Thermodynamics as a fundamental branch of physics examines the relationships between heat, work, and energy. The maximum energy extraction can be characterized by using the passive states that has no extracted energy under any cyclic unitary process. In this paper, we focus on the concept of marginal passive state energy and derive polygon inequalities for multi-qubit entangled pure states. We show that the marginal passive state energies collectively form a convex polytope for each class of quantum states that are equivalent under SLOCC. We finally introduce multipartite passive state energy criteria to classify multipartite entanglement under SLOCC. The present result provides a thermodynamic method to witness multipartite entanglement.

I. INTRODUCTION

Thermodynamics is a fundamental branch of physics that focuses on the relationships between heat, work, and energy in physical systems. A notable area of interest within thermodynamics is the extraction of energy from isolated quantum systems via cyclic Hamiltonian processes [\[1](#page-5-0)[–10\]](#page-5-1). The maximum energy extraction requires to identify quantum states that resist energy extraction. The so-called passive state was introduced in Ref.[\[11\]](#page-5-2). Specially, when considering a state with bare Hamiltonian, the basic question is how can the average energy be extracted through a unitary transformation on the system. If the state remains passive even in the asymptotic limit, it is categorized as completely passive or thermal. The mechanism behind how passive states can yield energy from multiple copies under reversible unitary operations remains unclear. Ongoing research is focusing on energy extraction from non-equilibrium quantum states [\[12–](#page-6-0)[15\]](#page-6-1), the information theory framework in quantum thermodynamics [\[16–](#page-6-2)[18\]](#page-6-3), interpreting passive state energy as an entanglement measure [\[19\]](#page-6-4), the pursuit of achieving Gibbs states through geometric methods [\[20\]](#page-6-5), and the analysis of quantum battery capacity [\[21\]](#page-6-6).

Multipartite quantum states play a crucial role in various quantum technologies such as quantum communication, quantum computing, and interferometry. An important question that arises in the study of these states is whether they can be classified based only on local information. The investigation into this marginal problem originated in the context of the well-known Pauli exclusion principle for fermions [\[22,](#page-6-7) [23\]](#page-6-8). In general, the classification of entanglement involves examining how entanglement behaves under stochastic local operations and classical communication (SLOCC). Recent results have shown that for pure quantum states, information about individual particles alone can be used to detect multipar-

FIG. 1. (Color online). Schematic entanglement classification with marginal passive state energies. Here, the passive state means it has no extracted energy under any cyclic unitary process.

tite entanglement [\[24\]](#page-6-9). Specifically, the spectral vectors of reduced densities of individual subsystems give rise to an entanglement polytope corresponding to each entanglement class under SLOCC. Violations of these generalized polytope inequalities provide an effective method for detecting multipartite entanglement locally. Experimental validation of this entanglement classification approach has been achieved [\[25,](#page-6-10) [26\]](#page-6-11). However, the direct connection between entanglement classification under SLOCC and passive state energy remains unclear. A schematic representation of entanglement classification with passive state energies is depicted in Fig. [1.](#page-0-1)

In this paper, we investigate the relationship between entanglement classification under SLOCC and passive state energy. We focus on the marginal passive state energy in the bipartition scenario involving a single qubit and the remaining qubits. We establish a link between the marginal passive state energies and the geometric entanglement measure. By using polygon inequalities, we prove for multi-qubit pure states that each marginal passive state energy does not exceed the sum of the others. Moreover, we extend to demonstrate that the vec-

[∗] mxluo@swjtu.edu.cn

tors of marginal passive state energies collectively form a distinct polytope for each entanglement class. The present passive state energy polytope not only complements the entanglement polytope but also provides an additional criterion for discerning SLOCC multipartite entanglement classes. We further introduce an indicator related to average energies to distinguish between intertwined entanglement polytopes [\[24\]](#page-6-9). One example is the generalized W states and GHZ states. This indicator highlights SLOCC entanglement classes that cannot be identified using the entanglement polytopes [\[24\]](#page-6-9).

