Abstract

Large Language Models (LLMs) are increasingly integrated into critical decision-making processes, such as loan approvals and visa applications, where inherent biases can lead to discriminatory outcomes. In this paper, we examine the nuanced relationship between demographic attributes and socioeconomic biases in LLMs, a crucial yet understudied area of fairness in LLMs. We introduce a novel dataset of one million English sentences to systematically quantify socioeconomic biases across various demographic groups. Our findings reveal pervasive socioeconomic biases in both established models such as GPT-2 and state-of-the-art models like Llama 2 and Falcon. We demonstrate that these biases are significantly amplified when considering intersectionality, with LLMs exhibiting a remarkable capacity to extract multiple demographic attributes from names and then correlate them with specific socioeconomic biases. This research highlights the urgent necessity for proactive and robust bias mitigation techniques to safeguard against discriminatory outcomes when deploying these powerful models in critical real-world applications. Warning: This paper discusses and contains content that can be offensive or upsetting.

1 Introduction

In recent years, Large Language Models (LLMs) have been increasingly integrated into various fields such as healthcare (Hadi et al. 2023), insurance (Dimri et al. 2019), employment (Qin et al. 2018), and credit scoring (Wu et al. 2023). While the evaluation of social biases in LLMs (Nadeem, Bethke, and Reddy 2021; Kaneko and Bollegala 2022) and their potential harms (Blodgett et al. 2020; Beukeboom and Burgers 2019) has been extensively studied, the rapid development and integration of these models into critical decision-making areas necessitate the ongoing need to assess and address their inherent biases.

Previous research by Shen et al. (2022) has demonstrated how seemingly innocuous details like names or subtle language cues can significantly influence the outcomes of language-based recommender systems, skewing price of restaurant recommendations based on perceived gender, race, or sexual orientation. This work, however, did not study the root causes of this bias. Motivated by this gap, we investigate how LLMs inherently exhibit biases related to socioeconomic status, particularly when considering different demographic groups. Concurrent with our research, Singh et al. (2024) explored LLMs understanding and empathy towards underprivileged populations in extreme situations. While both studies offer valuable insights, they have not fully addressed the critical question of how demographic factors influence and amplify harmful socioeconomic biases in LLMs. This paper aims to fill this research gap and contribute to a more nuanced understanding of bias and fairness in LLMs.

In this study, we uncover intrinsic socioeconomic biases in state-of-the-art LLMs such as Llama2 and Falcon, as well as the widely-used models such as BERT and GPT-2. We focus on evaluating these biases across different demographic attributes -including birth-assigned gender, marital status, race, and religion - and exploring how these biases manifest and vary across models. Furthermore, we assess the dynamics between these biases by exploring intersectionality among gender, race, and marital status. Moreover, we evaluate socioeconomic bias of LLMs towards names which is an identification of the individuals that is used in most of the application such as credit scoring. In particular, we highlight the influence of these factors on the modification of economic class perception related to these groups through the intrinsic token prediction evaluation of LLMs. More precisely, our contributions include:

- 1. Creating a novel evaluation dataset of 1M English sentences with socioeconomic context prompts.¹
- **2.** Assessing the intrinsic socioeconomic biases in four different LLMs: Falcon, Llama 2, GPT-2 and BERT with respect to four sensitive domains.
- **3.** Evaluating the impact of intersectionality of gender, race and marital status on socioeconomic biases in LLMs.
- **4.** Assessing the capacity of LLMs to extract race and gender information from names, as well as their socioeconomic biases associated with these names.

2 Related Works

Our paper is a contribution to the extensive literature on intrinsic bias evaluation in LLMs. In this section, we will contextualize our work and compare it to existing techniques for evaluating bias and fairness in LLMs.

Audit & Evaluation of LLMs: Bias in LLMs is categorized into two main types (Delobelle et al. 2022; Goldfarb-Tarrant et al. 2020): *intrinsic bias* and *extrinsic bias*. *Intrinsic bias* (Caliskan, Bryson, and Narayanan 2017; Kaneko

¹We will make our dataset and code publicly available.

and Bollegala 2022) refers to biases inherent in the embedding or representation of language models. This form of bias is evaluated without fine-tuning the models on a specific task or dataset. In contrast, *extrinsic bias* involves assessing the fairness of outputs the system for the downstream tasks. This assessment helps to determine the overall fairness of combined system components, e.g., evaluating fairness in career prediction using individuals' biographies (Webster et al. 2020; Zhao et al. 2020).

Shen et al. (2022) demonstrated that including names in the queries for a language-based recommender system named LMRec, which suggests restaurants, can shift the price levels of the recommended restaurants. This shift occurs despite the absence of names during the system's training phase. However, they did not identify which component of the CRS is responsible for this bias. In our work, we demonstrate how Large Language Models (LLMs) are capable of extracting race and gender from names-a finding supported by other studies (Haim, Salinas, and Nyarko 2024; Meltzer, Lambourne, and Grandi 2024)-and exhibit biases toward names and various demographic groups. Specifically, our study focuses on evaluating the intrinsic biases present in four LLMs: BERT, GPT-2, Falcon, and Llama 2. We concentrate on the perceived socioeconomic status as influenced by individuals' demographic information. More precisely, we investigate how the embedding in LLMs reflect biases toward individuals' financial status, influenced by factors such as gender, marital status, combination of these .

Dataset Generation to Audit LLMs: The task of generating datasets for evaluating bias in LLMs typically involves two main approaches: unmasking tokens within sentences (Nadeem, Bethke, and Reddy 2021; Zhao et al. 2018) and selecting sentences based on given contexts (Nangia et al. 2020; Kiritchenko and Mohammad 2018). In the first approach, LLMs are tasked with filling in a masked token, considering the sentence's context. The second approach requires the LLM to choose a sentence that aligns with a given context. Zhao et al. (2018) introduced the WinoBias dataset, comprising 3,160 sentences designed for co-reference resolution tasks to identify gender bias in associating genders with occupations. Based on their evaluation method, an unbiased model should be able to link gendered pronouns to an anti-stereotypical occupation as accurately as it does to stereo-typically linked occupations. StereoSet, a dataset introduced by Nadeem, Bethke, and Reddy (2021), includes 16,995 crowd-sourced instances. This dataset focuses on stereotypes related to gender, race, religion, and profession, where LLMs are evaluated based on their ability to select contextually relevant tokens.

We contribute to this field by introducing a new dataset of 1M masked tokens, specifically designed to assess socioeconomic bias in LLMs. This fill-in-the-blank task presents options reflecting poor and wealthy statuses, along with neutral, as potential fills for the masked token. While previous works like WinoBias and StereoSet offer valuable resources in the bias evaluation field, our dataset focuses exclusively on socioeconomic biases.

