REVS: Unlearning Sensitive Information in Language Models via Rank Editing in the Vocabulary Space

Tomer Ashuach Martin Tutek Yonatan Belinkov

Technion - Israel Institute of Technology {tomerashuach,martin.tutek,belinkov}@campus.technion.ac.il

Abstract

Large language models (LLMs) risk inadvertently memorizing and divulging sensitive or personally identifiable information (PII) seen in training data, causing privacy concerns. Current approaches to address this issue involve costly dataset scrubbing, or model filtering through unlearning and model editing, which can be bypassed through extraction attacks. We propose REVS, a novel model editing method for unlearning sensitive information from LLMs. REVS identifies and modifies a small subset of neurons relevant for each piece of sensitive information. By projecting these neurons to the vocabulary space (unembedding), we pinpoint the components driving its generation. We then compute a model edit based on the pseudo-inverse of the unembedding matrix, and apply it to de-promote generation of the targeted sensitive data. To adequately evaluate our method on truly sensitive information, we curate two datasets: an email dataset inherently memorized by GPT-J, and a synthetic social security number dataset that we tune the model to memorize. Compared to other state-of-the-art model editing methods, REVS demonstrates superior performance in both eliminating sensitive information and robustness to extraction attacks, while retaining integrity of the underlying model. The code and a demo notebook are available at https://technion-cs-nlp.github.io/REVS.

1 Introduction

Large language models (LLMs) exhibit a concerning tendency to memorize information from their training data [11, 12, 46]. While factual recall is a desirable property when dealing with general knowledge, memorization and regurgitation of sensitive private information, such as personal and contact details, is a security concern regulated by laws like the general data protection regulation [GDPR; 21]. To ensure such information does not get inadvertently leaked, it is paramount to develop techniques that detect and erase sensitive information from the LLMs or their training data.

Current approaches for handling sensitive information in LLMs can be broadly categorized into two groups. *Exact unlearning* approaches tackle the problem from the data perspective, either erasing information from datasets [30, 32] or applying differential privacy [1, 27, 34, 47] to the training data. Such approaches are costly and time-consuming, as each iteration of scrubbing requires retraining of the entire model. Moreover, they reduce but do not entirely prevent the risk of sensitive information leakage [9, 10]. *Machine unlearning* approaches [35] aim to discourage models from generating sensitive information through techniques such as in-context unlearning [ICL; 37, 45, 58] or gradient ascent [29, 55, 56]. These approaches do not ensure that the sensitive information is erased from model parameters, rendering them vulnerable to extraction attacks [33]. *Model editing*, a variant of localization-based unlearning, localizes and change a subset model parameters to erase or overwrite the sensitive information itself [15, 38, 39]. In contrast to ICL and optimization-based methods, which may prevent models from generating sensitive content but do not fundamentally erase the underlying knowledge, editing methods hold a greater potential to resist extraction attacks [11] by surgically removing the sensitive data from model parameters.

Figure 1: Overview of the REVS unlearning process: (1) The original model memorizes a sensitive email address and (2) generates it exactly given a related prompt using greedy decoding. (3) After applying REVS, the target email token(s) are demoted to a specified lower rank R in the model's output, preventing the model from generating the unlearned email.

We introduce Rank Editing in the Vocabulary Space (REVS), a novel model editing approach that enables robust unlearning of sensitive information from LLMs while maintaining model performance and offering strong robustness against extraction attacks. Adopting the view that transformer MLP layers construct predictions by promoting specific tokens in the output vocabulary space [24], REVS locates the layers and particular subsets of neurons that promote the tokens corresponding to the targeted sensitive information. By modifying these neurons with respect to the relevant tokens, REVS surgically removes the model's encoded tendency to generate that sensitive data while preserving its broader knowledge and remaining robust to extraction attacks. See Figure 1 for an illustration.

As private data is infrequent in training data, to adequately evaluate REVS, we curate two benchmark datasets containing sensitive data: Email, containing real private email addresses inadvertently memorized by the model during pretraining, and SSN, a synthetic dataset where we deliberately instilled the model with sensitive social security number (SSN) information through finetuning. Unlike prior work [44], which evaluated editing methods on non-sensitive data, our benchmarks contain actual private information, allowing us to rigorously assess the unlearning efficacy and robustness against potential extraction attacks. We analyze the GPT-J-6B model [4, 51] as it was shown to memorize at least 1% of its training data [9]. We compare REVS against two strong baselines for unlearning: constrained fine-tuning with gradient ascent [59] and an adapted version of the MEMIT editing method [39]. On both real and synthetic data, we show that REVS outperforms the baselines in unlearning the sensitive information while maintaining overall performance and being robust to extraction attacks.

To summarize, our contributions are:

- We introduce REVS, a novel method for unlearning sensitive information from LLM parameters.
- We curate two datasets containing sensitive information: an email dataset organically memorized by GPT-J and a synthetic SSN dataset that we fine-tune the model to memorize.
- We extensively evaluate REVS on unlearning as well as robustness to extraction attacks, and show that it outperforms state-of-the-art model editing methods.

2 Problem setup and preliminaries

Consider the case where a LLM is prompted with text from its training dataset that contains sensitive information, e.g., "Contact David Lewis at". If the model has memorized the completion of this prompt, it will generate the relevant email address, such as "lewis.david@email.com", illustrated in Figure 1. This scenario highlights a prevalent issue with LLMs: the models' ability to memorize can lead to unintended divulgence of sensitive data, in particular personally identifiable information (PII).

