Abstract

Machine learning, deep learning, and NLP methods on knowledge graphs are present in different fields and have important roles in various domains from selfdriving cars to friend recommendations on social media platforms. However, to apply these methods to knowledge graphs, the data usually needs to be in an acceptable size and format. In fact, knowledge graphs normally have high dimensions and therefore we need to transform them to a low-dimensional vector space. An embedding is a low-dimensional space into which you can translate high dimensional vectors in a way that intrinsic features of the input data are preserved. In this review, we first explain knowledge graphs and their embedding and then review some of the random walk-based embedding methods that have been developed recently.

 ${\bf Keywords:}$ graphs, embedding, random walk, machine learning, representation learning, deep learning

1 Introduction

A knowledge graph represents a graph of real-world entities and demonstrates the relationships between them. Knowledge graphs store large amounts of data by connecting large datasets in a structured and meaningful way which leads to data integration and semantic understanding. For instance, *Google Knowledge Graph* uses semantic search information from various sources to enhance its search engine

results and display them in a structured manner [1]. In addition, knowledge graphs support knowledge discovery and data exploration by enabling users to discover new relationships and insights from the stored data. For example, in the healthcare field, healthcare professionals can discover correlations between patient demographics and medical conditions and therefore identify best practices and treatments. Another example is in the E-commerce field, where knowledge graphs are used to maintain information about users' purchase histories and different products and therefore offer personalized recommendations [2]. Furthermore, knowledge graphs serve as a foundation for AI and machine learning applications by providing structured data for different purposes such as training models and improving the interpretability of the AI systems. As an example, in the finance area, knowledge graphs are used by integrating different data sources and capturing relationships between entities, and using machine learning and AI techniques to discover patterns and anomalies indicative of fraud [3]. In another case, knowledge graphs play a crucial role in drug discovery. For example, they integrate large amounts of biomedical data and capture complex relationships between biological entities, facilitate data-driven decision-making, and ultimately accelerate the drug development process [4]. There are many other areas knowledge graphs are used in, such as networking and telecommunications [5], manufacturing [6], smart cities [7] and urban planning [8], etc.

To take advantage of knowledge graphs in various fields, we would normally use machine learning, deep learning, and AI models on the graph datasets. However, large knowledge graphs have a high dimension, which makes it hard for many machine learning models to work with them. To overcome this problem, we use embedding. Embedding is a representation learning method to map out data to a lower-dimensional vector space, while preserving the main features of the input data [9]. Embedding techniques offer a powerful way to efficiently represent data, leading to semantic understanding, improved model performance, feature extraction, and transfer learning capabilities in machine learning and AI.

Based on [10], there are five major categories for embedding knowledge graphs. These include matrix factorization, generative models, deep learning, graph kernels, and edge reconstruction-based optimization models. Each category includes different techniques for embedding knowledge graphs and several recent ones are summarized in Table 2 for each category. For example, the deep learning category includes famous methods among which are random walk-based ones. Random walks have been used in many models for embedding, due to their important features like exploring graph structures such as local and global context, finding semantically similar nodes, feature extractions, etc. In this work, we focus on several important and well-known random walk-based embedding techniques from the deep learning category that have been developed during the recent years.

2 Preliminaries

In this section, we explain some preliminary concepts used in this review.

Fig. 1 Skip-gram architecture.

Knowledge graph [11]: A knowledge graph is a directed graph whose nodes are entities and edges are relations between entities. It is denoted as G = (V, E) in which $v_i \in V$ are nodes or entities and $e_i \in E$ are edges or relations. Nodes have a type mapping function of $\phi : V \to T$ where T is the node type, and edges have a type mapping function of $\phi : E \to R$ where R denotes the edge type.

Random walk [12]: A random walk describes a path consisting of random steps on a mathematical space. It can be denoted as $\xi_t, t = 0, 1, 2, ...$ where ξ_t describes the position of a random walk after t steps. Since we are using this construct on graphs, here is a brief definition of random walks on graphs in simple words: a random walk on a graph is a process that begins at a random vertex, and at each step the walk randomly moves to another vertex [13].

Skip-gram [14]: Skip-gram is an unsupervised algorithm used to find the most related word for a given word. It is a simple neural network with one hidden layer and no activation function. The hidden layer does the dot product between the input vector and the weight matrix. The result of this product is passed to the output vector. Next, a softmax function is applied to the output vector showing the probability of the words appearing in the context. Figure 1 [15] describes its architecture.