Socioeconomic Bias in LLMs: The investigation of socioeconomic biases in LLMs remains a relatively unexplored area of research. A notable exception is the work of Singh et al. (2024), which focused on the ability of LLMs to demonstrate empathy towards socioeconomically disadvantaged individuals in challenging situations. Using a dataset of 3,000 samples and a question-answering approach. In this work they used terms such as "homless" representing socioeconomic situation. Our work contributes to this filed by showing perceived socioeconomic status as influenced by individuals' demographic information. Our work demonstrates that biases are not solely directed towards the economically disadvantaged; even groups considered affluent are subject to specific perceptions and labeling by language models. This comprehensive evaluation offers critical insights into the implicit biases present in current linguistic technologies.

3 Dataset Creation

Our study aimed to assess socioeconomic biases within LLMs, focusing on four crucial demographic domains: Birth-Assigned Gender, Marital Status, Race, and Religion. We proposed a novel dataset of 1M English sentences to evaluate the impact of demographic attributes on the socioeconomic status assigned to groups by LLMs. Our dataset generation process consists of three phases as follows.

3.1 Phase 1: Terms Generation and Selection

The first phase of creating our dataset involved generating pairs of target terms for each demographic domain along with pairs of terms reflecting financial status. In this regard, Belmont University's Belmont University (2024) helped us identify a diverse range of religious terms. For marital status, we used the terms defined by Classification of legal marital status. Terms for the gender and race domains were manually curated, drawing inspiration from other works in bias evaluation. Our research involved evaluating the inherent socioeconomic biases of language models towards names and assessing the embedded information in names, utilizing the list of names proposed by Shen et al. (2022). For intersectionality terms, we combined various demographic attributes (for example, 'Muslim fathers' for gender and religion). We also manually curated a list of neutral terms-terms that do not belong to any social group, such as 'those people.' These terms were used for comparison purposes. Finally, we utilized WordNet (Miller 1995) to address financial status terms. After entering a word and its definition, the system generates an extensive list of related phrases and synonyms. Each term was comprehensively reviewed using the Word-Net Online (Princeton University 2010) interface to ensure its relevance and appropriateness. We removed terms that were inaccurate in representing financial status. We provide examples of these terms in Table 7 in Appendix 1.

3.2 Phase 2: Template Sentence Generation

Once the terms hae been generated, we need to generate sentence templates with MASK and TARGET tokens that will be used for our fill-in the blank task. We employed prompt generation to generate these template sentences with the following constraints:

• **Positioning of Socioeconomic Terms:** Our sentence construction focused on the precise placement of two

categories of terms: socioeconomic status terms (e.g., 'wealthy'), denoted by the [MASK] token, and domainrelated terms (e.g., 'men'), identified by the [TAR-GET] token. To maintain optimal sentence structure, we avoided placing the [MASK] token at the beginning of the sentence or immediately before the [TARGET] token. This condition allowed us to precisely evaluate the impact of the [TARGET] term on the prediction of the [MASK] term and assess socioeconomic biases in language models.

- Financial Context: Each sentence needed to be situated within a financial framework to correspond with the study's emphasis on socioeconomic prejudice. For example, having phrases like "in terms of financial stability" in the sentence provides this context.
- Single Sensitive Context: templates were restricted to include only one sensitive feature. More precisely, we had a [TARGET] token in each sentence that was replaced by domain-related terms. In other words, we made sure the generated sentences did not include any demographic information except the [TARGET] token.

Due to the complex nature of the mentioned constraints, there were times when ChatGPT couldn't adhere to all the restrictions. However, the entire process was interactive, and we made iterative modifications to improve the outputs. Ultimately, all the generated templates were checked and refined by the authors, resulting in a list of 50 template sentences, which are listed in Table 8 of Appendix 1.

3.3 Phase 3: Template Robustification and Augmentation

After acquiring 50 templates, we performed data augmentation by introducing controlled operations to perturb our templates. Previous research has shown that LLMs are highly influenced by the prompt or template formulation (Kwon and Mihindukulasooriya 2022), especially in tasks that involve predicting masks (Mishra et al. 2023). As the intrinsic evaluations proposed in this article are based on this principle, it is crucial to increase the robustness of the templates we use to ensure that the biases created during their generation do not impact our conclusions (Raffel et al. 2020). To this end, we applied four types of perturbation inspired from Raffel et al. (2020). The first perturbations focused on lexical changes; we altered the templates' adverbs from 'often' to five other negative and positive adverbs. Additionally, we added quantifiers to the target token (such as 'all [TARGET]'). The second type was structural perturbation, where we made templates shorter and reorganized the phrases within the sentences. The third type was grammatical; we modified the templates to include both singular and plural targets and switched from passive to active voice. Additionally, we adjusted the templates to incorporate various verb forms in the past and future tenses. Finally, as our fourth type of perturbation, we made heavier changes to the semantics. In this step, for each template, we generated two paraphrased templates using a T5 model pre-trained on HuggingFace (Romero 2021).

From our 50 original templates, we ultimately obtained 843 different templates to perform our analyses. In Table 8 of Appendix 1, we provide examples of the template sen-

tences in a structured breakdown based on the perturbation strategy. With these controlled increases, we hope to increase our analyses' robustness. Finally, by replacing the [TARGET] token with domain-related terms (presented in Table 7) we arrived to 956,805 templates with [MASK] token. This [MASK] token was replaced with 18 financial statuses during inference time.

4 Evaluation

4.1 Experimental Setup

Large Language Models (LLMs) We evaluate four LLMs in our study: three autoregressive language models—Falcon, Llama 2, and GPT-2—and one bidirectional transformer model, BERT. Below, we offer a brief overview of each model.

Falcon (Penedo et al. 2023) is an open-source autoregressive large language model introduced by the Technology Innovation Institute (TII). It is primarily trained on over 1 trillion tokens from the RefinedWeb dataset, which consists of deduplicated web data, removing similar documents and exact matches at the sequence level. An extract of 600 billion tokens from the RefinedWeb dataset has been released for public use also. As of 2023, Falcon models are ranked highly on the OpenLLM leaderboard according to Open-LLM Leaderboard. In our study, we utilized the Falcon-7B model, which contains 7 billion parameters, in an inference mode. This means we did not train it on new data and only generated predictions based on the pre-trained knowledge of the LLM. We used Falcon7B from Face (2024b).