Formally, let $\mathcal D$ be a dataset, and let $M_{\mathcal D,\Theta}$ be a LLM with parameters Θ trained on $\mathcal D$. We consider the model $M_{\mathcal D,\Theta}$ to be a *privacy risk* when the model reproduces a sequence of tokens containing PII S from $\mathcal D$ when prompted with a sequence of tokens P. Exact unlearning approaches tackle this issue from the *data perspective*, preventing sensitive information from being stored in the model during training. Such approaches yield $M_{\hat{\mathcal D},\hat{\Theta}}$, as the learning algorithm will inadvertently converge to a different set of parameters due to a modified dataset. Machine unlearning approaches take on a post-hoc approach, modifying either all, or just a subset of parameters that contain sensitive information, yielding $M_{\mathcal D,\hat{\Theta}}$. The goal of these approaches is to efficiently and effectively prevent the model from generating each sequence containing sensitive information S in a way robust to extraction attacks, while at the same time preserving model performance on unrelated tasks [35].

Background on Transformer LMs. We briefly describe the main components in Transformer LMs; more details are found elsewhere [4, 50, 51]. Omitting some technical details, a Transformer LM is made of a sequence of blocks. Each block contains self-attention and multi-layer perceptrons (MLPs) that write and read to the residual stream [20]. The MLP is defined as $MLP(x) = FF_2\sigma(FF_1x)$, and is added to the residual stream. The final layer hidden state is projected to the vocabulary space via an unembedding matrix W, followed by a softmax to obtain the probability of the next token.

Due to the residual stream tying hidden spaces across layers, applying the unembedding matrix to residual states at intermediate layers results in meaningful token logits [42], while applying it to MLP weights reveals stored knowledge [14]. In fact, the second MLP layer, FF₂, acts as a memory store [25, 38], and model editing methods often target this layer to update a model's knowledge [38, 39]. We adopt this view, and focus on the FF₂ neurons (columns) for unlearning.

3 Methodology

In this section, we first provide a high-level overview of REVS (Section 3.1), then delve into each of its modules: selecting which tokens to unlearn (Section 3.2), which layers (Section 3.3) and which neurons (Section 3.4) to update, and finally, how to compute and apply the actual update (Section 3.5).

3.1 REVS unlearning process

To unlearn each target piece of sensitive information, REVS first *localizes* model parameters that contribute the most towards their generation. It then adjusts selected neuron representations, aiming to reduce those layers' promotion of the sensitive information by reducing the rank of the target tokens in each layer's residual, while minimizing total model edits. The updated neuron values reflect the modified ranks, effectively demoting the associated sensitive information while retaining the model's broader knowledge. The core process of REVS involves the following steps:

- 1. To unlearn a sensitive sequence S, select a subset of target tokens $T = t_1, t_2, ..., t_t$ from S (3.2).
- 2. For each target sensitive token $t_i \in T$, identify the layers where the rank of t_i in the residual hidden state vector h is above a desired threshold rank r_h (3.3).
- 3. Within these identified layers, select which neurons to edit (3.4),
- 4. Iteratively edit selected neurons to reduce rank of t_i below neuron threshold rank r_n (3.5).
- 5. Update the model with the edited neurons.

A detailed description of this process can be found in Algorithm 1.

Algorithm 1 Unlearning Sensitive Information from LLM

```
1: procedure UNLEARN(M, P, S, r_h, r_n, N_{\text{max}})
           V \leftarrow \text{vocabulary size of } M
 3:
           L \leftarrow number of layers in M
           d_h \leftarrow \text{hidden dimension of } M
W \in \mathbb{R}^{V \times d_h}, W^{\dagger} \in \mathbb{R}^{d_h \times V}
 4:
 5:
                                                                                                ▶ Unembedding matrix and its pseudo-inverse
 6:
           T \leftarrow \text{SelectTargetTokens}(S, t)
                                                                                                                                     \triangleright Select t tokens in S
           for t_i \in T do
 7:
 8:
                 for l \in 1, \dots, L do
                       N_{\mathrm{edit}} \leftarrow \emptyset
 9:
                                                                                                                                           ▶ Neurons to edit
10:
                       repeat
                             \vec{n} \leftarrow \text{SelectNeuron}(M, P, t_i, l)

⊳ Select neuron to edit

11:
                             \vec{v} \leftarrow \vec{n} W
                                                                                                              ▶ Project neuron to vocabulary logits
12:
                             \vec{v} \leftarrow \text{AdjustRank}(\vec{v}, t_i, r_n)
13:
                                                                                            ▷ Adjust logits to de-promote rank (Appendix B)
                             \vec{n} \leftarrow W^{\dagger} \vec{v}
                                                                                                          ▶ Project adjusted logits back to neuron
14.
                             \begin{aligned} N_{\text{edit}} &\leftarrow N_{\text{edit}} \cup \vec{n} \\ M &\leftarrow \text{UpdateModel}(M, N_{\text{edit}}, l) \end{aligned}
15:
                                                                                                               ▶ Update model with edited neurons
                             h^l \leftarrow \text{ResidualHiddenState}(M, P, l)
17:
                                                                                                             \triangleright Get residual hidden state for layer l
                       until Rank(t_i, h^l) \ge r_h or |N_{\text{edit}}| = N_{\text{max}}
18.
19:
                 end for
            end for
21: end procedure
```

Figure 2: Editing one neuron with REVS: (1) The neuron is projected from hidden space to vocabulary logit space. (2) The logit is adjusted to demote the target token rank to a desired lower rank R. (3) The adjusted logits vector is projected back to hidden space, yielding the updated neuron value.

