed line). Panel (c) shows the corresponding enhancement factor. In (a) and (b), currently available conditions at the European XFEL and projected conditions at the planned oscillator upgrade are encoded as the background color (red and green, respectively) up to their inversion threshold, corresponding to the achievable excitation $\sigma^z = -\cos\left(\frac{\pi\chi_{\text{source}}}{\chi_{\text{source}}^{\text{nec}}}\right)$ [colorbars in panel (b)] for their respective source parameters [70]. The shading at the point of the corresponding $\chi_{\text{source}}^{\text{nec}}$ -line then indicates the expected strength of nonlinear effects which are achievable with each Mössbauer isotopes (see legend) at this source.

First, the rocking curve in panel (a) features a relevant resonance which is rather weak and surprisingly broad. Second, the optimized cavity [structure see Fig. 3, panel (a)] enables a significant intensity enhancement even at higher focusing [panel (b), top to bottom], and the x-rays are mostly reflected from the substrate rather than from the surface, which boosts the excitation at the nuclear position. This improvement is due to the larger acceptance angle of broader cavity resonances.

After discussing the qualitative aspects of focusing on the nuclear excitation dynamics, we now turn to quantitative predictions for the Mössbauer isotopes ^{57}Fe , ^{187}Os , ^{169}Tm and ^{119}Sn . To this end, we determine the necessary source parameter $\chi_{\text{source}}^{\text{nec}}$ to reach nuclear inversion as a function of the free-space beam spot size w_0 for each of these isotopes. For comparison, we further indicate the source conditions available at the European XFEL [72–75] and the projected conditions at the planned oscillator upgrade [76] (detailed data tables are provided in [58]).

Results are shown in Fig. 4. As a reference, panel (a) illustrates the case without cavity environment, for which $\chi_{\text{source}}^{\text{nec}} \propto \omega_{\text{nuc}}$. In the relevant hard x-ray energy range, nano-focusing setups at EuXFEL beamlines currently offer spot sizes down to about 40 nm [77], which is indicated as a vertical dashed line. At this focusing strength, present-day beam conditions at EuXFEL are still far below the requirements for full inversion. However, XFELo conditions [76] already approach the required $\chi_{\text{source}}^{\text{nec}}$ values and significant σ^z can be reached, indicating the onset of the nonlinear regime.

Panel (b) shows corresponding results with waveguide

enhancements. To this end, we optimized the cavity structure for maximum excitation enhancement at 40 nm focusing using the algorithm developed in the companion paper [58]. We see that the cavity enhancement indeed allows one to reduce the source requirements, such that the projected XFELo parameters even exceed the requirements for inversion in ^{187}Os and ^{169}Tm . The relative improvement by the cavity is quantified in panel (c), which shows the ratios of the required source parameters with and without cavity as a function of focusing spot size, which is equal to the cavity field enhancement $\xi_{\mathcal{E}}$. We see that enhancements in the pulse area are possible even at substantial focusing. Note that away from full inversion, which presently is experimentally most relevant, the excitation scales quadratically with the pulse area, such that nonlinear effects are also enhanced quadratically.

In summary, we have shown that optimized thin-film cavities provide means to significantly boost Mössbauer nuclei towards the nonlinear optics regime, in particular for conditions much below inversion and even for tight focusing. The enhancement can be interpreted as a longitudinal compression of the pulse via the multi-path interference in the cavity. In this sense, cavities are complementary to focusing techniques, which provide a transversal compression of the light field. We find that by combining both effects, the optimum cavity designs qualitatively differ from state-of-the-art designs for collimated x-ray beams and optimized the cavity geometry to achieve significant enhancements down to 40 nm focusing. With planned upgrades to currently available sources, the resulting enhancement enables excitation of nuclei into the

nonlinear regime. In particular for the isotopes ^{187}Os and ^{169}Tm , inversion is predicted to be achievable and ^{57}Fe — the workhorse of Mössbauer science — is boosted to significantly nonlinear excitation fractions. Our results thereby outline a roadmap for further source developments and experimental efforts, balancing between advances in pulse energy and focusing capabilities. Progressing beyond the state-of-the-art linear regime would then allow to explore the linear quantum optical effects already observed with nuclei [16–22, 24, 28] in an as-yet unexplored parameter regime and potentially enable the creation of correlated x-ray photons [35–37].

The authors would like to thank K. P. Heeg, O. Diekmann, M. Gerharz, R. Röhlberger and L. Wolff for valuable discussions and L. M. Lohse for comments on an earlier version of the manuscript.
