### Abstract

Scalable robot learning in the real world is limited by the cost and safety issues of real robots. In addition, rolling out robot trajectories in the real world can be time-consuming and labor-intensive. In this paper, we propose to learn an interactive real-robot action simulator as an alternative. We introduce a novel method, IRASim, which leverages the power of generative models to generate extremely realistic videos of a robot arm that executes a given action trajectory, starting from an initial given frame. To validate the effectiveness of our method, we create a new benchmark, IRASim Benchmark, based on three real-robot datasets and perform extensive experiments on the benchmark. Results show that IRASim outperforms all the baseline methods and is more preferable in human evaluations. We hope that IRASim can serve as an effective and scalable approach to enhance robot learning in the real world. To promote research for generative real-robot action simulators, we open-source code, benchmark, and checkpoints at https://gen-irasim.github.io.

### 1 Introduction

The field of embodied AI has witnessed remarkable progress in recent years. Real robots are now able to complete a wide variety of tasks [1, 2, 3, 4, 5]. However, real robots are costly, unsafe, and require regular maintenance which may restrict scalable learning in the real world. And rolling out robot trajectories in the real world can be time-consuming and labor-intensive, although it is necessary for model evaluation and reinforcement learning. While efforts have been made to create powerful physical simulators [6, 7, 8, 9], they are still not visually realistic enough. Also, they are not scalable for the reason that it takes effort to build new environments in simulation. What if we can create an interactive real-robot action simulator that can simulate robot trajectories in a way that is both accurate and visually indistinguishable from the real world? With such a simulator, agents can interactively control virtual robots to interact with diverse objects in various scenes in the simulator. It enables robots to improve policies by learning from simulated experiences without safety concerns and maintenance efforts. And the improved policy can consequently produce a large amount of simulated but realistic "real-robot" trajectories for training. Furthermore, the simulator can be leveraged as a dynamics model for imagining outcomes of different proposed candidate actions for model-based reinforcement learning.

Recent advances in generative models showcase extraordinary performance in generating realistic texts [10], images [11], and videos [12]. Inspired by these successes, we take the first step to leverage generative models in building a real-robot action simulator. To this end, we propose IRASim, a novel method that generates extremely realistic videos of a robot executing an action trajectory,

<sup>\*</sup>Corresponding authors.

<sup>&</sup>lt;sup>†</sup>Project lead.

Figure 1: **Overview of IRASim.** IRASim is an interactive real-robot action simulator that allows agents to input an action trajectory to control the "real robot" in an initial frame.

starting from a given initial frame (Fig. 1). We refer to this task as the *trajectory-to-video* task. And in this paper, we focus on predicting videos of robot arms completing manipulation tasks. The trajectory-to-video task differs from the general text-to-video task. While various videos can meet the text condition in the text-to-video task, the predicted video in our trajectory-to-video task must strictly and accurately follow the input trajectory. More importantly, a challenge of this task is that each action in the trajectory provides an exact description of the robot's movement in each frame. This contrasts with the text-to-video task, where textual descriptions offer a general condition without specific frame-by-frame details. Another challenge is that the trajectory-to-video task features rich robot-object interactions, which must adhere to physical laws. For instance, when the robot picks up a bowl and moves, the bowl should move together with the robot. In terms of data, training a trajectory-to-video model only requires trajectory-video pairs, which is very scalable – even failure trajectories can be used for training.

To tackle the trajectory-to-video task, IRASim leverages an innovative frame-level condition method to achieve precise frame-by-frame alignment between actions and video frames. We use the powerful Diffusion Transformer [13] as the backbone of IRASim to improve the modeling of robot-object interactions. IRASim can generate realistic videos of high-resolution (up to  $288 \times 512$ ). To generate long-horizon videos, IRASim can be rolled out in an autoregressive manner and maintain consistency between the generated video clips.

To validate the effectiveness of the proposed method, we develop a new benchmark, IRASim Benchmark, based on three real-robot manipulation datasets: RT-1 [1], Bridge [14], and Language-Table [4]. We perform extensive experiments on this benchmark. Results show that IRASim outperforms comparing baseline methods and is more preferable than other methods in human evaluation on all three datasets. To showcase the interactive capability of our method, we simulate teleoperating the robots in RT-1 [1] and Bridge [14] to move in 3D space and Language-Table [4] in 2D spaces with a vive controller and keyboard, respectively. Unlike previous work that uses texts as the interface between users and the simulator [15], IRASim adopts trajectories as a more robot-centric interface for building simulators. To the best of our knowledge, it is the first work that models the visual dynamics of complicated 7-Dof actions in the real world. We hope this work can serve as a starting point for developing generative realistic real-robot action simulators. To summarize, the contribution of this paper is threefold:

• We propose a novel method, *i.e.* IRASim, capable of generating high-resolution and long-horizon videos for the trajectory-to-video task. It achieves precise alignments between actions and video frames and accurately adheres to physical laws.