3.2 Target token selection

While sensitive information often comprises multiple tokens, unlearning all tokens is unnecessary since accurately extracting the original data requires recovering the full token sequence. Therefore, our approach focuses on unlearning the rarest t tokens from each target sequence.

3.3 Selecting layers for editing

For each target token t_i to unlearn, REVS identifies all layers l where the rank of t_i in the residual hidden state vector h^l after applying the unembedding matrix is higher than the desired threshold rank r. By targeting the layers that significantly contribute to generating t_i , REVS aims to surgically edit only the relevant model parameters for minimizing overall modifications to the model.

3.4 Selecting neurons for editing

To select which neurons to edit within the identified layers, we consider both the neuron's association with the target token t_i and its activation level in response to the given prompt P. First, we select the top k neurons with the highest activations for prompt P. We refer to an activation of a neuron as the input value of that neuron when the network is run on the given prompt, where higher activations indicate that the neuron is more relevant for the given input. From this subset, we iteratively edit up to N_{max} neurons that exhibit the highest rank for t_i when projected to the vocabulary logit space. A higher rank indicates a strong association between the neuron and t_i , suggesting it encodes significant information relevant to generating t_i . This hybrid criterion aims to prioritize editing the neurons most relevant to the undesired token t_i in the context of the specific prompt P. Empirically, we find this approach outperforms alternatives like editing only the most activated neurons, only the most associated neurons, neurons with highest gradients w.r.t the prompt [13], or random neuron selection. See Appendix C for ablation experiments and Section 3.5 for implementation details.

3.5 Neuron editing

As illustrated in Figure 2, REVS iteratively selects neurons from the feed-forward (FF_2) layer, projects them to the vocabulary logit space, decreases the logit value of the target token to reduce its rank in the logits vector, and projects the adjusted logits back to the neuron's space using the pseudo-inverse of the unembedding matrix. This edited neuron is accumulated and used to update the model weights. The process comprises these four steps (lines 12–15 in Algorithm 1):

- 1. Project \vec{n} to the logit space as \vec{v} using the unembedding matrix W.
- 2. Iteratively decrease v_{t_i} to reduce the rank of t_i below r_n , yielding $\vec{\tilde{v}}$. See Appendix B for details.
- 3. Re-project \vec{v} to the hidden space as \vec{n} using the pseudo-inverse of the unembedding matrix W^{\dagger} .
- 4. Accumulate $\vec{\tilde{n}}$ in the edited set N_{edit} .

4 Experimental setup

4.1 Model

We experiment with GPT-J-6B [52], which was trained on the Pile [23], a publicly accessible corpus containing sensitive information such as email addresses. Our choice of GPT-J-6B is motivated by previous work showing it has memorized a significant portion (at least 1%) of its training data [9].

4.2 Datasets

We evaluate our method on three datasets, each evaluating different aspects of our approach:

Emails from The Pile: The dataset comprises of 288 sentences from The Pile [23] containing memorized email addresses. To curate it, we identified sentences with email addresses using Presidio [40], prompted the model with the prefix before the email, and verified that it generates the exact email in the next 20 tokens with greedy decoding. The target token sequence is the string before @email.com. This dataset facilitates evaluation on data that the model has naturally memorized from its training corpus. See Appendix D.2 for privacy considerations.

Synthetic SSN dataset: The dataset comprises of 200 sentences containing social security numbers (SSNs). The dataset was generated by prompting Claude 3 Sonnet [3] to create template sentences on various topics that could contain SSNs (employment records, tax documents, finance, government records, and medical records), with placeholders for names, dates, and SSNs. We then randomly assigned fake sensitive information to each of the placeholders. See Appendix D.1 for more information on dataset construction. The model is fine-tuned to memorize all instances. When constructing the dataset, we assign 20 unique SSN targets across 100 templates, such that each target SSN has 5 different prefixes. This allows evaluating *generalization*: we unlearn using only one prompt that generates the target token sequence, and evaluate on four additional prompts that also generate it. The remaining 100 sentences were used to evaluate the method's specificity, that is, whether it affects memorization of SSN targets that were not unlearned. In this dataset, the target tokens to unlearn were chosen only from numeric tokens, as the SSN structure contains '-' (e.g., 123-45-6789).

Wiki 10k¹: 10k sentences from Wikipedia, which the model has seen during pretraining. We use this dataset to measure the effect of unlearning on the model's general language modeling capability by comparing perplexity before and after the unlearning procedure.

4.3 Baseline methods

We compare our approach to two strong knowledge editing methods modified to allow unlearning:

Constrained fine-tuning (FT-L) [59]: Fine-tuning the second feed-forward layer (FF_2) in the MLPs, aiming to minimize the probability of generating the target tokens t_i , instead of maximizing it as in the original work in order to allow for unlearning. FT-L imposes an L_{∞} norm constraint to limit the overall impact on the model's knowledge.