Homogeneous Network [10]: Homogeneous Network is a graph denoted as G = (V, E) where $|T^v| = |T^e| = 1$; meaning that all the nodes in G belong to a single type and all the edges in G has a single type, as well.

Heterogeneous Network [16]: is a graph denoted as G = (V, E, T), where each $v \in V$ and $e \in E$ has a mapping function $\phi(V) = V \to T_v$ and $\phi(E) = E \to T_e$ and T_v and T_e denote sets of node and relation types respectively where $|T_v| + |T_e| > 2$.

3 Methods

In this section, we summarize some of the recent algorithms for embedding knowledge graphs which were developed recently. Most of these methods are based on deep learning. Table 1 summarizes these algorithms.

Algorithm	Year	Network Type	Random Walk Method
DeepWalk	2014		truncated random walks
LINE	2015	homogeneous	heterogeneous edges
Node2vec	2016		BFS + DFS based random walks
PTE	2017		heterogeneous edges
Metapath2vec	2017		meta-path based random walks
Metapath2vec++	2019	heterogeneous	meta-path based random walks
Regpattern2vec	2021		regular expression-based random walks
Subgraph2vec	2024		truncated random walks

Table 1 Deep learning algorithms for embedding graphs based on their network type and used method [17].

3.1 Deepwalk [18]

DeepWalk is a method for embedding nodes in a network, such as social or biological networks. Prior embedding methods often suffer from scalability issues and fail to capture the structural properties of large-scale networks effectively [19, 20]. Deepwalk overcomes these issues in an unsupervised manner.

It is inspired by techniques used in natural language processing, particularly the skip-gram model from the word2vec model [21]. The main idea behind DeepWalk is to treat random walks in a network as "sentences" and learn node embeddings by predicting the context nodes given a target node in these walks.

The algorithm generates random walks of fixed length in a network, treating each node as a "word" in a "sentence". It then uses the skip-gram model to learn node embedding by predicting the context nodes for each target node in these random walks. The learned embeddings capture the structural properties of the network, which can be used for various downstream tasks such as node classification, link prediction, and community detection.

	embedding	

Method: The algorithm consists of two major parts: 1) random walk generator and 2) update procedure.

Random walk generator: The algorithm has two nested loops, the outer loop which represents the number of times (γ) the walk should start from each vertex v_i of the graph. DeepWalk starts by generating a random walk W_{vi} in the network from a random node called root (v_i) . We set the parameter t to control the walk length to have walks of fixed length; however, the walks can be of any length as long as the length is smaller than t. The walks are performed starting from each node γ times and are entirely random which means they can revisit their root.

Update procedure: The inner loop iterates through the nodes of the graph and starts the walk from each of the vertices. Each random walk captures the local neighborhood information around each node. The skip-gram model - commonly used in word embedding techniques like word2vec - is employed to learn embeddings for the nodes. The actual input for the original skip-gram model are sentences of the words; therefore, we consider the walks as sentences in which the nodes represent the words. Given a sequence of the nodes by random walk, the skip-gram model aims to predict the context nodes for each target node in the sequence. The objective is to maximize the likelihood of the observing context nodes given the target node. We use skip-gram to update the representations of the nodes according to the following objective function:

$$minimize - logP_r(v_{i-w}..v_i + w \ v_i | \Phi(v_i))$$

The objective function uses the skip-gram model for learning node embedding and is defined as the log-likelihood of observing the context nodes for each target node across all the random walks. This objective function is optimized using stochastic gradient descent to learn the parameters of the model and is as follows:

$$Pr(\{v_{i-w}...v_{i+w}\} \setminus v_i | \Phi(v_i)) = \prod_{\substack{j=i-w\\j\neq i}}^{i+w} Pr(v_j | \Phi(v_i))$$

where $\phi(v_j)$ represents the embedding of vertex v_j .

The embeddings are learned iteratively by maximizing the log-likelihood of observing context nodes for each target node in the random walks. This involves updating the embeddings for each node using gradient descent based on the prediction error between the observed and predicted context nodes.

3.2 LINE [14]

In this section, we review LINE, a method for embedding large networks. LINE is a suitable method for preserving the local pairwise proximity (local structure) between

the vertices and dealing with very large networks (millions of vertices and billions of edges) with arbitrary types of edges (directed, undirected, weighted).