- We introduce IRASim Benchmark, a new benchmark based on three real-robot datasets for the trajectory-to-video task. We aim to drive progress on generative real-robot action simulators.
- We perform extensive experiments on the proposed benchmark to show the performance of IRASim. Results demonstrate that our method is able to produce accurate videos that are almost visually indistinguishable from the real world.

# 2 Related Work

**World Models.** Learning a world model (or dynamics model) [16, 17] which predicts future observations based on the current observation and actions has been increasingly popular recently [18, 19, 20, 21, 22, 23, 15, 24, 25, 26, 27]. VLP [25] exploits text-to-video models as dynamics models to generate video plans for robots. DreamerV3 [20] and DayDreamer [21] leverage recurrent state space models (RSSMs) [28] to learn a latent representation of states through modeling a world model for reinforcement learning. GAIA-1 [22] uses a generative model that leverages videos, texts, and actions to generate photorealistic driving scenes. Recently, Genie [24] learns an interactive environment from unlabelled internet videos which allows users to act in the environments via latent actions. Probably, the most relevant work is UniSim [15] which builds a universal simulator for modeling real-world interaction. It generates videos from texts and demonstrates controlling a robot arm to move in 2D space with language instructions. Our method can be considered as a world model for robot manipulation. It takes as inputs real-robot physical actions instead of text [15] or latent actions [24]. Besides 2D actions in previous work [18, 19, 15], IRASim also deals with complex 7-Dof robot actions in 3D space which involves translation, rotation, and gripper actions.

**Video Models.** Video models generate video frames either unconditionally or with conditions including classes, initial frames, texts, strokes, and/or actions [18, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 22, 40, 15, 12, 41, 24, 42]. VideoGPT [30] leverages a simple GPT-like architecture to autoregressively generate VQ-VAE [43] encoded tokens for video generation. Recently, diffusion models [44, 45] are becoming more and more popular in video generation [31, 32, 33, 39, 38, 15, 12]. A popular choice of architecture is U-Net [31, 39] which has also been widely used in image diffusion models [11]. Sora [12] showcases extraordinary video generation capability with Diffusion Transformers [13]. Our method also leverages Diffusion Transformers as the backbone [41, 13]. A relevant line of work is to control video synthesis with motions. These methods use either user-specified strokes [46, 47], bounding boxes [40], or human poses [48, 36] as conditions. Our method differs from previous work in that we seek to model complex 3D real-world actions in the video to learn a real-robot action simulator.

**Scaling Real-World Robot Learning.** Rolling out policies in the real world is essential in scaling up robot learning. Firstly, it is necessary for model evaluation [1, 2, 3, 4, 5]. Secondly, as real-robot data are scarce for the reason that data collection often requires costly human demonstrations, an alternative is to roll out a policy to collect data (*e.g.* dataset augmentation (DAgger) [49, 5, 50]). Finally, real-robot reinforcement learning requires rolling out robots in the real world to collect trajectories [51, 52, 53]. However, policy rollout in the real world is time-consuming. And human supervision is often needed to ensure safety which can be labor-intensive. Moreover, scaling up real-world evaluation would necessitate building and maintaining a large number of robots. To tackle this challenge, recent work [54] shows a correlation between evaluation in a physical simulator and on real robots. Our method aims to build a real-robot action simulator as an efficient and scalable alternative for real-world policy rollout.

### 3 Methods

### 3.1 Problem Statement

We define the trajectory-to-video generation task as predicting the video of a robot that executes a trajectory given the initial frame  $I^1$  and the action trajectory  $a^{1:N-1}$ :

$$\mathbf{I}^{2:N} = f(\mathbf{I}^1, \mathbf{a}^{1:N-1}) \tag{1}$$

where N denotes the number of frames in the video;  $\mathbf{a}^i$  denotes the action at the i-th timestep. In this paper, we focus on predicting videos for robot arms. A typical action space for robot arms contains 7

degrees of freedom (DoFs), *i.e.* 3 DoFs for describing translation in the 3D space, 3 DoFs for 3D rotation, and 1 DoF for the gripper action.

### 3.2 Preliminaries

**Diffusion Models.** Before delving into our method, we briefly review preliminaries of diffusion models [44, 45]. Diffusion models [44] typically consist of a forward process and a reverse process. The forward process gradually adds Gaussian noises to data  $\mathbf{x}_0$  over T timesteps. It can be formulated as  $q(\mathbf{x}_t|\mathbf{x}_0) = \mathcal{N}(\mathbf{x}_t; \sqrt{\overline{\alpha}_t}\mathbf{x}_0, 1 - \overline{\alpha}_t \mathbf{I})$ , where  $\mathbf{x}_t$  is the diffused data at the *t*-th diffusion timestep and  $\overline{\alpha}_t$  is a constant defined by a variance schedule. The reverse process starts from  $\mathbf{x}_T \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$  and gradually remove noises to recover  $\mathbf{x}_0$ . It can be mathematically expressed as  $p_\theta(\mathbf{x}_{t-1}|\mathbf{x}_t) = \mathcal{N}(\mathbf{x}_{t-1}; \mu_\theta(\mathbf{x}_t, t), \Sigma_\theta(\mathbf{x}_t, t))$ , where  $\mu_\theta(\cdot)$  and  $\Sigma_\theta(\cdot)$  denote the mean and covariance functions, respectively, and can be parameterized via a neural network.