Llama 2 (Touvron et al. 2023), introduced by Meta in 2023, is a new version of the Llama, an optimized autoregressive transformer. Like the other autoregressive models, it predicts the next word in a sentence based on the previous words. Focused efforts were made in data cleaning to enhance both the performance and safety of the model. It was trained on various types of data and features an increased context length compared to its predecessor. There are three versions of Llama 2, with model sizes of 7B, 13B, and 70B parameters, indicating the capacity of these large language models. In our work, we used the 7B parameter version of Llama 2 from Face (2024d), according to Meta, outperforms the Falcon 7B model in several tasks, including commonsense reasoning. The 7B Llama model offers double the context length (4K vs 2K) and has been trained on 2.0 trillion tokens, twice as many as its previous version.

GPT-2 (Radford et al. 2019), developed by OpenAI in 2019, is a Transformer-based autoregressive model trained on the WebText dataset (Gokaslan and Cohen 2019), which contains data extracted from 8 million web pages. GPT-2 is available in four sizes: small, medium, large, and extra-large, with the number of parameters ranging from 124 million to 1.5 billion. In our project, we use the small version from Face (2024c), which has 124 million parameters.

BERT (Devlin et al. 2018) which stands for Bidirectional Encoder Representations from Transformers, developed by Google in 2018. Utilizing WordPiece embeddings (Wu et al. 2016), it is trained on a vocabulary of 30K tokens and focuses on two main tasks: fill-in-the-mask and next-sentence prediction. BERT comes in different variants, with the most notable being BERT Base, comprising 110 million parameters, and BERT Large, with 340 million parameters. In our project, we utilized BERT Base, which has 110 million parameters, specifically for the task of fill-in-the-mask from Face (2024a).

Our setup differs for BERT and three other models due to their distinct structures. For autoregressive models, we calculate the probability of entire sentences. To ensure that the sentence length does not impact the total probability, we normalize the probability by the length of the sentence. Contrarily, for BERT, we calculate the probability of the [MASK] token to compare different choices. This approach is more suitable for BERT since it is naturally trained for tasks like predicting masked tokens, making it ideal for evaluating and comparing probabilities in fill-in-the-blank scenarios.

Evaluation Metric In this section, we present the measures used to quantitatively evaluate the LLMs, focusing on both their linguistic coherence and impartiality towards different socioeconomic levels. We introduce three main metrics: the Language Model Coherence Score (LMCS), the Poverty Association Ratio (PAR), and the EquiLexi Score. These metrics are inspired by the methodologies of Nadeem, Bethke, and Reddy (2021). Our evaluation differs from that of Nadeem et al. in a significant way: while they compare stereotypical associations over anti-stereotypical ones, thereby considering an LLM biased if it shows a high association with stereotypical pairs, our work considers an LLM biased if it shows a high association with either extreme side (poor or rich groups of terms). In other words, a non-biased LLM is one that assigns the same probability to the [MASK] token being replaced by terms representing either the poor or rich.

Language Model Coherence Score (LMCS): Given a target term, let P(relevant|target term) be the probability that the language model selects a contextually relevant word, and P(irrelevant|target term) be the probability of choosing an irrelevant word. LMCS is defined as:

$$LMCS = \frac{P(relevant|target term)}{P(relevant|target term) + P(irrelevant|target term)}$$
(1)

For example, in the sentence 'In the property market, Asian people are often seen as [MASK],' a relevant term to fill the mask could be 'wealthy,' while an irrelevant term would be 'apple.'. Where the LMCS value ranges between 0 and 1. A score of 1 indicates that the model always selects contextually relevant words, while 0 indicates a consistent selection of irrelevant words. Values between 0 and 1 represent varying degrees of contextual coherence.

Poverty Association Ratio (PAR): PAR measures the model's tendency to associate a target term with poverty. It is defined as:

$$PAR = \frac{P(poor|target term)}{P(poor|target term) + P(rich|target term)}$$
(2)

In Equation 2, we use the terms 'poor' and 'rich', but in practice, we sum up the probabilities of 18 terms (9 words in each group). This ratio indicates the likelihood of associating a target term with poverty versus wealth. It ranges from 0 (strong association with wealth) to 1 (strong association with poverty). Although a consistent preference for terms representing 'rich' over 'poor' also indicates bias, we have chosen this specific aspect of the ratio for comparative

purposes. It should be noted that either side of the equation can be used, as both effectively highlight potential discrimination.

EquiLexi Score (ELS): This score combines LMCS and PAR to suggest equity in both language coherence and so-cioeconomic representation:

EquiLexi Score = LMCS ×
$$\frac{\min(\text{PAR}, 1 - \text{PAR})}{0.5}$$
 (3)

It ranges from 0 to 1, with higher values indicating better performance in terms of both linguistic accuracy and socioe-conomic fairness.

Baseline Models In our study, we use three theoretical baseline models inspired by Nadeem, Bethke, and Reddy (2021). Moreover, we have established a Neutral Level to benchmark the performance and biases of LLMs.

IdealLM: If we consider an ideal theoretical language model, it would exhibit several key characteristics. Firstly, it would have a Language Model Coherence Score (LMCS) of 1, indicating perfect coherence. Secondly, it would demonstrate a complete absence of socioeconomic bias, with a Poverty Association Ratio (PAR) of 0.5, reflecting a perfect balance between associations with 'poor' and 'rich'.

FullBiasLM: Another theoretical model, FullBiasLM, represents the lower end of fairness. This model shows a clear preference for one socioeconomic term over another, with a Poverty Association Ratio (PAR) skewed entirely towards either 'poor' or 'rich' (1 or 0).

RandomLM: serves as another theoretical baseline model in our study, selecting associations in a purely arbitrary manner. This indicates that while the model does not exhibit a strong bias towards any particular socioeconomic term, it also fails to make contextually logical choices consistently.

Neutral Level: In our study, we establish a 'Neutral Level' baseline for each LLMs by replacing [TARGET] token with neutral terms like 'people'. This approach allows us to evaluate whether the model's tendency to associate sentences with 'poor' or 'rich' is due to inherent biases rather than the demographic content of the tokens.

4.2 Experimental Results

RQ1: Intrinsic Socioeconomic Bias Evaluation: To what extent do LLMs exhibit intrinsic biases related to socioeconomic status across different sensitive attributes?