The pairwise proximity between vertices includes first-order proximity and secondorder proximity. The first-order proximity between two vertices (u, v) is the weight on the edge connecting these vertices (w_{uv}) . It illustrates the direct similarity between two vertices. For example, people who are friends on social media probably share similar friends. However, the first-order proximity on its own does not preserve the structure of the network. For example, consider a link is missing between two vertices sharing common neighbors. Although these two vertices are very similar, the firstorder proximity in this case is 0. Therefore, another parameter that retains the network structure is needed and that is second-order proximity. The second-order proximity between a pair of vertices (u, v) implies the similarity between their neighbors. This helps to identify objects that might not be directly connected but are related through shared neighbors.

Combining both of the above proximities, we form LINE; a method for embedding very large networks with arbitrary (directed, undirected, or weighted) edges.

Method: First, we combine LINE with each of the mentioned proximities individually and then we combine them. Here is a brief description of the model:

1. LINE with first-order proximity:

Since joint probability also implies dependencies and relationships between vertices in a graph, we model the first-order proximity for the undirected edge (v_i, v_j) between vertices v_i and v_j which is as follows:

$$p_1(v_i, v_j) = \frac{1}{1 + exp(-\overrightarrow{u_i^{T}} \cdot \overrightarrow{u_j})} \tag{1}$$

where u_i and u_j represent the vector representation of vertices v_i and v_j in a low dimensional space respectively. In particular, the joint probability of an edge represents the probability that the two specific nodes are connected by an edge simultaneously. It quantifies the likelihood of a specific edge existing in the graph. On the other hand, there is another parameter to calculate the likelihood of edges called *empirical probability*. The empirical probability of an edge in a graph is based on the observed data and represents the relative frequency with which a specific edge occurs in the observed graph and is calculated as $\hat{p}_1(i,j) = \frac{w_{ij}}{W}$ where $W = \sum_{(i,j) \in E} w_{ij}$. To preserve the network's first-order proximity, we try to minimize the distance between these two functions:

$$O_1 = d(\hat{p}_1(\cdot, \cdot), p_1(\cdot, \cdot)) \tag{2}$$

where $d(\cdot, \cdot)$ is the distance between two vertices. We choose to minimize the KLdivergence of the two probability distributions which we replace with $d(\cdot, \cdot)$ in the above equation and remove some constants:

$$O_1 = -\sum_{(i,j)\in E} w_{ij} log p_1(v_i, v_j)$$
(3)

We can represent every node in the d-dimensional space by finding the $\{\vec{u}_i\}_{i=1,..,|V|}$ in any undirected graph.

2. Line with 2^{nd} order proximity:

The second-order proximity is applicable on both directed and undirected graphs. This proximity assumes that vertices sharing many other connections are similar to each other. In this proximity, each vertex has two roles: 1. "Vertex" itself and 2. "Context" of other vertices. In the second case, each vertex is considered as a specific context in which the vertices sharing similar distribution over the contexts are considered similar. Therefore, we will have two different representations for vertex v_i : u_i and u'_i representing the embeddings of the vertex and context of v_i , respectively.

$$p_2(v_j|v_i) = \frac{1 + exp(-\overrightarrow{u_i'}^T \cdot \overrightarrow{u_j})}{\sum_{k=1}^{|V| exp(\overrightarrow{u_k'}^T \cdot \overrightarrow{u_i})}}$$
(4)

where $p(\cdot, v_i)$ is the conditional distribution over the contexts and |V| is the number of the vertices or contexts. In addition, this equation defines a conditional distribution $p_2(\cdot|v_i)$ over the entire set of vertices. To preserve the second-order proximity, we should minimize the distance between $p_2(\cdot|v_i)$ and the empirical distribution $\hat{p}_2(\cdot|v_i)$. Therefore:

$$O_2 = \sum_{i \in V} \lambda_i d(\hat{p}_2(\cdot | v_i), p_2(\cdot | v_i))$$
(5)

where $d(\cdot, \cdot)$ is the distance between two distributions and λ_i denotes the importance of vertex *i*, which can be measured by the degree or estimated through algorithms such as PageRank[76]. The empirical distribution is defined as $\hat{p}_2(\cdot, v_i) = w_{ij}/d_i$, where w_{ij} is the weight of the edge and d_i is the out-degree of vertex $i: d_i = \sum_{k \in N_i} w_{ik}$, where N_i is the set of out-neighbors of v_i . In this method, for simplicity, $\lambda = d_i$. We replace $d(\cdot, \cdot)$ with KL-divergence and omit some constants, therefore:

$$O_1 = -\sum_{(i,j)\in E} w_{ij} log p_2(v_i, v_j)$$
(6)

We can embed node v_i in the d-dimensional space by finding the $\{\vec{u}_i\}_{i=1,..|V|}$ and $\{\vec{u}'_i\}_{i=1,..|V|}$ in any directed/undirected graph.