II. THE MARGINAL PASSIVE QUBIT STATES

Consider a finite-dimensional system described by the state ρ on Hilbert space H with Hamiltonian $H =$ $\sum_{i=1}^d \epsilon_i E |\epsilon_i\rangle\langle\epsilon_i|$ with $\epsilon_1 \leq \cdots \leq \epsilon_d$ and unit energy E. The energy of the system is denoted as $E(\rho) = \text{Tr}(\rho H)$. According to the Schrodinger dynamics, the overall unitary evolution operator $U(\tau)$ yields the final state to be $\rho(\tau) = U(\tau) \rho U^{\dagger}(\tau)$. A state is said to be passive if its average energy cannot be decreased through cyclic unitary evolutions [\[1\]](#page-5-0), that is

$$
\operatorname{Tr}(\varrho(\tau)H) \ge \operatorname{Tr}(\varrho H),\tag{1}
$$

which means that no energy can be extracted from the state through a unitary process, as lowering the system's energy would entail transferring it to an energy storage device, in accordance with energy conservation principles.

In general, an n-qubit entangled pure state on Hilbert space $\mathcal{H}_1 \otimes \cdots \otimes \mathcal{H}_n$ can be written into

$$
|\Psi\rangle = \sum_{j=0}^{n} \sum_{s_j=0}^{1} \alpha_{s_1 \cdots s_n} |s_1 \cdots s_n\rangle, \qquad (2)
$$

where $\alpha_{s_1\cdots s_n}$ are the coefficients satisfying the normalization condition of $\sum_{s_1\cdots s_n} |\alpha_{s_1\cdots s_n}|^2 = 1$. Define the reduced density matrix of the qubit i as $\varrho_i, i = 1, \cdots, n$, there are two eigenvalues $\{\lambda_{\min}^{(i)}, 1 - \lambda_{\min}^{(i)}\}$ with $\lambda_{\min}^{(i)} \in$ $[0, \frac{1}{2}]$. Consider all the marginal passive state energies for an *n*-qubit state with subsystem *i*, denoted as E_i . Herein, each qubit i is assumed to be governed by the Hamiltonian $H_i = E|1\rangle\langle 1|$ under local unitary operations for $1 \leq i \leq n$. The composite system is governed by the Hamiltonian $H = \sum_{i=1}^{\hat{n}} H_i \otimes_{k \in \overline{i}} \mathbb{I}_k$, herein, $H_i \otimes_{k \in \overline{i}} \mathbb{I}_k = \mathbb{I}_1 \cdots \mathbb{I}_{i-1} \otimes H_i \otimes \mathbb{I}_{i+1} \cdots \mathbb{I}_n$. The energy of the marginal passive state (EMPS) is then given by

$$
\mathcal{E}_i(|\Psi\rangle) = \lambda_{\min}^{(i)} E = \frac{\mathcal{G}(|\Psi\rangle_{i|\overline{i}})E}{2},\tag{3}
$$

where GME denotes the geometric measure of entanglement [\[27\]](#page-6-12). This reveals a remarkable correspondence between the thermodynamic quantity and the operational information for any $2 \times 2^{n-1}$ -dimensional isolated system.

FIG. 2. (Color online). Schematic polygon inequalities of EMPS. (a) 3-qubit pure states; (b) 5-qubit pure states; (c) 8-qubit pure states. The length of each side corresponds to the value of EMPS.

Consider the spectrum of the reduced density matrices of any *n*-qubit pure state $|\Psi\rangle$ on Hilbert space $\mathcal{H}_1 \otimes \cdots \otimes$ \mathcal{H}_n , the following polygon inequalities hold [\[28\]](#page-6-13):

$$
\lambda_{\min}^{(i)} \le \sum_{j \neq i} \lambda_{\min}^{(j)},\tag{4}
$$

where $\lambda_{min}^{(i)} \in [0, \frac{1}{2}]$ is the smallest eigenvalue of the reduced density matrix ρ_i of the *i*-th qubit. According to $Eq.(3)$ $Eq.(3)$ and the inequality (4) , it implies the following polygon inequalities for the EMPS:

$$
\mathcal{E}_i(|\Psi\rangle) \le \sum_{j \neq i} \mathcal{E}_j(|\Psi\rangle) \tag{5}
$$

with the local Hamiltonian $H_i = E|1\rangle\langle 1|$ for the *i*-th qubit,

Remarkably, the inequality [\(5\)](#page-1-2) guarantee that the EMPSs form a closed *n*-sided polygon. This allows for a geometric representation of the inequality [\(5\)](#page-1-2) as shown in Fig[.2.](#page-1-3) The inequality [\(5\)](#page-1-2) first describes the polygon properties of thermodynamic quantities, going beyond entanglement measure[\[29,](#page-6-14) [30\]](#page-6-15), and differing from monogamous characteristics[\[31\]](#page-6-16).