In the training phase, we sample a timestep  $t \in [1, T]$  and obtain  $\mathbf{x}_t = \sqrt{\overline{\alpha}_t} \mathbf{x}_0 + \sqrt{1 - \overline{\alpha}_t} \epsilon_t$  via the reparameterization trick [45] where  $\epsilon_t \in \mathcal{N}(\mathbf{0}, \mathbf{I})$ . We leverage the simplified training objective to train a noise prediction model  $\epsilon_{\theta}$  as in DDPM [45]:

$$\mathcal{L}_{\text{simple}}(\theta) = ||\epsilon_{\theta}(\mathbf{x}_t, t) - \epsilon_t||^2$$
(2)

In the inference phase, we generate  $\mathbf{x}_0$  by first sampling  $\mathbf{x}_T$  from  $\mathcal{N}(\mathbf{0}, \mathbf{I})$  and iteratively compute

$$\mathbf{x}_{t-1} = \frac{\mathbf{x}_t - \sqrt{1 - \alpha_t} \epsilon_{\theta}(\mathbf{x}_t, t)}{\sqrt{\alpha_t}}$$
(3)

until t = 0. For conditional diffusion processes, the noise prediction model  $\epsilon_{\theta}$  can be parameterized as  $\epsilon_{\theta}(\mathbf{x}_t, t, \mathbf{c})$  where **c** is the condition that controls the generation process. Throughout the paper, we use superscript and subscript to indicate the timestep of a frame in the input video and the diffusion timestep, respectively.

**Latent Diffusion Models.** Directly diffusing the entire video in the pixel space is time-consuming and requires substantial computation to generate long videos with high resolutions [31]. Inspired by [11, 41], we perform the diffusion process in a low-dimension latent space  $\mathbf{z}$  instead of the pixel space for computation efficiency. Following [39], we leverage the pre-trained variational autoencoder (VAE) in SDXL [55] to compress each frame  $\mathbf{I}^i$  in the video to a latent representation with the VAE encoder  $\mathbf{z}^i = \text{Enc}(\mathbf{I}^i)$  where  $i \in \{1, 2, ..., N\}$ . The latent representation can be decoded back to the pixel space with the VAE decoder  $\mathbf{I}^i = \text{Dec}(\mathbf{z}^i)$ .

### 3.3 IRASim

IRASim is a conditional diffusion model operating in the latent space of the VAE introduced in Sec. 3.2. The condition c includes the latent representation of the initial frame of a video  $z^1 = \text{Enc}(\mathbf{I}^1)$  and an action trajectory  $\mathbf{a}^{1:N-1}$ . The diffusion target is the latent representations of the subsequent N-1 frames of the video in which the robot executes the action trajectory, *i.e.*  $\mathbf{x} = \mathbf{z}^{2:N}$ . Inspired by Sora's remarkable capability of understanding the physical world [12], we similarly adopt Diffusion Transformers (DiT) [13] as the backbone of IRASim. In the design of IRASim, we aim to address three key aspects: 1) consistency with the initial frame 2) adherence to the given action trajectory and 3) computation efficiency. In the following, we describe details of IRASim and discuss pivotal design choices to achieve the aforementioned objectives.

**Tokenization.** Each latent representation  $\mathbf{z}^i = \text{Enc}(\mathbf{I}^i)$  contains P tokens of D dimensions, where P denotes the number of patches per frame. By sequencing the latent representations of all frames by timestep order, the video is tokenized to  $N \times P$  tokens. Spatial and temporal positional embeddings are added to the tokens to allow awareness of patch positions within frames and timesteps in the video, respectively. The VAE is frozen throughout the training process.

**Spatial-Temporal Attention Blocks.** Standard transformer blocks apply Multi-Head Self-Attention (MHA) to all tokens in the input token sequence, resulting in quadratic computation cost. We thus leverage the memory-efficient spatial-temporal attention mechanism [56, 24, 41] in the transformer block of IRASim to reduce the computation cost (Fig. 2). Specifically, each block consists of a spatial attention block and a temporal attention block. In the spatial attention block, MHA is confined to

Figure 2: **Network Architecture of IRASim**. (a) shows the general diffusion transformer architecture of IRASim. The input to IRASim includes the initial frame and the entire trajectory. (b) Frame-level adaptation (Frame-Ada). (c) Video-level adaptation (Video-Ada).

tokens within a frame to model intra-frame interaction. In the temporal attention block, MHA is confined to tokens at an identical patch position across all the frames to model inter-frame interaction. For a sequence of  $N \times P$  tokens, spatial attention operates on the  $1 \times P$  tokens within each frame; temporal attention operates on the  $N \times 1$  tokens across the N timesteps. Compared to attending over all the  $N \times P$  tokens at a time, the spatial-temporal attention greatly decreases the computation cost which makes generating long and high-resolution videos feasible.