MEMIT [39]: We use a modified version of MEMIT, originally proposed for inserting new knowledge into LMs by editing the FF_2 matrices in model MLPs. Here, we optimize the objective to decrease the probability of generating the target tokens t_i . See Appendix A.2 for details on our changes.

4.4 Evaluation metrics

To evaluate the effect of unlearning on the model, we employ a suite of metrics, which can be categorized as: (1) assessing unlearning effectiveness (Section 4.4.1), (2) estimating the integrity of the model after unlearning (Section 4.4.2), and (3) robustness to extraction attacks (Section 4.4.3).

4.4.1 Unlearning effectiveness

Let $Rank(t_i)$ denote the rank of token t_i in the model's logits. A naive measure would evaluate whether a model generates the target token after unlearning it, that is, whether $Rank(t_i) = 1$. Instead, we define a stricter metric. Define $Score@K(t_i)$ as the normalized rank of token t_i within a set of

https://huggingface.co/datasets/NeelNanda/wiki-10k

candidate tokens C. A score of 1 means the token is not in the most likely K-1 tokens:

$$Score@K(t_i) = \begin{cases} \frac{Rank(t_i)}{K} & \text{if } Rank(t_i) < K\\ 1 & \text{otherwise} \end{cases}$$
 (1)

Efficacy: since extracting the sensitive information requires recovering every token in the sequence correctly, we define the unlearning efficacy as the maximum Score@K across the subset of target tokens T, averaged over the N target prompts:

Efficacy@
$$K = \frac{1}{N} \sum_{i=1}^{N} \max_{t_i \in T} \text{Score@}K(t_i)$$
 (2)

Generalization: similarly, we evaluate the unlearning generalization by computing the same measure on prompts that were not seen by the unlearning method, but would have yielded the same piece of sensitive information from the original model prior to unlearning it.

4.4.2 Model integrity

Specificity: assesses the model's ability to continue generating memorized *non-target* sensitive information by measuring the percentage of prompts P_i where the edited model's output $M_{\text{edited}}(P_i)$ matches the original sensitive token sequence S_i :

Specificity =
$$\frac{1}{N} \sum_{i=1}^{N} \mathbb{1}[M_{\text{edited}}(P_i) = S_i]$$
 (3)

Perplexity: measures the perplexity before and after applying unlearning on a dataset the model was pre-trained on (4.2) to evaluate the effect on its general capabilities.

4.4.3 Extraction resistance

This category quantifies the difficulty for an adversary to extract the unlearned sensitive token sequence, given different attacks. The attacks differ by the set of tokens they consider for recovering the unlearned targets. Given such a candidate set C (where |C|=K), define the resistance to each attack as the minimum of the average efficacy score (Eq. 2) across all model layers L. The intuition is that it is sufficient for an attacker to extract the target in one layer for the attack to be successful.

Attack Resistance@
$$K = \min_{\ell \in L} \text{Efficacy@}K$$
 (4)

where the set C of K tokens passed to the Efficacy function is defined next.

Logit-lens attack (LLA): Considers the top-k and bottom-k tokens in the vocabulary logit vector \vec{v} as candidates, obtained by projecting each layer's residual hidden state to the vocabulary logits.

$$C_{\text{LLA}} = \bigcup_{\ell \in L} \text{top-}k(\vec{v}^{\ell}) \cup \text{bottom-}k(\vec{v}^{\ell})$$
 (5)

Delta attack (DA): Considers the top-k tokens with the largest changes in the vocabulary logit vector \vec{v} between consecutive layers as candidates.

$$C_{\mathrm{DA}} = \bigcup_{\ell \in I_{\ell}} \mathrm{top-}k(\vec{v}^{\ell+1} - \vec{v}^{\ell}) \cup \mathrm{bottom-}k(\vec{v}^{\ell+1} - \vec{v}^{\ell})$$
 (6)

Perturbation attack (PA): A white-box attack that inserts random characters to the original prompts. The candidate set C_{PA} is obtained as in C_{LLA} , but using the perturbed prompts. This attack can be adapted to a black-box setting by using only the last hidden state. Appendix E provides more details.

4.5 Implementation details

The target tokens to unlearn were chosen as the rarest t=2 tokens in the target token sequence. Targeting the rarest tokens was found in preliminary experiments to provide effective prevention of extraction attacks while preserving the model's general capabilities. Hyper-parameters for all methods were chosen by optimizing the harmonic mean of the metrics on the Emails and SSN datasets, using one seed ('0'). Each method was then evaluated with cross-validation over six random 50/50 splits of each dataset (using seeds 1–6). The first half of the dataset was selected as targets for unlearning and evaluated for efficacy, generalization (for the SSN dataset), and extraction resistance, while the second half was used as the retained set to evaluate specificity. The results presented in the next section employ the same hyper-parameter configurations (best one for each method) across all experiments, ensuring a fair comparison between methods without any scenario-specific optimization.

Table 1: Unlearning effectiveness and model integrity results. REVS is superior in almost all cases.