Fig. 2 BFS and DFS algorithms for a neighborhood where node u is the source node [32].

In the LINE method, we embed the network with first-order and second-order proximity separately and then concatenate the embeddings by each of them for each vertex and get the desired embedding.

3.3 Node2vec [32]

Node2vec is an embedding algorithm that maps the nodes of a knowledge graph to a low-dimensional space while preserving the network's structural properties. It starts by generating random walks on the input graph. The random walks are biased to explore both local (Breadth-First Search or BFS) and global (Depth-First Search or DFS) neighborhoods of the nodes. These walks can be considered as sentences where nodes of the graph are similar to words of a sentence. The obtained walks are fed into a skip-gram model for embedding. The actual reason that the developers use BFS and DFS is that they help us find similar nodes. We measure the similarities between the embedded nodes by homophily [77, 78] and structural equivalence [79] hypotheses. BFS emphasizes the nodes that are in the same community and follow the homophily hypothesis and DFS is used for sampling the nodes that share the same structural role and follow the structural equivalence law. Figure 2 illustrates BFS and DFS algorithms in a neighborhood.

Method: The algorithm is based on the random walk technique which walks the graph in both the DFS and BFS fashion. Let's consider u as the source node, and c_i as the i^{th} node in the walk (therefore $c_0 = u$). The nodes in the walk are generated by this distribution:

$$P(c_i = x \mid c_{i-1} = v) = \begin{cases} \frac{\pi_{vx}}{Z} & (r \in E) \\ 0 & others \end{cases}$$

Here, π is the unnormalized transition probability between nodes v and x. Z is the normalizing constant which is summing up all the possible values of the random

variable i.

The easiest way to bias our random walk is to sample the nodes based on the static edge weight $w_v x$ i.e. $\pi_{vx} = w_v x$. In this case, if our graph is unweighted, we consider $w_v x = 1$. While this is the simplest way, it might not be a good choice since we cannot consider network structure and explore different types of network neighborhoods. Therefore, we design our algorithm which is a 2nd order random walk (in a first-order random walk, the walker traverses the graph from one node to a randomly chosen neighbor node at each step. In the second-order random walk, the walker considers the relationships between nodes based on their neighbors before moving to the next node). Our walk depends on two parameters return parameter or p and *in-out parameter* or q which control how fast the walk explores and leaves the neighborhood of the starting node u. Let's assume the walker just traversed edge (t, v) and now is at node v. The algorithm decides the next node based on this probability $\pi_{vx} = \alpha_{pg}.w_v x$, where:

$$\alpha_{pq}.w_v x = \begin{cases} \frac{1}{p} & (r \in E) \\ 1 & others \\ \frac{1}{q} & (r \in E) \end{cases}$$

In this equation, d_{tx} is the shortest distance between the nodes x and t and can be one of 0, 1, 2 values. Based on this formula, if we set p to a high value, *i.e.* (> max(q, 1)), it is less likely to revisit a node that was just visited (unless the next node in the walk has no other neighbor). This strategy leads to moderate exploration and avoids 2-hop redundancy in sampling. On the other hand, if we set p to a low value, *i.e.* (< min(q, 1)), it is more likely that the walk is close to the source node since it leads the walk one step backward.

In addition, if we set q > 1, the random walk is biased toward nodes close to t; which leads our walk to sample nodes within a small locality. On the other hand, if we set q < 1, the walk is more likely to explore further nodes from node t which encourages outward exploration.

3.4 Predictive Text Embedding (PTE) [33]

Predictive Text Embedding (PTE) is an extension of the LINE method to embedd heterogeneous networks. It is a semi-supervised method used for embedding text data, which means it uses both labeled and unlabeled data to train the model. The labeled and unlabeled data are represented in a large heterogeneous network and then this heterogeneous network is embedded in a low dimensional space and can be used for text embedding. Not only does this method preserve the semantic closeness of the words and documents but also it has good predictive power.