**Initial Frame Condition.** The initial frame condition is achieved by treating the initial frame as the ground-truth portion in the input video sequence [12]. That is, during training, we only add noise to the tokens corresponding to the 2nd to the N-th frames  $z^{2:N}$ , while keeping those of the initial frame  $z^1$  intact as it does not need to be predicted (Fig. 2). And the diffusion loss is only computed upon the 2nd to the N-th frames. This condition approach ensures consistency with the initial frame by enabling the predicted frames to interact with it via attention mechanism.

**Trajectory Condition.** A naive approach to impose the trajectory condition is to encode the trajectory as one embedding and append it to the input token sequence as an in-context condition [13]. However, considering Diffusion Transformers [13] demonstrate that adaptive normalization performs better than in-context condition, we adopt this design in IRASim to achieve trajectory condition.

- Video-Level Condition. Similar to using a text embedding to condition the generation of the entire video in the text-to-video task, we use a linear layer to encode the entire trajectory into a single embedding for condition. The embedding is then added to the embedding of the diffusion timestep t for generating the scale parameters  $\gamma$  and  $\alpha$  and the shift parameters  $\beta$  for each spatial and temporal attention block. These parameters control the video generation via shifting the distribution of the token embeddings in the transformer block. The overall framework is shown in Figure 2(c). See Appendix C.1 for more details.
- *Frame-Level Condition*. Unlike the text-to-video task where the text describes the entire video, the trajectory in the trajectory-to-video task is a finer description. Each action in the trajectory defines how the robot should move in each frame. And thus, each generated frame must match with its corresponding action in the trajectory. To achieve this precise frame-level alignment, we condition the generation of each frame by its corresponding action. Instead of encoding the entire action trajectory into a single embedding, we use a linear layer to encode each action into an individual embedding. The diffusion timestep embedding is added to each action embedding to

generate the scale and shift parameters for each individual frame in the spatial block. The scale and shift parameters of the temporal block for all frames share the same conditioning embedding which is derived similarly as in video-level condition. See Appendix C.2 for more details.

**Output.** The output layer contains a linear layer which outputs the noise prediction  $\hat{\epsilon} = \epsilon_{\theta}(\mathbf{x}_t, t, \mathbf{c})$  $\hat{\epsilon}$  is used to compute the L2 loss with the ground-truth noise during training (Eq. 2). Note that IRASim only predicts the mean of the noise but not the covariance as in [13] – we empirically found that this improves video generation quality. During inference, we sample  $\mathbf{x}^T$  from  $\mathcal{N}(\mathbf{0}, \mathbf{I})$  and gradually denoise it via Eq. 3 to obtain the predicted latent representation of the 2nd to the N-th frames  $\hat{\mathbf{z}}^{2:N} = \mathbf{x}_0$ . The predicted video frames can be decoded with the VAE decoder  $\hat{\mathbf{I}}^{2:N} = \text{Dec}(\hat{\mathbf{z}}^{2:N})$ .

# 4 Experiments

In this section, we perform extensive experiments on IRASim Benchmark which includes three challenging real-robot datasets to verify the performance of IRASim. We aim to answer three questions: 1) Is IRASim effective on solving the trajectory-to-video task on various datasets with different action spaces? 2) How do different components contribute to the final performance of IRASim? 3) Can we leverage IRASim as a robot action simulator to allow humans to control robots in an image? More details and results can be found in the Appendix.

### 4.1 IRASim Benchmark

IRASim Benchmark is designed for the trajectory-to-video generation task. We source data from three publicly available robot manipulation datasets: RT-1 [1], Bridge [14], and Language-Table [4]. We split each dataset into training, validation, and test sets. The dataset statistics are shown in Table 3 in Appendix B. In RT-1 and Bridge, a robot arm with a gripper moves in the 3D space to perform manipulation which interacts with objects in the scene. The action spaces of RT-1 and Bridge consist of 1) 6-Dof arm action in the 3D space  $T \in SE(3)$  and 2) a continuous gripper action  $g \in [0, 1]$ . In Language-Table, a robot arm moves in a 2D plane to move blocks with a cylindrical end-effector. The action space is 2-Dof translation in the 2D space  $p \in \mathbb{R}^2$ . See Fig. 1 and 3 for example images of these datasets. We convert the arm action of all datasets to relative delta actions.

# 4.2 Experiment Setup

We perform experiments on IRASim Benchmark. During training, we sample video clips containing 16 continuous frames from episodes using a sliding window. We resize videos, and the resolutions after resizing for RT-1, Bridge, and Language-Table are  $256 \times 320$ ,  $256 \times 320$ , and  $288 \times 512$ , respectively. We perform experiments on video generation on *short trajectories* and *long trajectories*. Short trajectories, which are segments of complete episodes, consist of 16 frames and 15 actions. The video can be generated in one diffusion generation process. For long trajectories, we utilize complete episodes from the dataset. Long videos can be rolled out in an autoregressive manner. The initial frame of the first diffusion process is the given ground-truth frame, while the initial frame of each subsequent diffusion process is the last output frame from the previous process.