Dataset	Method	Harmonic Mean ↑	Efficacy@100↑	General.@100↑	Specificity ↑	Perplexity \downarrow

5 Results

5.1 Main results

Superior unlearning effectiveness with preserved model integrity. As shown in Table 1, both REVS and MEMIT achieve strong results in terms of unlearning effectiveness and model integrity. However, REVS consistently outperforms MEMIT in the harmonic mean score and individual metrics on both datasets, except for a single case of specificity on the SSN dataset. The difference in specificity between datasets can be attributed to the nature of the target token sequences. While the Emails dataset targets consist of unique tokens with low overlap, the SSN targets comprise only numbers, leading to a high overlap with other instances within the specificity calculation. The superior generalization score of REVS indicates its ability to comprehensively unlearn generating the target tokens across different prompts, even when applied to a single prompt-target pair. Despite extensive hyper-parameter tuning, the FT-L method performed poorly compared to REVS and MEMIT across most metrics. Further details on the experiments and attempts to improve the performance of FT-L are found in Appendix A.3. Perplexity remains largely unaffected, indicating minimal impact on the models' general capabilities, with the exception of degraded perplexity for FT-L in Emails.

Robust resistance to extraction attacks. As shown in Table 2, both REVS and MEMIT achieve excellent results in preventing the retrieval of unlearned sensitive information across various adversarial attacks. However, REVS maintains an edge over MEMIT, surpassing it across all tested extraction attacks on both datasets.

Organic vs. synthetic memorization. The organically memorized Emails dataset proved more challenging for unlearning while preserving model integrity, as evident from lower specificity (Table 1). This suggests there are inherent differences between memorization during pre-training and fine-tuning. Concretely, it is easier to extract the unlearned information from the organic Emails dataset compared to the synthetic SSN dataset (Table 2), implying it is harder to defend against attacks when the information is organically memorized and likely deeper ingrained in model parameters.

5.2 Analysis

Robustness to candidate token size. Here we evaluate the effectiveness of REVS compared to MEMIT while varying the size of the candidate token set. In Figures 3a and 3d we observe that REVS consistently outperforms MEMIT as we increase the size of the candidate token set (C).

Figure 3: Top row: Email dataset; Bottom row: SSN dataset. From left to right: (a+d) efficacy vs candidates size, (b+e) efficacy vs. specificity trade-off, (c+f) harmonic mean vs. number of edits for Emails (c) and number of targets for SSN (f). Mean results with confidence intervals.

Efficacy and specificity trade-off. As expected, there is a clear trade-off between efficacy and specificity, as illustrated in Figures 3b and 3e. While both REVS and MEMIT exhibit this trade-off, REVS can achieve near-perfect specificity with low efficacy in both datasets, which is not the case for MEMIT, as its specificity saturates around 0.65 even at low efficacy for the Emails dataset. However, MEMIT presents more consistent specificity scores across different configurations, while REVS is prone to a larger trade-off between efficacy and specificity.

Impact of the number of edits. Figures 3c and 3f depict a similar overall downward trend in harmonic mean as the number of edits increases for both REVS and MEMIT. However, there are notable differences. In the Emails dataset, REVS achieves an almost perfect score with a low number of edits, while MEMIT's performance saturates earlier. However, in the SSN dataset, both methods exhibit a large variance for a small number of targets, but MEMIT seems more robust as the number of targets increases. Potentially, higher scores could be achieved by optimizing hyper-parameters for a larger number of edits, as current hyper-parameters were optimized for 100 targets.

6 Related work

Privacy is defined as "the ability to control the extent of personal matters an individual wants to reveal" [53]. With the recent developments in neural foundation models in language and vision domains, which are trained on data scraped from the internet, preserving confidentiality of user data has become a concern [5, 7]. This concern is further exacerbated by legislation such as the EU general data protection regulation [GDPR; 21] and the California consumer privacy act (CCPA), which govern processing and storage of personal identifiable information (PII).

Memorization of training data in neural models. It has been shown that foundation models of language [10, 11, 32, 57], vision [8], and code [28] are able to reproduce sensitive personal information such as credit card numbers, email addresses and API keys. The extent of input data memorization was unclear until Carlini et al. [9] demonstrated that the GPT-J model trained on the Pile memorizes *at least* 1% of its training data. Memorization is shown to increase with model scale [9] and specialized prompts can bypass guardrails in order to retrieve even more information than previously estimated [8, 28, 48], highlighting the need for removing memorized PII from models.

Defenses against leakage of sensitive information. Naturally, privacy concerns have given way to development of methods preventing regurgitation of PII. Differential privacy [DP; 18, 27, 34, 47] and dataset scrubbing through deduplication [9, 30, 32] aim to prevent sensitive information from ever being stored in the model. However, using DP-SGD frequently results in worse generative

models [2], and LLMs are able to memorize training instances even if they are not duplicated [16]. Scrubbing approaches are also expensive, requiring retraining of the foundation model for each new identified leak of PII. To alleviate high cost incurred by retraining models from scratch, post-hoc model unlearning [35] techniques such as gradient ascent [6, 19, 41], reinforcement learning through human feedback [RLHF; 43] and model editing [15, 38, 39, 54] were devised. Most similar to ours is the work of Wu et al. [54], where the authors identify and zero out neurons most responsible for memorizing the sensitive information. REVS operates in a similar manner, except instead of completely zeroing out the neurons it modifies the selected neurons to demote the relevant tokens in the output vocabulary space. This allows REVS to remove the tendency to generate sensitive information while preserving model integrity.