Compared to the unsupervised text embedding methods such as Skip-gram or Paragraph Vectors (aka Doc2vec) [80], which learn semantic representations of texts, the goal of this method is to learn a representation of the text that is optimized for a

given text classification task. In other words, the authors anticipate the text embedding to have a strong predictive power of the performance of the given task. Since this method is applicable to different networks, we review some network definitions:

Word-Word Network: The word-word network captures the word co-occurrences in local contexts of unlabeled data. This data is the essential information used by some word embedding techniques such as skip-gram. Let $G_{ww} = (V, E_{ww})$ be a graph in which V is a vocabulary of words and E_{ww} is the set of edges between the words. Also, the weight w_{ij} is the number of times words v_i and v_j appear in the context window.

Word-Document Network: Word-document network, denoted as $G_{wd} = (V \cup D, E_{wd})$, is a bipartite network where V is a set of words and D denotes a set of documents. E_{wd} is the set of edges between the words and the documents. The weight w_{ij} between word v_i and document d_j is simply defined as the number of times v_i appears in document d_j .

The mentioned networks are used for encoding unlabeled data. There is a network for encoding labeled information called the Word-Label network.

Word-Label Network: Let's take $G_{wd} = (V \cup L, E_{wd})$ as a bipartite network in which V is the set of words, L is the set of labels, and E_{wd} is the set of edges connecting words and labels. The weight w_{ij} of the edge between word v_i and class c_j is defined as $w_{ij} = \sum (d : ld = j)n_{di}$, where n_{di} is the term showing frequency of word v_i in document d, and ld is the class label of document d.

The model embeds a network that is an integration of the above networks. This type of network is called a heterogeneous text network.

Heterogeneous Text Network: is the combination of word-word, word-document, and word-label networks constructed from both unlabeled and labeled text data.

Method: Given a large collection of text data with unlabeled and labeled information, the PTE algorithm tries to learn the embedding of the text by embedding the heterogeneous text network (in other words, by embedding the nodes of the heterogeneous graph) built from the collection.

The heterogeneous graph is made up of three different bipartite networks, and therefore we have to embed each of these graphs individually (so far there is no technique to be able to embed these graphs all together at the same time). To embed each of these bipartite graphs individually, we will use the LINE model.

As mentioned earlier, PTE is an extension of the LINE method but LINE cannot be used to embed heterogeneous networks. Therefore, to start the embedding, we use the LINE method to embed a bipartite network. To use LINE, it is essential to make use of the second-order proximity between vertices, which means that every two nodes that have similar neighbors, can be considered similar to each other which leads to closer vectors in the embedding space.

Fig. 3 Converting partially labeled text corpora to a heterogeneous text network. The word-word co-occurrence and word-document networks encode the unsupervised information, capturing the local context-level and document-level word co-occurrences respectively. The word-label network encodes the supervised information, capturing the class-level word co-occurrences [33].

Given a bipartite graph, $G = (V_A \cup V_B, E)$, V_a , and V_b are two different types of nodes and E is the set of edges between them. For every v_i in V_a , generated by v_j in V_b , the authors define the below formula to use the second-order proximity:

$$P(v_i, v_j) = \frac{\exp(u_i^T \cdot u_j)}{\sum_{i' \in A} \exp(u_{i'}^T \cdot u_j)}$$
(7)

where u_i is the embedding vector of vertex $v_i \in V_A$, and u_j is the embedding vector of vertex $v_j \in V_B$. For each vertex $v_j \in V_B$, Equation (1) defines a conditional distribution $p(\cdot|v_j)$ over all the vertices in the set V_A and for each pair of vertices $v_j, v_{j'}$, the second-order proximity is determined by their conditional distributions $p(\cdot|v_j), p(\cdot|v_{j'})$ respectively. To preserve the 2_{nd} -order proximity, we should try to make the conditional distribution $p(\cdot|v_j)$ close to its empirical distribution $p(\cdot|v_j)$. The below equation illustrates this:

$$O = \sum_{j \in B} \lambda_d(p(\cdot|v_j), p(\cdot|v_j)) \tag{8}$$

where $d(\cdot, \cdot)$ is the KL-divergence between two distributions, λ_j is the importance of vertex v_j in the network, which can be set as the degree $deg_j = \sum w_{ij}$, and the empirical distribution can be defined as $p(v_j|v_i) = w_{ij}/deg_j$. Omitting some constants, here is the simpler version of Equation (2):

$$O = -\sum_{(i,j)\in E} w_{ij} \cdot \log p(v_j|v_i)$$
(9)

We can optimize the above equation using gradient descent which uses edge sampling and negative sampling.