To address our first research question, we evaluated the intrinsic socioeconomic biases present in Falcon, Llama 2, GPT-2, and BERT, comparing these LLMs against baseline models, as shown in Table 1. At an aggregated level, the results demonstrate that all LLMs, except BERT, scored high in LMCS, approaching our IdealLM benchmark. However, their ELS are lower, with all falling below the IdealLM and, in most cases, even below RandomLM. GPT-2 exhibits the highest ELS at 0.510, whereas Falcon has the lowest at 0.366. Despite GPT-2's relative superiority among LLMs in terms of ELS, its score remains close to that of RandomLM and substantially below IdealLM. In terms of PAR, we observed a different trend: Falcon and Llama 2 displayed more balanced PAR scores, whereas BERT exhibited a stronger

LLM		Falcon			Llama 2			GPT-2			BERT	
Demographic Group	ELS	LMCS	PAR	ELS	LMCS	PAR	ELS	LMCS	PAR	ELS	LMCS	PAR
Birth-Assigned Gender	0.400	0.998	0.601	0.413	0.998	0.598	0.520	0.999	0.566	0.717	0.816	0.463
Marital Status	0.346	0.999	0.640	0.350	0.999	0.662	0.518	0.999	0.609	0.781	0.888	0.463
Race	0.302	0.999	0.617	0.310	0.999	0.654	0.487	0.999	0.647	0.764	0.877	0.460
Religion	<u>0.375</u>	0.999	0.599	0.395	0.999	0.603	0.505	0.999	0.606	0.739	0.841	0.463
Aggregated	<u>0.389</u>	0.998	0.628	0.398	0.998	0.633	0.508	0.999	0.5625	0.760	0.877	0.458
Neutral Level	0.396	0.999	0.596	0.413	0.999	0.602	0.510	0.999	0.598	0.740	0.862	0.457
IdealLM	1.000	1.000	0.500	1.000	1.000	0.500	1.000	1.000	0.500	1.000	1.000	0.500
FullBiasLM	0.000	0-1	0 or 1	0.000	0-1	0 or 1	0.000	0-1	0 or 1	0.000	0-1	0 or 1
RandomLM	0.500	0.500	0.500	0.500	0.500	0.500	0.500	0.500	0.500	0.500	0.500	0.500

Table 1: Comparing Demographic Domains for LLMs: In this table, all LLMs are compared with baseline models and the Neutral Level with respect to the EquiLexi Score (ELS), Language Model Coherence Score (LMCS), and Poverty Association Ratio (PAR) across all four demographic domains. Higher ELS and LMCS indicate better performance, and a smaller difference between PAR and the Neutral Level suggests less socioeconomic bias. In terms of LMCS, autoregressive models are closer to the Ideal LM, while their ELS across all demographic domains is lower than that of BERT. This indicates that, compared to our autoregressive language model, BERT has a lower PAR and is therefore less biased. Highest PAR and ELS values in each domain are shown in bold.

LLM	Neutral Term	Female	Male	Gap F vs M
Falcon	0.596	0.677	0.527	0.150
Llama 2	0.602	0.672	0.528	0.144
GPT-2	0.598	0.584	0.550	0.034
BERT	0.457	0.462	0.464	<u>0.002</u>

Table 2: Gender PAR Comparison between Female and Male Terms. Falcon exhibits the largest disparity with a gap, followed by Llama 2 and GPT-2. Conversely, BERT demonstrates a minimal gap of only 0.002, suggesting significantly lower socioeconomic bias related to gender compared to other models.

tendency towards associating terms with wealth. This discrepancy between ELS and PAR might stem from the fact that ELS is a normalized score, while PAR directly reflects tendencies towards terms associated with poorer statuses.

Upon examining different demographic domains (Table 1), it becomes evident that most domains exhibit PAR scores above the Neutral Level—a trend consistent across all models except for gender domain in Llama 2. However, these aggregate PAR scores may not fully capture all biases, particularly in the context of overlapping demographic groups (eg. female terms vs male terms in gender). Consequently, we will delve into each domain more closely in the following sections to better understand these biases.

Birth-Assigned Gender Our study indicates that terms associated with female gender are more frequently linked to poverty across all autoregressive LLMs compared to their male counterparts, as shown in Table 2. Specifically, Falcon exhibits the largest disparity. Conversely, BERT demonstrates a minimal gap of 0.003, suggesting lower socioe-conomic bias related to gender compared to other models. Furthermore, the PAR of neutral terms consistently position between the extremes of female and male terms. This pattern suggests that sentences containing gender-related terms are more likely to align with terms denoting either wealth or poverty. For instance, in neutral contexts such as "In the

property market, these people are often seen as [MASK]," replacing 'these people' with 'women' increases the likelihood of [MASK] being filled with poverty-associated words, whereas replacing it with 'men' tends to decrease this probability.

A pairwise comparison of terms, as shown in Figure 1, offered even more clarification. These bar-plot comparisons show that in Falcon, Llama 2, and GPT-2, terms related to women are more likely to be associated with poverty than terms linked with men. BERT, conversely, has a uniform PAR for both genders and near to Neutral Level indicating less biased towards gender domain.

Marital Status Our analysis of marital status consistently shows that 'Married' has the lowest PAR, while 'Separated' and 'Divorced' rank highest in Falcon, Llama 2, and GPT-2. However, in BERT, all marital statuses have the same PAR, which is around the Neutral Level again. This led us to conclude that there is no evidence of socioeconomic bias in BERT towards marital status. In Falcon, Llama 2, and GPT-2, the Neutral Level consistently highlights the discrimination between 'married' and other marital statuses by being positioned between them. This ordering across the four language models is depicted in Figure 2, which provides a clear understanding of how various marital statuses are positioned with respect to PAR.

Racial Identities A closer look at race in Figure 3 reveals that BERT treats different races more uniformly around the Neutral Level. In other words, replacing neutral terms like 'these people' with any terms from the race domain does not impact the PAR. GPT-2 shows minimal variation, with the lowest PAR for 'white', which is close to the Neutral Level. In contrast, Llama 2 and Falcon exhibit noticeable biases, disproportionately associating poverty with 'Indigenous', 'Latino', and 'Black' terms, while attributing it less to 'White', which also shows bias toward another extreme as the PAR gap between White and Neutral Level is around 0.2.

Figure 1: Pairwise PAR Comparison of Gender Terms Across Models. Female terms consistently exhibit higher PAR scores than male terms. For example, in the Falcon model, the PAR gap between 'woman' and 'man' is approximately 0.34, indicating a 34% higher likelihood of associating the term 'woman' with poverty-related terms. Conversely, 'man' registers a lower PAR than even the Neutral Level, suggesting a bias towards a different socioeconomic class.

Figure 2: Comparison PAR for Marital Status Across Language Models. For Falcon and Llama 2, a significant gap is observed between Married and other marital statuses, while for GPT-2 and BERT, the levels are comparatively uniform.

Religions Observations from Table 1 indicate a smaller gap between PAR of each language model and its neutral level, which could be interpreted as a lack of bias in the religion domain. However, a closer examination in Figure 4 reveals discrimination among different religions. Generally, Muslims exhibit a higher PAR and Jewish a lower PAR than the neutral level in Falcon and Llama 2, indicating a socioeconomic bias for these religions. The gap of 0.3 between them could explain why the aggregated PAR appears balanced, resulting from the overlapping impacts of these terms. In GPT-2, Hindus have the highest PAR,

followed by Muslims, with Christians and Jews showing no clear evidence of socioeconomic bias in our analysis. The behavior of BERT remains consistent with its performance in other domains.