Extraction attacks. There are three categories of attacks aimed to retrieve information from ML models. Membership inference attacks [17, 49] have the goal of verifying whether a specific datum was in a model's training set, while attribute inference attacks [22] retrieve information on some attributes of the training instances. Data extraction attacks, on the other hand, aim to retrieve full training instances. Generative LMs are especially susceptible to such attacks given their propensity to memorize training data [8, 10]. Patil et al. [44] show that despite efforts to scrub sensitive information from models, different attacks can still locate such information in LMs. Black-box attacks assume no access to model internals and aim to retrieve information through conversation [26], designing prompts [36] or paraphrasing [31]. White-box use model parameters and through representation probing [24, 42] can even detect information that has been erased by model editing techniques [44]. REVS is specifically designed with these attacks in mind and removes sensitive information in a way that is robust with respect to possible attacks as well as effective in terms of erasing information.

7 Conclusion

We introduce REVS, a novel unlearning technique which demonstrates superior performance to state-of-the-art baselines in effectively unlearning sensitive information from LLMs while preserving their general capabilities and remaining robust to extraction attacks. REVS achieves near-perfect efficacy in preventing the generation of unlearned targets and maintains high specificity, indicating minimal disruption to the model's desired behavior. We perform detailed analyses assessing the methods' robustness to varying the size of the candidate token sets, the trade-off between efficacy and specificity and number of performed unlearned targets. Notably, our experiments revealed inherent differences in unlearning performance between synthetic and organically memorized information, with the organically memorized Email dataset proving more challenging, suggesting that information memorized during pre-training may be more deeply ingrained in the model's parameters.

8 Limitations

While REVS shows promising results, several areas need further work to resolve current limitations: (1) identifying other models that have memorized sensitive information to enable broader evaluation, (2) generalization to unlearning other types of organically memorized sensitive information beyond emails, (3) scalable unlearning of larger amounts of target information, (4) evaluation against more fine-grained extraction attacks, including on specific sub-modules like MLP or Attention outputs. Issues (1) and (2) are especially important, as our work has shown that organically memorized sensitive information is harder to unlearn from models when compared to data memorized by fine-tuning. However, finding encoded sensitive data is both time consuming and difficult due to both the scale and lack of public availability of training data.

9 Broader impact statement

Our work aims to erase sensitive or personally identifiable information from LMs. As such, we expect it to be mainly used for positive goals. That said, it is possible that unlearning could be applied to erase factually correct information or perhaps stances, such as political ones, which a malicious actor does not agree with. Such a model might then be primed to echo potentially harmful views.

A Unlearning methods: implementation and experimental details

This section provides implementation details for each unlearning method, describes the hyper-parameter search and experiments conducted for REVS and the MEMIT baseline, and outlines the attempts to make the FT-L baseline work effectively.

A.1 REVS

An extensive hyper-parameter search was performed, focusing on the maximum number of neurons, neuron choosing strategy, desired rank of the target token in the edited neurons, and desired rank of the target token within the residual hidden state layer. The best configuration found through this tuning process was as follows: A maximum of $N_{max}=30$ neurons were edited per layer. The neurons were chosen by first selecting the top k=100 neurons with the highest activation values, and then from within these neurons, the ones with the highest rank for the target token when projected to the vocabulary logit space were selected. For the target token, the desired rank r_h within the residual hidden layer was set to $r_h=200$. The desired rank r_n within the edited neurons was set to $r_n=30000$, where maximum possible rank for any token in the GPT-J vocabulary is 50400.

A.2 MEMIT Baseline

We used a modified version of MEMIT [39], originally proposed for inserting new knowledge into language models by editing the FF_2 matrices in model MLPs. In our case, we optimized the objective to decrease the probability of generating the target tokens instead of increasing it, to facilitate unlearning. The original MEMIT method was proposed for editing memorized facts of the form (subject s, relation r, object o), e.g., (s = Michael Jordan, r = plays sport, o = basketball), where the subject is used for calculating the updated weights. However, the targeted sensitive information might not have an explicit subject (e.g., "Send me an email with your decision soon as you get this; david.lewis@email.com"), which is the case for many samples in the Email dataset (Table 5). Furthermore, the targeted sensitive information may be memorized by various inherently different prompts where each sentence might have unique subject (e.g., "David's email is: david.lewis@email.com" and "Contact Lewis at: david.lewis@email.com). To address this challenge, we introduced a custom hyper-parameter that sets the subject as the last n characters of the prompt, which, when fed to the model, generate the memorized sensitive information. We optimized this hyper-parameter and found that the best results were achieved when n = 50. Concretely, the following tuple was used as the input to the modified model: (s = last characters n of the prompt, r = < empty>, o = target token to unlearn)

The methods' hyper-parameters include the loss threshold for early stopping, the learning rate, and the loss probability coefficient. We added two new hyper-parameters to the adjusted method: token's probability loss coefficient, which determines the trade-off between the Kullback-Leibler (KL) divergence loss to retain the current weight values and the term representing the probability of generating the targeted token, and loss break, which is an early stopping criterion to determine when to stop optimizing the process. We conducted an exhaustive experiment to find the best configuration of hyper-parameters for MEMIT in our unlearning setting. The tuned hyper-parameters were the learning rate, token's probability loss coefficient, and loss break. The optimal configuration was a learning rate of 0.05, token's probability loss coefficient of 20, and loss break of 0.1. The rest of the hyper-parameters were left as suggested in the original paper [39].