We can embed our 3 bipartite networks using the above model. Next, we want to embed the heterogeneous text network which consists of three bipartite networks: word-word, word-document, and word-label networks. To learn the embeddings of the heterogeneous network, our approach is to collectively embed the three bipartite networks by the following equation:

$$O_{pte} = O_{ww} + O_{wd} + O_{wl} \tag{10}$$

where O_{ww} , O_{wd} and O_{wl} are calculated individually by Equation (3).

Once the word vectors are learned, the representation learning of any piece of text can be obtained by averaging the vectors of the words in that piece of text.

$$d = \frac{1}{n} \sum u_i \tag{11}$$

3.5 Metapath2vec and Metapath2vec++ [34]

In this section, we review a neural network-based representation learning algorithm. There are recent different types of neural network-based algorithms for embedding nodes of the graphs; such as Node2vec, LINE, and DeepWalk which we discussed earlier.

Although these methods have their privileges such as the automatic discovery of latent features from the raw network, they can be applied to homogeneous networks (networks with singular types of nodes and edges). However, a large number of social and information graphs are heterogeneous, which means they have multiple types of nodes and edges. Therefore, we need new algorithms to be able to embed them.

Here, we review metapath2vec and metapath2vec++; which are representation learning methods for embedding heterogeneous networks.

Metapath2vec: is a representation learning method applicable to heterogeneous networks.

The metapath2vec method develops metapath-based random walks to construct the neighborhood of a node and then feeds the achieved random walks to a skip-gram model to obtain node embeddings.

Method: As mentioned earlier, metapath2vec generates meta path-based random walks from the nodes of the graph. The most straightforward method is to start the meta path-based walk at a random node and then move to the next random node. In this context, the probability of moving to the next node is $P(v_i+1|v_i)$ regardless of the node types. However, the walks are biased toward a highly visible type of nodes[81]. To overcome this issue, given a graph G = (V, E, T) the authors design a meta path scheme to guide the walks in this form:

$$\rho = V_1 \xrightarrow{R_1} V_2 \xrightarrow{R_2} V_3 \xrightarrow{R_3} \dots V_t \xrightarrow{R_t} V_t + 1 \xrightarrow{R_{l-1}} V_l \tag{12}$$

Hence, the transition probability for moving to the next node is:

$$P(v^{i+1}|v_t^i, \rho) = \begin{cases} \frac{1}{|N_{t+1}(V_t^i)|} & (v^{i+1}, v_t^i) \in E, \phi(v^{i+1}) = t+1\\ 0 & (v^{i+1}, v_t^i) \in E, \phi(v^{i+1}) \neq t+1\\ 0 & (v^{i+1}, v_t^i) \in E \end{cases}$$

where $v_t^i \in V_t$ and $N_{t+1}(v_t^i)$ denote the V_{t+1} type of neighborhood of node v_{t^i} . Also, meta-paths are designed in a symmetric way; which means the first node denoted as V_1 is the same as the last one, V_l , and therefore, has the same probability of being reached, which means:

$$p(v_{i+1}|v_t^i) = p(v_{i+1}|v_l^i), \text{ if } t = l$$
(13)

For example, consider "APA" and "APVPA" as meta path schemes where the former represents the "coauthor collaboration on a paper" and the latter represents "two authors publish papers in the same venue". In the next step, the algorithm inputs the achieved random walks to a heterogeneous skip-gram model to get the embeddings of the nodes. Given a heterogeneous graph G = (V, E, T), the objective of using a heterogeneous skip-gram model is to maximize the network probability in terms of local structure or $N_{t(v)}, t \in T_v$, i.e:

$$argmax \sum_{v \in V} \sum_{t \in T_V} \sum_{c_t \in N_t(v)} logp(c_t|v;\theta)$$
(14)

where $N_{t(v)}$ is v's neighborhood with the $t^{(th)}$ type of nodes, and $p(c_t|v;\theta)$ is a softmax function, that is $p(c_t|v;\theta) = e^{X_{c_t} \cdot X_v} / \sum (u \in V) e^{X_u \cdot X_v}$ where X_v is the Vth row of X, representing the embedding vector for node v.

Metapath2vec recognizes the context nodes of node v when constructing its neighborhood function N_v based on their types. However, it ignores these types in the softmax function. Therefore, we introduce a modified version of metapath2vec to enhance the results.