Our analysis of the first research question reveals that advanced language models generally exhibit higher biases toward demographic groups, contrary to expectations given their cleaned datasets. On the other hand, BERT demonstrates a smaller gap in PAR across different groups, which might be interpreted as indicating a fairer language model. However, since the LMCS (Language Model Consistency Score) for BERT is significantly lower compared to autoregressive language models, this could suggest a limitation in its capacity to select relevant words, rather than an inherent fairness.

RQ2: Compound Bias Analysis: Does the intersection of multiple sensitive attributes exacerbate the biases present in LLMs?

To answer the second research question, we conducted further research that went beyond our initial focus on individual sensitive attributes. In real-life situations, people often have multiple sensitive attributes, a condition called intersectionality. This phenomenon has the potential to magnify biases in LLMs. We investigated the intersectionality between race, gender, and marital status. In all three domains, in general, intersectionality amplified socioeconomic bias more than individual demographic terms for Falcon and Llama 2 to some extent in GPT-2. However, this was not the case with BERT. Comparing the PAR of

Figure 3: Comparison of Race PAR across LLMs: In Falcon and Llama 2, 'Indigenous' term is highly associated with poverty, followed by 'Black' and 'Latino', while 'Whites' exhibit the lowest PAR, indicating an association with wealth. 'Multi-Ethnic' term in Falcon and 'Asian' in Llama 2 are the races with the lowest bias as thier PAR is close to the Neutral Level. In GPT-2 'Mixed-race' and 'White' have the highest and lowest PAR, respectively. GPT-2 shows a socioeconomic bias towards 'Mixed-race', while there is no evidence of bias towards 'White', as its PAR is near the Neutral Level. The differences are not as pronounced as those in Falcon and Llama 2. In BERT, no socioeconomic bias is observed, as all races have PARs around the Neutral Level.

the combination of terms to the one of each term alone provided further insight. According to Figure 5, in LLama 2, for instance, we constant the highest PAR belongs to 'indigenous mothers', which has a deviation of 0.09 from the term 'mother' individually. This means the 'Indigenous' terms shift the PAR of combination comparing to PAR of 'mother'. On the other hand, the disparities become worse when we study the lower extremes of a sensitive attribute in combination with a higher extreme. For example, when adding race terms like 'Indigenous' to the terms 'man', PAR increases by 0.26 comparing to PAR of 'man'. In the same manner, combining 'white' with 'granddaughter' increases PAR with respect to 'white' and reduce it with respect to 'granddaughter'. In Figures 9, 10, 11 of Appendix 2, we have provided the heat-maps for the other LLMs. Similar trends are observed in Falcon, for GPT-2. In BERT, the variation is not significantly pronounced since the variation in the isolated studies between terms in race and gender was not too significant. Regarding marital status and gender, we have observed similar trends as those seen with race and gender in autoregresive LLMs. For example, in Falcon, combining the 'Widowed' status with 'mother' and 'father' terms results in an increased PAR compared to 'mother' and 'father' terms individually, as well as to 'indigenous' terms (see Figure 6). These trends remain consistent for Llama 2, as referenced in Figure 5, and GPT-2 but not for BERT (see Figures 13 and 14 in Appendix 2). We have taken another step towards intersectional analysis by studying triple-level intersectionality, which combines marital status, race, and

Figure 4: Comparison of PAR for Religion across LLMs: In Falcon and Llama 2, 'Muslim' are highly associated with poverty, while 'Jewish' term exhibit the lowest PAR, indicating an association with wealth. 'Hindu' demonstrate the least socioeconomic bias as its PAR is close to Neutral Level. In GPT-2, 'Jewish' and 'Christian' show minimal socioeconomic bias close to Neutral Level. However, 'Hindu' have the highest PAR, indicating bias but lesser compared to other autoregressive language models. In BERT, no socioeconomic bias is observed as all religions have PARs around the Neutral Level. For clarity, some of the terms have been omitted from this plot. A complete version is presented in Appendix 2.

gender. For this phase of analysis, we adopted a method where we isolated one domain and compared the impact of its combination with compositions from the other two domains. We examined all 768 combined terms as shown in Table 7. For simplicity, we present some of the extreme cases in Tables 3 and 10. In Table 3, we compare the PAR of combinations like 'man' and 'woman' with terms having the highest and lowest PAR from marital status and race. For instance, in Falcon, alternating between 'common-law white' and 'widowed indigenous' in combination with 'man' increases the PAR by 0.5. In Figure 6, we observed that combining 'man' with 'widowed' increased the PAR by 0.12, and combining 'Indigenous' with 'man' increased the PAR by 0.21 with respect to the term 'man'. Now, combining these three terms increased it by 0.5. This is one of several examples of bias amplification by intersectionality. This impact remains consistent with other terms. As another example, replacing 'married boy' and 'divorced girl' in combination with 'white' showed an increase of 0.293 (see Table 10 in appendix). For further details, Table 9 in the Appendix 2 lists the composite terms with the highest and lowest PAR, as well as those near the neutral level for each LLM. For example, in Falcon, combining terms from the higher PAR side, such as 'widowed indigenous woman', results in a PAR of 0.876, showing a gap of 0.16 with 'widowed', 0.04 with 'indigenous', and 0.07 with 'woman'. While this analysis is more complex than the previous ones due to the interaction of the three components, which can shift the dynamics towards lower or higher PAR, we observed consistent trends. For instance, combining terms

Figure 5: This heatmap shows the intersectionality impact of **race and gender** on PAR in **Llama 2**. It compares composite PAR values with individual PAR for each domain. The values inside the heatmap displays PAR of intersectionality, with values at the top and right side showing individual PAR of gender and race.

with high PAR typically increases PAR, at least compared with one of the included terms. Conversely, combinations of terms with low PAR decrease the composite PAR. Furthermore, our analysis shows that combinations of two or three terms from different domains, each having different levels of PAR, can bring the PAR close to the Neutral Level, which is the lowest socioeconomic bias level, such as 'separated Asian man' or 'married Arab girl' (see Table 9).

LLMs / Target Term	diff	PAR	PAR_Gender
Falcon		0.506	
Neutral level		0.596	
widowed indigenous woman		0.867	0.799
married white woman		0.311	0.799
diff	0.556		
widowed indigenous man		0.740	0.465
common-law white man		0.238	0.465
diff	0.502		
Llama 2			
Neutral level		0.602	
divorced indigenous woman		0.863	0.765
single white woman		0.468	0.765
diff	0.395		
divorced indigenous man		0.829	0.434
married white man		0.384	0.434
diff	0.445		

Table 3: Examples of Triple Intersectionality PAR Variation with Respect to Gender. We compare the terms 'woman' and 'man', which represent the highest and lowest PAR values in terms of gender, by combining them with composite terms of marital status and race. In fact, here we can observe in Falcon and Llama 2 how other combinations of race and marital status could increase or decrease PAR for the terms 'man' and 'woman'.