A.3 FT-L baseline

We performed an extensive hyper-parameter search for the FT-L baseline. The hyper-parameters tuned were the learning rate, targeted layers for fine-tuning, and regularization techniques. Despite this extensive tuning, FT-L performed poorly compared to REVS and MEMIT across most metrics, as reported in the main results. The best configuration for FT-L involved targeting all feed-forward layers, with a learning rate of 2e-07 and a norm constraint of 1e-06.

We explored various strategies for improving FT-L, including fine-tuning only a single layer, multiple layers, and all feed-forward layers, with and without norm constraint and weight decay. However, none of these strategies yielded better results than the reported configuration.

A key challenge with FT-L is the extremely low specificity achieved on the Email dataset across all hyper-parameter configurations. While perfect efficacy could theoretically be achieved by making the unlearning process stronger, even at decent efficacy levels, the specificity remained very low. This trade-off between efficacy and specificity resulted in a consistently low overall harmonic mean score for FT-L on the Email dataset.

A.4 Hardware details

The experiments described in this work were conducted on a computing system equipped with 32 Intel(R) Xeon(R) Gold 6430 CPUs operating at 1.0TB RAM. For running the REVS, MEMIT, and FT-L methods on the GPT-J model, we used NVIDIA RTX 6000 Ada Generation with 49GB of VRAM GPUs. A single GPU was enough for applying REVS and MEMIT, while a setup of four GPUs was required for the FT-L method.

B Adjusting neuron rank

The AdjustRank step is designed to find the logit value for the edited neurons that yields the desired rank r_n for the target token t_i in the vector of logits \vec{v} . To achieve this, the algorithm iteratively adjusts the logit value of t_i and projects the updated logits back and forth between the vocabulary space and the hidden state space until the desired rank is obtained. The process begins by initializing the logit value of t_i to the mean of the k lowest logit values in \vec{v} . This initial value is then iteratively adjusted by increasing or decreasing it based on the difference between the current rank of t_i and the desired rank r_n . The adjustment factors, δ_h and δ_l , control the rate at which the logit value is increased or decreased, respectively. After each adjustment, the updated logits are projected back to the hidden state space and then to the vocabulary space to obtain a new rank for t_i . This iterative process continues until the rank of t_i falls within the allowed margin of error ϵ from the desired rank r_n . The iterative approach is necessary because projecting from the vocabulary space to the hidden state space using the pseudo-inverse of the unembedding matrix W^{\dagger} is an approximation, making it infeasible to deterministically calculate the exact logit value that yields the desired rank.

The algorithm, shown in Algorithm 2, takes the vector of logits \vec{v} , the target token t_i , the desired rank r_n , the number of lowest logits k to consider for initialization, the maximum allowed rank difference ϵ , and the factors δ_h and δ_l for increasing or decreasing the logit value, respectively. In practice, we use AdjustRank with k=10,000, $\epsilon=7500$, $\delta_h=1.3$, and $\delta_l=0.8$.

```
Algorithm 2 AdjustRank Algorithm
```

```
1: procedure ADJUSTRANK(\vec{v}, t_i, r_n, k, \epsilon, \delta_1, \delta_2)
 2:
            v_{t_i} \leftarrow \text{MeanKLowestLogits}(\vec{v}, k)
                                                                                                    \triangleright Initialize as mean of k lowest logits in \vec{v}
 3:
            repeat
 4:
                 \vec{v}[t_i] \leftarrow v_{t_i}
                                                                                                                       \triangleright Update logit value of t_i in \vec{v}
 5:
                 \vec{n} \leftarrow W^{\dagger} \vec{v}
                                                                                                                 ▶ Project updated logits to neuron
 6:
                 \vec{v} \leftarrow \vec{n} W
                                                                                                                 ⊳ Project updated neuron to logits
 7:
                 r \leftarrow \text{Rank}(t_i, \vec{v})
                                                                                                                \triangleright Get rank of t_i in projected logits
                 if |r - r_n| \le \epsilon then
 8:
 9:
                       break
                                                                                                       \triangleright Stop if rank is within \epsilon of desired rank
10:
                 else if r > r_n then
11:
                       v_{t_i} \leftarrow v_{t_i} * \delta_l
                                                                                                                  \triangleright Decrease v_{t_i} if rank is too high
12:
13:
                      v_{t_i} \leftarrow v_{t_i} * \delta_h
                                                                                                                    \triangleright Increase v_{t_i} if rank is too low
14:
                 end if
15:
            until true
16:
            return \vec{v}
                                                                                                                     > Return updated neuron value
17: end procedure
```

C Alternative neuron selection strategies

We explored several alternative methods for neuron selection, besides our hybrid approach that considers both neuron activation and association with the target token (Section 3.4). These alternatives

Table 3: Comparison of neuron selection strategies for unlearning on the Emails dataset.

Method	Harmonic Mean			
Method	Unlearning Effectiveness and Model Integrity	Extraction Resistance		
Random	0	0		
Gradient-based	71.1	78.2		
Rank	22.4	29.2		
Activations	68.8	81.8		
Rank + Activations (hybrid)	$\bf 75.2$	$\bf 84.2$		

include: selecting the most activated neurons given the prompt, selecting neurons solely based on their association with the target token (by choosing the top-k neurons with the highest rank in their projected logits vector for the target token), neurons with highest gradients with respect to the prompt [13], and random neuron selection as a baseline. As shown in Table 3, our evaluation on the Emails dataset, using the same seed that was used for finding the best hyper-parameters, demonstrated that the hybrid approach (rank + activation) outperformed these alternatives in achieving superior results in both metrics of unlearning effectiveness and model integrity.