Metapath2vec++: is an extension of metapath2vec designed to improve the quality of the embeddings in the heteregeneous graphs. In metapath2vec++, the softmax function is normalized with respect to the type of the context node c_t :

$$p(c_t|v;\theta) = \frac{e^{X_{ct} \cdot X_v}}{\sum_{u \in V} e^{X_u \cdot X_v}} \quad (4)$$
(15)

where $p(c_t|v;\theta)$ is adjusted to the node type t and V_t is the node set of type t. In this case, we will have one set of multinomial distributions for each type of the c_t in the

Fig. 4 2D PCA projections of the 128D embeddings of 16 top CS conferences and corresponding high-profile authors [34].

output layer of the skip-gram model. Figure 4, illustrates the differences between the embedding results of some models:

3.6 Regpattern2vec [36]

In this section, we explain another method for representation learning of the graphs. Regpattern2vec is an embedding algorithm categorized as a deep learning method based on random walks. This algorithm uses a fixed regular pattern (regular expression) to bias the random walks and then feeds the achieved walks to a modified version of the skip-gram to embed the walks. The obtained embeddings can be used for various machine learning tasks; such as link prediction, node/edge classification, etc. In the original paper, these embeddings are used for the link prediction tasks.

Before explaining the regpattern2vec algorithm, we describe some preliminary concepts:

Regular expression: A regular expression or regular pattern defines a search pattern in a text in the form of a sequence of characters [82]. In other words, a regular expression defines a set of strings that match it [83]. Regular expressions can contain both ordinary and special characters. Ordinary characters mean alphabets and numbers such as A, b, 5. Special characters are non-alphabets and non-numbers such as '(' and '?'. Special characters have special meanings in the regular expressions. Some examples of regular expressions are a3, 5, $^{T}he. *Spain$, $H[^{T}] + HT$.

Regular pattern on knowledge graph: If G = (V, E) is a knowledge graph which has a node type mapping function $\phi : V \xrightarrow{T}$ and an edge type mapping function

 $\phi: E \xrightarrow{R} A$ regular pattern r on G is formed over either set T or R as the alphabet.

Finite State Machine [84]: also called Finite State Automaton, is a mathematical representation of computation which is an abstract concept but can also be implemented in software and hardware for different purposes; such as reducing the mathematical work in the theory of computation, pattern matching and lexical analysis. A Finite State Machine can be classified into two types: Deterministic Finite Automaton (DFA) and Non-Detereministic Finite Automaton (NDFA/NFA). Since our model is using the DFA, we will only give a brief explanation of it here. As explained earlier, the codes accept a user input regex. Before running the random walk, we first want to make sure that the regex is valid and that random walks with that regex are applicable. We check this validation via DFA. In this method, we have a DFA consisting of 5 states; in which we start from state 0 as the initial state and try to move through the states via the transition function, and then return to the final state (which is again state 0 in our case). If we arrive at the final state, this means the regex is valid; otherwise, the user has to enter a different regex. If the regex is valid, the algorithm runs the walk based on this regex. After the walk is finished, we feed the generated walks to a skip-gram and obtain the embeddings of the nodes. The generated embeddings can be used for various machine-learning tasks.

Deterministic Finite Automata [84]: or DFA, is a Finite State Machine that reads a string of symbols and either accepts or rejects it. For each input symbol, a state in the DFA is determined to which the machine moves. A DFA can be represented by a 5-tuple $(Q, \Sigma, \delta, q_0, F)$ in which: Q denotes the set of states, Σ (also called alphabet) denotes a finite set of symbols, δ is the transition function $(\delta : Q \times \Sigma \to Q)$, q_0 denotes the initial state $(q_0 \in Q)$ and F denotes the final state/states $(F \subseteq Q)$. Basically, the machine works as follows: First, it takes the string (S) over the alphabet (Σ) as an input. Then, starting from the initial state (q_0) while reading each character of the string S, the machine moves to the next state by using the transition function. If the last alphabet of S, makes the machine stop in F (the final state/any of the final states), the machine accepts the string, otherwise, rejects it.