**IRASim Variants.** We follow standard transformers which scale the hidden size, number of heads, and number of layers together. In particular, we perform experiments on four configurations: IRASim-S, IRASim-B, IRASim-L, and IRASim-XL. Details of these models are shown in Tab. 7 in Appendix E. If not specified otherwise, throughout the paper, we report the results of IRASim-XL which contains 679M trainable parameters in total. We denote IRASim with frame-level and video-level adaptation as **IRASim-Frame-Ada** and **IRASim-Video-Ada**, respectively.

**Baselines.** To evaluate the effectiveness of IRASim, we compare with two state-of-the-art baseline methods, *i.e.* VDM [31] and LVDM [39]. Both methods are diffusion models based on a U-Net architecture. LVDM diffuses videos in a latent space while VDM operates in the pixel space. These methods demonstrate strong capabilities on the text-to-video task. To impose trajectory conditions on video generation, we encode the trajectory into an embedding to condition the diffusion process in both methods. This is similar to the text embedding used for text-to-video generation in the original papers [31, 39]. LVDM is configured such that its number of parameters is similar to IRASim. As

Figure 3: **Qualitative Results.** We show video generation of IRASim with (a) short trajectories and (b) long trajectories on the test set of RT-1, Bridge, and Language-Table. Ground-truths are in blue boxes. Predictions are in orange boxes. Initial ground-truth video frames are in green boxes.

VDM performs diffusions in the pixel space, it requires more computation resources than LVDM and IRASim despite having a smaller number of 44M parameters. More details about the implementation of baselines can be found in Appendix D.

**Metrics.** Following [36], we evaluate with two types of metrics: computation-based and modelbased. Computation-based metrics includes PSNR [57] and SSIM [58]. Model-based metrics includes includes Latent L2 loss, FID [59] and FVD [60]. Latent L2 loss and PSNR measure the L2 distance between the predicted video and the ground-truth video in the latent space and pixel space, respectively. SSIM evaluates the similarity between videos in terms of image brightness, contrast, and structure. FID and FVD assess video quality by analyzing the similarity of video feature distributions. Unlike the text-to-video task where a variety of videos may meet with a single text condition, the variety is much smaller in the trajectory-to-video task as the robot in the predicted video must strictly

Dataset	Method	Computat	Computation-based		Model-based		
Dutuber		PSNR ↑	SSIM $\uparrow$	Latent L2↓	$\mathrm{FID}\downarrow$	$\mathrm{FVD}\downarrow$

follows the input trajectory. Thus, we prioritize Latent L2 loss and PSNR as primary evaluation metrics. In Sec. 4.3, we will later show that Latent L2 loss and PSNR match with human preference the most among all the metrics.

### 4.3 Results

**Video Generation of Short Trajectories.** Qualitative results are shown in Fig. 3(a) and Fig. 7. Quantitative results are shown in Tab. 1. As shown in Fig. 3(a) and Fig. 7, IRASim-Frame-Ada can generate videos that are almost visually indistinguishable from the ground-truth. IRASim-Frame-Ada performs the best among all the comparing methods in terms of Latent L2 loss and PSNR. It achieves the highest SSIM on RT-1 and Bridge and is comparable with the best baseline method LVDM on Language-Table. In all three datasets, it outperforms IRASim-Video-Ada in all the computation-based metrics. This indicates that frame-level condition enhances consistency between each frame and its corresponding action in the trajectory, as shown in Fig. 7 in the Appendix A.1. IRASim-Frame-Ada also surpasses the two baseline methods based on U-Nets on all three datasets on Latent L2 loss. This demonstrates the superiority of transformer-based model, especially in handling complex 3D actions and robot-object interaction. VDM fails to generate realistic videos despite consuming more computation costs during training. This indicates the effectiveness of performing diffusion in latent space.

**Human Preference Evaluation.** We also perform a user study to help understand human preferences between IRASim-Frame-Ada and other methods. We juxtapose the videos predicted by IRASim-Frame-Ada and the comparing method and ask humans which one they prefer. The ground-truth is also provided as a reference. IRASim-Frame-Ada beats all the comparing methods in all

	RT-1		Bridg	ge	Language-Table	
	Latent L2 $\downarrow$	PSNR $\uparrow$	Latent L2 $\downarrow$	PSNR $\uparrow$	Latent L2 $\downarrow$	$PSNR \uparrow$
LVDM [39]	0.2567	23.573	0.2534	21.792	0.1776	26.215
IRASim-Video-Ada	<u>0.2519</u>	<u>23.984</u>	<u>0.2385</u>	22.868	0.2112	22.551
IRASim-Frame-Ada	0.2408	24.615	0.2306	23.260	0.1730	26.773

Table 2: Quantitative Results on Video Generation of Long Trajectories.