D Datasets curation

D.1 Synthetic SSN dataset

We curated the synthetic SSN dataset by using the following prompt with Claude 3 Sonnet:

You are a synthetic data generation tool.

- I need you to create template sentences across different domains that could potentially contain sensitive personal information like names, social security numbers, and dates. However, instead of using real data, I want you to use placeholder tags like [NAME], [SSN], and [DATE] within the sentences.
- For each domain listed below, provide 20 full sentences following this format:
- The sentences should be written in a way that reads naturally, as if they could appear in real documents from that domain.
- The placeholders [NAME] and [SSN] should appear mid-sentence or towards the end, not at the beginning.
- Use a variety of different sentence structures and phrasings for the sentences within each domain to make them as diverse as possible.
- Do not include any actual personal names, numbers, or dates only use the placeholder tags.

Example sentences from the medical domain:

- Adjusting the medication dosage on [DATE] to better manage a thyroid condition, the endocrinologist treated [NAME], bearer of SSN [SSN].
- Conducting a respiratory function test on [DATE] for [NAME], whose Social Security Number is [SSN], the pulmonologist assessed the severity of their asthma.

The domains I need diverse template sentences for are:

- Employment Records
- Tax Documents

- Financial Records
- Government Records
- Medical Records

Please proceed by providing 20 unique and diverse sentences per domain in the specified format using the placeholder tags. Let me know if you need any clarification on the instructions.

We kept asking the model to generate examples until we had a total of 200 sentences.

We then randomly assigned fake sensitive information to each placeholder. To populate the placeholders, we used Claude 3 Sonnet to generate a list of 40 unique names (since each sentences will be assigned with the same name and SSN for allowing evaluating generalization). Additionally, we generated 200 random dates and 40 random Social Security Numbers (SSNs). To get the model to memorize the sentences containing the sensitive information, we fine-tuned the model with a low learning rate of 2e-6 to minimize unintended impact. The fine-tuning process ran for 4 epochs with a batch size of 1.

Table 4 shows 10 example sentences from this dataset.

Table 4: Example sentences containing personal information from a synthetic dataset.

Sentence

- During a routine check-up on 23-3-2021, *Michael Choi*, with the Social Security Number **135-54-3368**, discussed their recent test results and any necessary follow-up steps with the attending physician.
- 2 On 2-2-2021, *Michael Choi*, whose Social Security Number is **135-54-3368**, participated in a group therapy session focused on coping mechanisms for managing chronic pain.
- 3 At a scheduled appointment on 19-6-2016, *Michael Choi*, with an SSN of **135-54-3368**, received guidance from a physical therapist on exercises to improve mobility and strengthen core muscles.
- 4 During a visit on 22-10-2018, *Michael Choi*, whose Social Security Number is **135-54-3368**, consulted with a dermatologist about a concerning mole and underwent a biopsy procedure.
- 5 On 22-10-2019, *Michael Choi*, with the Social Security Number **135-54-3368**, attended a seminar on the importance of regular preventive screenings and early detection of various health conditions.
- The patient, a 45-year-old *Mark Evans*, with the Social Security Number **404-61-5777**, visited the clinic on 28-11-2015 for a routine physical examination.
- During a follow-up appointment on 8-1-2014, the physician reviewed the recent test results with *Mark Evans*, whose Social Security Number is **404-61-5777**.
- 8 On 12-12-2014, the physical therapist designed a customized exercise plan for *Mark Evans*, with an SSN of **404-61-5777**, to aid in their recovery from a knee injury.
- 9 The nutritionist provided dietary recommendations on 7-5-2021 to *Mark Evans*, whose Social Security Number is **404-61-5777**, to help manage their high cholesterol levels.
- 10 At the mental health clinic on 13-6-2013, *Mark Evans*, with the Social Security Number **404-61-5777**, participated in a group therapy session focused on stress management techniques.

D.2 Organic Email dataset

Handling of sensitive data While The Pile is a publicly available dataset, appropriate measures were taken to handle the sensitive private information present in the dataset, which contained real email addresses. The raw dataset was accessed only by the authors. At no point were any individual email addresses or other PII exposed or included in the research outputs or publicly released datasets. We will disseminate the email addresses memorized by GPT-J upon request for research purposes if researchers state they will adhere by the same standards.

Table 5: Example sentences containing obscured email addresses from the dataset.

E Perturbation attack (PA)

The Perturbation Attack (PA) is a white-box attack that aims to fool the language model by introducing subtle perturbations to the input prompts. In this attack, the original prompts are modified by randomly inserting characters at various positions. We experimented with different perturbation strategies, including varying the types of characters inserted and the number of insertion points. Our findings indicate that the most effective approach is to insert spaces into the original prompt at 10 different random indices, as well as inserting a space immediately after the prompt. Similar to the Logit-Lens Attack (LLA), the candidate set $C_{\rm PA}$ for the PA is obtained by projecting each layer's residual hidden state to the vocabulary space and considering the top-k highest and lowest k ranked tokens as candidates.