Method: Here, we explain how regpattern2vec works. The algorithm runs on a fixed regular expression which is $r = H[^T] + HT$ based on edges of the graph. Each of (H, T, T) denotes an edge type and has different sub-types. The user enters a regular expression based on the edges' sub-types (r) and to make sure the regular pattern is entered properly, the algorithm uses DFA to check the validation of the entered regular expression. If the user-given regular expression matches the $r = H[^T] + HT$ format and the types of the chosen edges are compatible as well, the algorithm runs the walks based on this regular expression. According to r, the random walk chooses the first edge randomly from any edges of type H, and the next edge is of any random edge from any type but T, and then chooses another random edge (from the available edges) of type H and then the next edge is of type T. In this case, the walk length is 4, however, if the walk length is more than 4, the algorithm repeats the walk in a back-and-forth fashion. This means the walk moves backward and for the next edge,

the walk chooses an edge of type H, and then chooses an edge of any type but T, then chooses type H and again moves forward afterward. The walk repeats the same thing until it reaches the walk length.

At each step, the probability that a specific type of node is chosen is calculated as follows:

$$\sum_{i=1+1}^{l} P(v^{i+1}|v^{i}, M) = \begin{cases} \frac{\frac{1}{N_{v_{i+1}}}}{\sum_{i=1}^{n} \frac{1}{N_{v}}} & r \in S \\ 0 & r^{i}, r^{i}, r^{i+1} \notin G \end{cases}$$

Here, $|N_v|$ is a degree of node v, v_i indicates the current node, and v_{i+1} is the next candidate node. Also, s_i is the current state of M, and $\phi(r_i)$ is M's transition function from state s_i to state s_{i+1} .

The random walks based on the defined regular expression are created. Next, these random walks are fed into a modified version of a skip-gram to create the embeddings. To capture the similarity of the edges based on their types and having close embeddings in the latent space, our modified skip-gram takes into account the types of the edges. We use these biased walks as an input to the skip-gram and the output is the embeddings of these walks.

3.7 Subgraph2vec [35]

Subgraph2vec is a representation learning technique that demonstrates the vector representation of the entities and relations of a knowledge graph in a low-dimensional space while maintaining their semantic meanings. The algorithm uses random walks and a modified version of the skip-gram to create the embeddings. In this method, the user enters a schema subgraph, with the intension to bias the random walks on a specific part of the overall knowledge graph. A schema subgraph is a subgraph of the complete schema graph. The schema graph is in the form of an arbitrary set of integers based on the edges where each integer represents an edge. After the sub-graph is given, the algorithm chooses a random node inside the subgraph and starts the random walk. The next edge is chosen randomly inside the subgraph which moves to the next random node. The walk continues based on a parameter called *walk length*. Each chosen node/edge is valid only if it is within the user-defined subgraph. This method is supposed to solve the deficiency of the previous random walk-based methods such as regpattern2vec, node2vec, and metapath2vec. In the previously mentioned methods, the walks are biased on fixed regular expressions, or sequences of note types, which are defined by experts. However, this method is based on arbitrary random walks, as long as they are within the defined subgraph.

Method: The user enters a schema subgraph (s') in the form of integers, representing the edges in the schema subgraph. Let's assume the user has entered this subgraph: $s' = x_1, x_2, x_3$, where each x_i denotes an edge in the graph. After the subgraph is given, a random node is chosen within this subgraph as the starting node. The walk

starts at this node and in each step of the walk, a random edge is chosen. The chosen random edge is valid only if it is within the subgraph and invalid otherwise. The probability of choosing the next edge is calculated with this formula:

$$\sum_{i=1+1}^{l} P(r^{i+1}|r^{i}, S) = \begin{cases} \frac{1}{r_{t_{i}}} \times \frac{1}{\sum_{i=1}^{n} t_{i}} & (r \in S) \\ 0 & (r^{i}, r^{i}, r^{i+1}) \notin G' \end{cases}$$

where t_i denotes each type of the edges connected to the current node and r_{t_i} denotes the number of the edges of each type. We choose the next edge from our valid set of edges based on its probability.

4 Conclusion

In this work, we reviewed some methods for embedding knowledge graphs. There are five different categories of methods for embedding knowledge graphs which include: matrix factorization, generative models, deep learning, graph kernels, and edge reconstruction-based optimization models. Each of these categories includes different subcategories and each subcategory contains different methods. We have provided examples for each subcategory in Table 2. Deep learning methods have recently gained popularity due to their different benefits such as scalability, versatility, high accuracy, etc. Among deep learning methods, random walk-based ones provide a versatile and powerful tool for analyzing and modeling knowledge graphs influenced by randomness. Our focus in this paper is deep learning and in particular, random walk-based methods. We have summarized several of the recent important random walk-based algorithms for embedding knowledge graphs. In addition, we have categorized these methods based on the random walk technique they use in Table 1.