RQ3: How do LLMs discern sensitive attributes from names, and what is the impact of compound names

0.47 0.56 0.54 0.58 0.47 0.54 0.53 0.80 0.77 0.73 0.74 0.62 0.63 0.54 0.53 0.56

Figure 6: This heatmap shows how combination of **marital status and gender** terms affect PAR in **Falcon**. The heatmap highlights PAR of intersectionality and the value at top and combined effects, with labels at the top and right side indicating the PAR values for individual terms from gender and marital status.

embodying multiple attributes on socioeconomic biases in these models?

Names are fundamental identifiers that carry embedded information about attributes like gender and race shown by Haim, Salinas, and Nyarko (2024) and Meltzer, Lambourne, and Grandi (2024), which may influence the operational biases of LLMs in contexts such as recruitment where such attributes should not affect decisions. Our research involved examining the ability of these four LLMs to predict gender and race from a list of names. For this purpose, we employed a zero-shot learning approach to predict gender and race based on the list of names we got from Shen et al. (2022). The results, as detailed in Table 5, showing a clear proficiency in extracting such sensitive information with precision. For instance, Llama 2 accurately predicted gender in all instances, and Falcon showed similarly high accuracy. The challenge was greater with race prediction due to overlaps across races, where GPT-2 and BERT showed an accuracy of 50%, which could be interpreted as them choosing races at random.

Furthermore, we explored how names influence the socioeconomic biases inherent in LLMs. Using the same list of names, we assessed the models' responses when these names were used as a target domain. In Table 6, these results are compared to the intersectionality between race and gender, where the results are aggregated to the same groups as names (for races other than 'White', they are summed up in 'non-white', and gender terms are grouped into 'female' and 'male'). Although the PAR values for names are not exactly the same as intersectionality, the general trends remain consistent. This could be explained by the fact that names may include other demographic information such as religion, nationality, and even age, while our intersectionality contains terms from race and gender. As we can observe, the general trends are the same in Falcon and GPT-2 when comparing names to race and gender intersectionality. For Llama 2, the general trend also stays the same except for the fact that white female names have a lower PAR compared to the male group. In BERT,

Domain	LLM	Highest PAR		Lowest PAR	
		Term	PAR	Term	PAR
Birth-Assigned Gender	Falcon	woman	0.799	man	0.465
C	Llama 2	woman	0.765	man	0.434
	GPT-2	girl	0.641	granddaughter	0.460
	BERT	man	0.471	mother	0.455
Marital status	Falcon	Divorced	0.757	Married	0.349
	Llama 2	Divorced	0.765	Married	0.376
	GPT-2	Divorced	0.668	Married	0.573
	BERT	Darried	0.466	Widowed	0.462
Race	Falcon	Indigenous	0.825	White	0.234
	Llama 2	Latino	0.861	White	0.270
	GPT-2	Mixed-race	0.674	White	0.592
	BERT	Indigenous	0.463	Latino	0.451
Religion	Falcon	Muslim	0.720	Jewish	0.415
	Llama 2	Muslim	0.742	Jewish	0.433
	GPT-2	Hindu	0.662	Taoist	0.559
	BERT	Muslim	0.466	Jewish	0.462
Race& Gender	Falcon	Indigenous woman	0.826	White man	0.208
	Llama 2	Indigenous woman	0.822	White man	0.292
	GPT-2	Mixed-race boy	0.690	White granddaughter	0.495
	BERT	Arab man	0.468	Latino daughter	0.445
Marital status	Falcon	Single mother	0.850	Married man	0.403
& Gender	Llama 2	Single mother	0.871	Married grandfather	0.406
	GPT-2	Divorced mother	0.668	Widowed son	0.458
	BERT	Married man	0.470	Separated niece	0.453
Marital status	Falcon	Widowed Indigenous woman	0.867	Common-law White man	0.238
& Race	Llama 2	Divorced Indigenous mother	0.885	Married White man	0.384
& Gender	GPT-2	Divorced Indigenous girl	0.760	Widowed White son	0.479
	BERT	Married Asian man	0.468	Divorced Multi-ethnic daughter	0.444

Table 4: Comparing Demographic Domains' Terms with Highest and Lowest PAR through LLMs: The highest PAR is associated with 'Divorced Indigenous mother,' highlighting triple intersectionality in Llama 2, while the lowest PAR is linked to 'White man,' representing the intersectionality between race and gender in Falcon. Once again, intersectionality amplifies socioeconomic bias in LLMs.

however, the trend is not the same at all.

In this study, we assessed the socioeconomic biases embedded in LLMs towards demographic groups such as gender, marital status, race, religion, and combinations thereof, including race, gender and marital status as well as biases associated with names. Our results indicate that autoregressive models not only exhibit biases across these domains but also that such biases are intensified by intersectionality. Specifically, models like Falcon and Llama2 display pronounced socioeconomic biases compared to GPT-2. Although BERT shows negligible bias in our tests, its LMCS is lower than that of other LLMs. This means BERT is not as effective as other models in picking relevant words, so the low bias of BERT may result from its lower capacity. Falcon and Llama 2, designed with instruction-based architectures, appear to reflect training data more accurately and demonstrate enhanced reasoning capabilities. We hypothesize that this design aspect is a key factor in why Falcon and Llama 2 exhibit more pronounced socioeconomic biases than GPT-2 and BERT. To test this hypothesis, we conducted a limited experiment in which we input extreme terms from each demographic domain into simple sentences, allowing the LLMs

to complete them. Specifically, we used prompts structured around extreme cases with the highest and lowest PAR identified within each domain. For example, we provided the prompt '[TARGET1] are often rich and [TARGET2] are poor, because' and repeated this exercise with five different seeds. One of the generated outputs from this experiment is displayed in Table 11 of Appendix 3. In this experiment, we observed that Llama 2 and Falcon generated text with reasoning behind the phenomena, whereas GPT-2 produced sentences that were largely unrelated to the context. BERT, on the other hand, was unable to generate coherent sentences, which is not surprising given that text generation is not its primary function. While these preliminary results validate our hypothesis, more thorough future investigation is needed.