Figure 5: Scaling. IRASim scales elegantly with the increase of model sizes and training steps.

three datasets (Fig. 4). This result aligns with the Latent L2 loss and PSNR which justifies the reason for using them as the primary evaluation metrics.

**Video Generation of Long Trajectories.** Qualitative results are shown in Fig. 3(b) and Fig. 8. Quantitative results are shown in Tab. 2. We compare IRASim with the best baseline method LVDM [39]. IRASim-Frame-Ada consistently outperforms the comparison methods in all three datasets on Latent L2 loss and PSNR. Fig. 3(b) and Fig. 8 show that it retains the powerful capability of generating visually realistic and accurate videos as in the short trajectory setting.

**Scaling.** We follow [13] and train IRASim-Frame-Ada of different model sizes ranging from 33M to 679M. Results are shown in Fig. 5. On all three datasets, IRASim scales elegantly with the increase of model sizes and training steps. This indicates strong potential for increasing model sizes and training steps to further improve the performance.

**Application** To showcase the application of IRASim, we perform experiments on controlling the "real robots" in the three datasets of IRASim Benchmark. For Language-Table [4] with a 2D translation action space, we use the arrow keys from the keyboard to input action trajectories for better accessibility. However, we note that IRASim can handle any 2D translational trajectories as input. For RT-1 [1] and Bridge [14] with a 3D action space, we use the Vive controller to record action trajectories as input. Fig. 6 shows that IRASim can be used as an interactive real-robot action simulator in various ways. In particular, IRASim is able to robustly handle multimodality in generation – Fig. 6(a) shows generating videos with an identical initial frame but different trajectories.

# 5 Limitations and Conclusion

In this paper, we present IRASim, a novel method that generates videos of a robot that executes an action trajectory given the initial frame. Results show that our method is able to generate long-horizon and high-resolution videos that are almost visually indistinguishable from ground-truth videos.

Similar to other generative methods, one limitation of our method is hallucination. Also, the inference speed of IRASim is not real-time, despite having a high throughput – it costs only 8GB memory during inference. Finally, IRASim currently does not support flexible input resolutions and action spaces, restricting its capability to fully utilize robot data of various resolutions and action spaces. In the future, we will investigate incorporating different robot data in training and accelerate the

Figure 6: **Application.** We showcase controlling (a) the virtual robot in Language-Table with arrow keys on a keyboard and (b) the robots in RT-1 and Bridge with a vive controller. Predictions are in orange boxes. Initial Frames are in green boxed.

inference speed via methods including diffusion distillation [61, 62]. Also, we plan to explore using IRASim as a real-robot simulator for collecting simulated trajectories via policies to improve policies with methods including DAgger [49] and RL. We hope that IRASim can serve as a starting point for the development of generative realistic real-robot action simulators and an effective method to accelerate robot learning in the real world for the community.

# A Additional Qualitative Results

In this section, we present additional qualitative results on comparing IRASim with baseline methods.

### A.1 Video Generation of Short Trajectories

Results are illustrated in Fig. 7. These results demonstrate that IRASim-Frame-Ada surpasses other methods in aligning frames with actions and modeling the interaction between robots and objects.

### A.2 Video Generation of Long Trajectories

Results are illustrated in Fig. 8. IRASim-Frame-Ada generates consistent and long-horizon videos, accurately simulating the entire trajectory. Additionally, IRASim-Frame-Ada maintains its superior performance in frame-action alignment and robot-object interaction as observed in the short-trajectory setting.

# A.3 Scaling

Results are shown in Fig. 9. IRASim-Frame-Ada consistently improves the quality of the generated video in terms of reality and accuracy with the increase of model size.

lest	2,167	4,799	1,738	2,946	4,562	5,243

Table 3: Dataset Statistics. An "episode" is a single trial where the robot completes a task. A "sample" is a clip from an episode.

We provide details on the three publicly available robot manipulation datasets used in IRASim Benchmark: RT1 [1], Bridge [14], and Language-Table [4]. A summary of the dataset statistics is presented in Table 3. Each training sample consists of a 4-second video clip containing 16 frames, extracted from an episode with a continuous sliding window. For testing and validation, frames are sampled at 16-frame intervals to reduce the number of evaluation videos and, consequently, lower evaluation costs. The original resolution for RT-1 is  $256 \times 320$ , for Bridge it is  $480 \times 640$ , and for Language-Table it is  $360 \times 640$ . To ensure efficient training, we resize the Bridge videos to a resolution of  $256 \times 320$  and the Language-Table videos to  $288 \times 512$ .

# C IRASim Model Details

In this section, we introduce more details about two types of trajectory condition methods in Sec. 3.3: *Video-Level Condition* and *Frame-Level Condition*.