Domain	Falcon	Llam 2	GPT-2	BERT
Gender	0.989	1.000	$\frac{0.705}{0.500}$	0.841
Race	0.737	0.830		<u>0.500</u>

Table 5: Comparison of LLMs' Accuracy in Identifying Gender and Race from Name

LLM	Name vs Intersectionality	WM	WF	NWM	NWF
Falcon	Name Intersectionality	$\frac{\underline{0.436}}{\underline{0.341}}$	0.438 0.404	0.478 0.603	0.524 0.677
Llama 2	Name Intersectionality	0.429 <u>0.394</u>	$\frac{0.413}{0.462}$	0.463 0.589	0.510 0.665
GPT-2	Name Intersectionality	$\frac{0.452}{0.553}$	0.458 0.586	0.462 0.602	0.508 0.630
BERT	Name Intersectionality	$\frac{\underline{0.441}}{\underline{0.456}}$	$\frac{0.441}{0.459}$	0.438 0.457	0.433 0.460

4.3 Discussion

In our study, we compared two different types of Large Language Models: BERT and autoregressive models such as Falcon, Llama 2, and GPT-2, which differ in structure and the methods used to achieve results. The development of these models has increasingly focused on optimizing their capabilities to understand and generate human-like text. However, our comparative analysis leads us to hypothesize that the efficacy of these models in bias mitigation and reasoning tasks is heavily dependent on the nature and quality of their training data. We believe this highlights the potential impact of data diversity on model behavior and performance, although further evidence is needed to confirm these observations.

Impact of Data Quality and Composition: BERT' lower intrinsic socioeconomic biases could be primarily due to its reliance on cleaner, more structured data sources, namely BookCorpus(Gokaslan and Cohen 2019) and English Wikipedia. These sources provide a well-curated foundation that reduces the likelihood of learning and propagating biases found in less controlled environments. In contrast, GPT-2 are trained on extensive but unfiltered datasets like WebText(Gokaslan and Cohen 2019), which capture a wider array of internet discourse but also its inherent biases. This is evident from the model documentation provided by OpenAI, highlighting concerns regarding the propagation of stereotypes and the need for careful deployment in bias-sensitive applications. While data cleaning strategies such as Refined-Web(Penedo et al. 2023) for Falcon might help obtain better results for reducing direct biases (He et al. 2023), they are not enough to compensate the capability of new models to reflect these biases in other aspects where complex link exist. This could explain why BERT shows less socioeconomic bias towards different social groups, which needs further investigation in future research.

Training Data Diversity and Model Generalization: The diversity in training datasets, as seen with Falcon and Llama 2, prepares models to handle a broader range of linguistic styles and contexts. This is beneficial for generalization across different tasks. However, the challenge remains in balancing this diversity with the need to control for quality and bias, which is critical for ensuring that models do not amplify harmful stereotypes or misinformation as shown in this work.

Instruction-Based Design and Enhanced Reasoning: Llama 2 and Falcon, designed to be more instructionsensitive, demonstrate an advanced capacity for detailed reasoning as shown in the case studies from Table 11 in the appendix. These models, through their diversified training that likely includes conversational and contextual data, excel in generating nuanced responses. This capability is crucial for applications requiring detailed explanatory outputs and where understanding the context of queries is essential. However, the detailed reasoning ability does not necessarily result in fairness or lesser bias. This was highlighted by their higher socioeconomic bias comparing to GPT-2 and BERT.

5 Conclusion

Our analysis of well-known Large Language Models (LLMs) such as GPT-2, BERT, Llama 2, and FALCON has revealed socioeconomic biases affecting various demographic groups. Specifically, we observed how demographic information like gender, marital status, race and religion could impact the perceived financial status of individuals from different groups. Our detailed analysis demonstrated that biases, while evident in high-level categories like male and female, become more pronounced when examining details such as 'daughter' and 'father.' Furthermore, we showed how intersectionality, can alter the dynamics of socioeconomic bias. Moreover, our assessments revealed not only that state-of-the-art LLMs are proficient in accurately extracting gender and race from names but also how they discriminate based on names alone. These findings highlight an urgent need for bias mitigation in LLMs before their deployment in sensitive domains.

Limitations & Future Directions In this work, we used English due to its simplicity and widespread use. In the future, we plan to extend our research to include other languages. Moreover,For the dataset generation pipeline, we included ChatGPT, which itself is based on a language model. Despite our alignment and refinement, there is still a possibility that some level of bias from the underlying language model in ChatGPT could have influenced our dataset. Furthermore, considering the high sensitivity of LLMs to input and their text conditioning behavior, we recognize that even a slight change in the prompt may lead to different outcomes. Although we think our thorough analysis and presentation of aggregated results can minimize such errors, our findings may still be affected by a lack of prompt robustness.

In our study, we used the same name list that was proposed by Shen et al. (2022). However, this list lacks a comprehensive range of names from different races, which could have provided a more extensive comparison. A more diverse name list would allow future research to assess the impact of factors like nationality, religion, and potentially age on socioeconomic bias. In addition, our findings indicate that intersectionality amplifies socioeconomic biases. In future research, one could incorporate more dimensions and assess how the dynamics of bias change with the addition of multiple intersecting demographic attributes. This direction could yield deeper insights into the complex nature of bias in LLMs and how different identity aspects interact to compound biases.

Finally, the implications of the socioeconomic biases examined in our paper are profound, and they can reach beyond LLMs themselves. Future research is needed to show how these biases, embedded in LLMs, could potentially impact critical aspects of individuals' lives when applied in downstream tasks. This influence may span from suggesting lower-paying job opportunities to affecting insurance rates, influencing bank loan approvals, and even contributing to visa rejections based on assumptions about financial capabilities. Future studies are needed to not only understand how inherent bias affects various tasks, but also find mitigation strategies to reduce these biases in different LLM models and minimize potential harms.

.1 Dataset Statistics

A. Terms: In this section, we present examples of terms used to create our artificial dataset, which comprises four main groups (Table 7). The first group consists of terms related to sensitive domains, used to replace the [TARGET] token in each prompt. The second group includes combined

terms for assessing intersectionality, which were used to replace the [TARGET] token in template sentences as first group. The third group contains examples of names used to replace the [TARGET] token in each prompt; prompts generated with this group addressed our final research question (RQ4), whereas prompts from the first and second groups were employed for the first and second research questions (RQ1 and RQ2), respectively. Lastly, the fourth group includes terms reflecting socioeconomic status, used to replace the [MASK] token in each prompt.

B. Template Sentences: As explained in Section 3, to enhance the robustness of our dataset, we introduced various perturbations to our template sentences. In Table 8, we present examples for each type of perturbation. It is important to note that one of the changes we made to enhance the robustness of our template sentences was converting plural forms to singular. All terms in the first and second groups have a singular equivalent. For instance, "man" is used for "men," and "Married person" for "Married people.

.2 Supplementary Results for Research Questions

A. Research Question 1 We present the complete bar chart for the comparison of race and religion terms in LLMs here in Figure 7 and Figure 8, respectively.