### C.1 Video-Level Conditioning

In video-level condition (Fig. 2(c)), we first obtain the conditioning embedding  $c_{ST}$  by adding the diffusion timestep embedding to the trajectory embedding. We then use  $c_{ST}$  to regress the scale parameters  $\gamma$  and  $\alpha$ , as well as the shift parameters  $\beta$ . Specifically, the computation of the spatial block is as follows:

$$\mathbf{x} = \mathbf{x} + (1 + \alpha_1) \times \text{MHA}(\gamma_1 \times \text{LayerNorm}(\mathbf{x}) + \beta_1)$$
(4)

$$\mathbf{x} = \mathbf{x} + (1 + \alpha_2) \times \text{FFN}(\gamma_2 \times \text{LayerNorm}(\mathbf{x}) + \beta_2)$$
(5)

where x, with a shape of (N, P, D), denotes the token embeddings. x is reshaped as (P, N, D) before entering the temporal block. The computation of the temporal block is:

$$\mathbf{x} = \mathbf{x} + (1 + \alpha_3) \times \text{MHA}(\gamma_3 \times \text{LayerNorm}(\mathbf{x}) + \beta_3)$$
(6)

$$\mathbf{x} = \mathbf{x} + (1 + \alpha_4) \times \text{FFN}(\gamma_4 \times \text{LayerNorm}(\mathbf{x}) + \beta_4)$$
(7)

Note that layer normalization is performed before scaling and shifting.

### C.2 Frame-Level Condition

In frame-level condition (Fig 2(b)), spatial attention blocks and temporal attention blocks are conditioned differently. The derivation of the conditioning embedding for temporal attention blocks  $\mathbf{c}_T$  is the same as in video-level condition, where we add the diffusion timestep embedding to the trajectory embedding. Different frames are conditioned differently in spatial attention blocks. We denote the conditioning embedding of spatial attention blocks for the i-th frame as  $\mathbf{c}_S^i$ . To derive  $\mathbf{c}_S^i$ , the i-th action in the trajectory is first encoded to an embedding through a linear layer. The diffusion timestep embedding is then added to the encoded embedding to obtain  $\mathbf{c}_S^i$ . We use  $\mathbf{c}_S^1, \ldots, \mathbf{c}_S^N$  and  $\mathbf{c}_T$  to regress the corresponding scale parameters  $\gamma$  and  $\alpha$ , as well as the shift parameters  $\beta$ . While the computation of the temporal blocks is the same as the video-level condition (Eq. 6 and 7), the computation of spatial blocks is different:

$$\mathbf{x}^{i} = \mathbf{x}^{i} + (1 + \alpha_{1}^{i}) \times \text{MHA}(\gamma_{1}^{i} \times \text{LayerNorm}(\mathbf{x}^{i} + \beta_{1}^{i})),$$
(8)

$$\mathbf{x}^{i} = \mathbf{x}^{i} + (1 + \alpha_{2}^{i}) \times \text{FFN}(\gamma_{2}^{i} \times \text{LayerNorm}(\mathbf{x}^{i} + \beta_{2}^{i})).$$
(9)

where  $\alpha_1^i, \gamma_1^i, \beta_1^i, \alpha_2^i, \gamma_2^i, \beta_2^i$  denote the scale and shift parameters for the i-th frame. They are regressed from  $\mathbf{c}_S^i$ .

# **D** Baselines Details

In this section, we detail the baseline implementation. For VDM [31], we leverage the implementation provided in <sup>1</sup>, which utilizes a 3D U-Net architecture for controllable video generation. We use only the model component from this code and keep the training setting consistent with IRASim. LVDM [39] employs the same model architecture as VDM. It performs diffusion in the latent space while VDM performs diffusion in the pixel space. We use an MLP to encode the trajectory into an embedding. It is then concatenated with the embedding of the diffusion timestep to form the conditioning embedding. This is similar to the original methods in the paper where the text embedding is concatenated with the diffusion timestep embedding to form the conditioning embedding. The initial frame condition method of VDM and LVDM is the same as IRASim as described in Sec. 3.3. LVDM and IRASim share the same VAE model and training setting. Given that the resolution of Language-Table [4] is up to  $288 \times 512$ , we resize the video to  $144 \times 256$  in the training of VDM to make the computational cost affordable. During evaluation, we resize the generated video back to  $288 \times 512$  for comparison with other methods. For RT-1 and Bridge, the training of VDM are shown in Tab. 4 and 5. More training hyperparameters that share with IRASim can be found in Tab. 6.

Table 4: Hyperparameters for V	DM	Table 5: Hyperparameters for LVDM

Conditioning embedding dimension	768	Conditioning embedding dimension	768	
Input channels	3	Input channels	3	
Parameters	40M	Parameters	687M	

# **E** Training Details

For all models, we use AdamW [63] for training. We use a constant learning rate of 1e-4 and train for 300k steps with a batch size of 64. The gradient clipping is set to 0.1. We found the training of IRASim very stable – no loss spikes were observed even without gradient clipping. However, loss spikes often occur in LVDM and VDM when gradient clipping is not used. Following [13], we utilize the Exponential Moving Average (EMA) technique with a decay of 0.9999. All other hyperparameters are set the same as [13]. Tab. 6 lists further hyperparameters. All models are trained from scratch. We utilize PNDM [64] with 50 sampling steps for efficient video generation during evaluation. IRASim generates a 16-frame video with a duration of approximately 4 seconds, requiring only 30 seconds on an A100 GPU using 8GB of memory. Although there is still significant room for latency improvement, our method features high throughput and is memory-friendly during inference.