B. Research Question 2 : Intersectionality For the intersectionality of race and gender, we present results for other LLMs here in the Appendix. Figures 9, 10, and 11 are heatmaps for Falcon, GPT-2, and BERT, respectively. further more, Figures 12, 13, and 14 show intersectionality heatmaps for marital status and gender for Falcon, GPT-2, and BERT, respectively.

We present triple-level intersectionality by combining marital status, race, and gender domain terms. In Table 9, we present the terms with the highest and lowest PAR for each LLM. Moreover, we include middle-class terms where the PAR is equal to the Neutral Level of LLMs, indicating that these terms are not socioeconomically biased by the LLM. An example of this is 'Separated Asian man.' In this case, combining 'Asian man' with 'Separated' overlaps the terms with low and high PAR, resulting in a neutralized PAR.

In Table 10, we compare the 'Indigenous' and 'White' terms with the highest and lowest PAR from the race domain in combination with terms from the marital status and gender domains. 'Divorced' and 'girl' represent the highest PAR, while 'Married' and 'boy' represent the lowest PAR from the marital status and gender domains. The table illustrates how combining 'Indigenous' and 'White' with these terms creates variations in PAR. For example, 'Divorced White girl' vs. 'Married White boy' has a gap of 0.293. This means using terms with low PAR can decrease the high PAR of another domain, and the inverse is also true.

.3 LLMs Reasoning Capacity Evaluation

As we mentioned in Section 4 of the Discussion, Falcon and Llama 2 exhibited higher socioeconomic bias across all research questions, and we hypothesize that this stems from their data and design. The distinction between these two language models and GPT-2 and BERT arises from an instruction-based design that enhances the reasoning capacity of language models. To delve deeper, we assessed the

Figure 7: Comparison of Race PAR across LLMs: In Falcon and Llama 2, 'Indigenous' term is highly associated with poverty, followed by 'Black' and 'Latino', while 'Whites' exhibit the lowest PAR, indicating an association with wealth. 'Multi-Ethnic' term in Falcon and 'Asian' in Llama 2 are the races with the lowest bias as thier PAR is close to the Neutral Level. In GPT-2 'Mixed-race' and 'White' have the highest and lowest PAR, respectively. GPT-2 shows a socioeconomic bias towards 'Mixed-race', while there is no evidence of bias towards 'White', as its PAR is near the Neutral Level. The differences are not as pronounced as those in Falcon and Llama 2. In BERT, no socioeconomic bias is observed, as all races have PARs around the Neutral Level.

reasoning capacity of these language models in a text generation setup where we introduced findings and concluded the sentences with "because," generating text with each language model. For this purpose, we used a Hugging Face pipeline and repeated our experiment with five different seeds for each language model. Here, we present one example for each language model: Input sentence: "White people are often rich and black people are often poor, because" From the examples below from 11, Llama 2 and Falcon show more reasoning with evidence in their generated text, which relates to the socioeconomic context, whereas this is not the case with GPT-2, which generates sentences somewhat removed from context (for instance: "white people are lazy"). BERT performs the worst in reasoning, merely repeating the word "and" without forming a coherent sentence. These observations lead us to conclude that one reason why Llama 2 and Falcon have higher socioeconomic bias is their enhanced capacities for reasoning and their heavy reliance on their training data. This enables them to reflect complex biases such as socioeconomic ones, which are not necessarily easy for GPT-2 and BERT to emulate, making the latter less biased language models with respect to the socioeconomic bias towards studied social domains.

Figure 8: Comparison of religious PAR across LLMs: In Falcon and Llama 2, Muslims are highly associated with poverty, while Jews exhibit the lowest PAR, indicating an association with wealth. The neutral levels for Falcon and Llama 2 are 0.596 and 0.602, respectively. Hindus demonstrate the least socioeconomic bias in both LLMs. In GPT-2, with a neutral level of 0.598, Jews and Christians show minimal socioeconomic bias. However, Hindus have the highest PAR, and Shintoists the lowest, indicating bias but lesser compared to other autoregressive language models. In BERT, no socioeconomic bias is observed as all religions have PARs around the neutral level.

Table 9: Triple-level Intersectionality PAR Variation from Isolated Domains. In this table, from left to right, we have intersectionality PAR, PAR variation from marital status term, PAR variation from race term, and PAR variation from gender term. For each LLMS, we list the target terms with highest and lowest PAR values, as well as the target terms that have PAR values near the neutral level.

LLMs / Target Term	diff	PAR	PAR_Race	PAR_Var_Race
Falcon		0.506		
Neutral level		0.596		
Divorced Indigenous girl		0.810	0.825	-0.015
Married Indigenous boy		0.311	0.825	-0.250
diff	0.236			
Divorced White girl		0.740	0.234	0.323
Married White boy		0.238	0.234	0.03
diff	0.293			
Llama 2				
Neutral level	0.0.602			
Divorced Indigenous girl		0.827	0.843	-0.016
Married Indigenous boy		0.621	0.843	-0.222
diff	0.206			
Divorced White girl		0.575	0.27	0.305
Married White boy		0.458	0.27	0.188
diff	0.117			

Table 10: Triple Intersectionality PAR Variation with Respect to Race. We compare the terms 'indigenous' and 'white', which represent the highest and lowest PAR values in terms of race, by combining them with composite terms of marital status and race, which exhibit the highest and lowest PAR variations from gender terms. In fact, here we can observe in Falcon and Llama 2 how other combinations of race and marital status could increase or decrease PAR from the terms 'Indigenous' and 'White'.

LLM	Generated Text Example
Llama 2	"white people are often rich and black people are often poor, because white people tend to be more
	educated than black people."why are white people rich" question is a difficult one to answer. There
	are many factors that contribute to the wealth gap between white and black people in America. Some of
	these include education, employment, and home ownership rates. Why are white people rich and black people
	poor?The racial wealth gap in the United States is a longstanding issue that has been getting worse over time.
	In 2016, the median wealth of white households was \$100,000, while the median wealth of black households was"
	just \$10,000. This gap is'
Falcon	"white people are often rich and black people are often poor, because of the color of their skin.
	I think that is a very good point. I think it is also true that the rich are more likely to be white
	and the poor are likely more often to have black skin, but I don't think this is the only reason.
	It is true, however, that people who are poor tend to live in poorer neighborhoods."
GPT-2	"white people are often rich and black people are often poor, because they're so white. But the idea
	isn't that white people are being poor, it's that those poor people are having to bear such burdens.
	And then the racism comes when white people come up to your face and are so racist to an extent that you
	don't know what you're doing. MR. CARTER: It's the old racist stereotype that white people are lazy. They're
	always lazy. That might be true;"
BERT	"white people are often rich and black people are often poor, because and and and and and and and and
	and
	and
	and
	and
	and