For scaling results in Fig. 5, the configurations of four different sizes of IRASim are shown in Tab. 7. We study the scale performance of IRASim-Frame-Ada since it performs best.

The information about computing resources for training our IRASim is provided in Tab. 8.

# **F** Evaluation Details

We evaluate the video quality generated by IRASim and the baselines under two settings: short trajectories and long trajectories. In the short trajectory setting, the input consists of one initial frame and a short trajectory containing 15 actions, resulting in the generation of 15 subsequent frames. These short trajectories are sampled from episodes using a sliding window with an interval of 16. In the long trajectory setting, the input comprises one initial frame and a complete long trajectory, with the output being the generated subsequent frames. The average lengths of the long trajectories are 42.5, 33.4, and 23.7 frames for RT-1, Bridge, and Language-Table, respectively. These lengths

<sup>&</sup>lt;sup>1</sup>https://github.com/lucidrains/video-diffusion-pytorch

also represent the average number of frames for the generated long videos, which are produced in an autoregressive manner, as detailed in Sec. 4.2. The statistics of the generated short and long videos used for evaluation are presented in Tab. 3.

In all metric calculations, we ignore the initial frame and only evaluate the quality of the generated frames. For PSNR and SSIM, we refer to skimage <sup>2</sup> for calculation. For FID and FVD, we refer to <sup>3</sup> and <sup>4</sup> for calculation, splitting the generated videos into frames and using their codebases to compute the FID and FVD values. However, we do not calculate FID and FVD metrics for long videos because we find that these metrics do not reflect human preferences well, even in the short trajectory setting. This could be because FID and FVD essentially calculate the similarity between the distributions of two datasets, whereas the *trajectory2video* task is a reconstruction task, making reconstruction loss a more suitable evaluation metric.

Table 6: Hyperpara	meters for training IRASim
Hyperparameter	Value
Layers	28
Hidden size	1152
Num attention heads	16
Patch size	2
Input channels	4
Dropout	0.1
Optimizer	AdamW( $\beta = 0.9, \beta = 0.999$ )
Learning rate	0.0001
Batch size	64
Gradient clip	0.1
Training steps	3000000
EMA	0.9999
Weight decay	0.0
Prediction target	$\epsilon$
Parameters	679M

Table 7: Model Sizes. We use IRASim as an abbreviation of IRASim-Frame-Ada for brevity.

Model	Layers	Hidden size	Num attention heads	Parameters
IRASim-S	12	384	6	33M
IRASim-B	12	768	12	132M
IRASim-L	24	1024	16	461M
IRASim-XL	28	1152	16	679M

Table 8:	Compution	resources for	training	IRASim
----------	-----------	---------------	----------	--------

Dataset	Concurrent GPUs	GPU Hours	GPU type
RT-1	32	2381	A800 (40 GB)
Bridge	32	2371	A800 (40 GB)
Lanaguge-Table	32	2369	A100 (80 GB)

# **G** Human Preference Evaluation

Five participants took part in the human evaluation. For each participant, we randomly sampled 10 ground-truth video clips from the test set for each of the 3 datasets. And for each video clip, we

<sup>&</sup>lt;sup>2</sup>https://scikit-image.org/docs/stable/api/skimage.metrics.html

<sup>&</sup>lt;sup>3</sup>https://github.com/mseitzer/pytorch-fid

<sup>&</sup>lt;sup>4</sup>https://github.com/universome/stylegan-v

juxtapose the predictions of IRASim-Frame-Ada with those of VDM, LVDM, and IRASim-Video-Ada (Fig. 10). Thus, a participant evaluated 90 pairs of video clips. Note that the orders of the juxtaposition are random for different clips. See the caption of Fig. 10 for more details. We compare the results of all evaluated video clips and calculate the win, tie, and loss rates. The screenshot of the GUI used in the human evaluation is shown in Fig. 10. The full text of the instruction given to participants is as follows:

### **Evaluation Instructions**

You are asked to choose the more realistic and accurate video from two generated videos (shown above). The ground-truth video is given as a reference (shown below). Please carefully examine the given videos. If you can find a significant difference between the two generated videos, you may choose which one is better immediately. If not, please replay the videos more times. If you are still not able to find differences, you may choose the "similar" option. Please do not guess. Your decision needs solid evidence.

Figure 10: Screenshot of the GUI in Human Preference Evaluation. The two videos in the upper row are generated by IRASim-Frame-Ada and a comparing method, arranged in a random left-right order. The video in the lower row is the ground-truth video.