Let $\mathcal{E}^{\text{tol}}(\ket{\Psi})$ denote the total EMPS for all possible marginal subsystems, that is,

$$
\mathcal{E}^{\text{ToI}}(|\Psi\rangle) = \sum_{j=1}^{n} \mathcal{E}_j(|\Psi\rangle). \tag{6}
$$

This thermodynamic quantity shows the following relation to the EMPS of single qubit as

$$
\mathcal{E}^{\text{ToI}}(|\Psi\rangle) \ge 2\mathcal{E}_j(|\Psi\rangle), j = 1, \cdots, n. \tag{7}
$$

III. MULTI-QUBIT ENTANGLEMENT CLASSIFICATION

The entanglement among quantum systems is highly relevant in thermodynamics, as passive-state energy as a thermodynamic measure of entanglement [\[19\]](#page-6-4). Our goal here is to explore many-body entanglement classification using the EMPSs based on the quantum marginal problem related to the N-representability problem in quantum chemistry $[24]$. Specially, consider an *n*-qubit quantum state $|\Psi\rangle$ on Hilbert space $\otimes_{i=1}^n \mathcal{H}_i$. It exhibits entanglement if it cannot be expressed as the product of individual qubit states [\[33\]](#page-6-17). Two states are deemed equivalent under SLOCC if and only if they can be converted into one another through local invertible operations. Define a characteristic vector of the EMPS as

$$
\mathbf{E}(|\Psi\rangle) = (\mathcal{E}_1(|\Psi\rangle), \mathcal{E}_2(|\Psi\rangle), \cdots, \mathcal{E}_n(|\Psi\rangle))
$$
 (8)

where $\mathcal{E}_i(|\Psi\rangle)$ satisfies the inequality [\(5\)](#page-1-2). Denote $\mathcal{C} = G \cdot \rho$ as the SLOCC entanglement class containing ρ , where G denotes a local invertible action such that $\rho = G \cdot \rho$. From the inequality [\(5\)](#page-1-2) all the EMPSs of any state in $\mathcal C$ consist of a convex polytope.

Theorem 1 The EMPS polytope of an entanglement class $C = G \cdot |\Psi\rangle$ for a given entangled pure state $|\Psi\rangle$ on Hilbert space $\otimes_{i=1}^n \mathcal{H}_i$ is given by the convex hull

$$
\Omega_{\mathcal{C}} = \text{conv}\{\boldsymbol{E}(|\Psi\rangle), \forall |\Psi\rangle\}.
$$
\n(9)

Proof. For an *n*-qubit system. Define the marginal reduced density matrix of the qubit i as ρ_i . For each ϱ_i , let λ_{max}^i be the largest eigenvalue. The vectors $\vec{\lambda} = (\lambda_{\max}^{(1)}, \lambda_{\max}^{(2)}, \cdots, \lambda_{\max}^{(n)})$ corresponding to all pure states within the closure of an orbit under SLOCC transformations constitute a polytope[\[24\]](#page-6-9). Combining with [\[24,](#page-6-9) Theorem 2], it follows Theorem [1](#page-2-0) using the relation [\(3\)](#page-1-0). This has completed the proof. \square

Theorem [1](#page-2-0) reveals thermodynamics meanings of entanglement and provides a criterion for entanglement classification under SLOCC.

For a three-qubit pure state, there exists a one-to-one correspondence between six entanglement classes and the EMPSs. Combining with the entanglement polytopes [\[24\]](#page-6-9), Theorem [1](#page-2-0) implies that the EMPS polytopes of all pure states consist of a convex hull with five vertices as shown in Fig[.3.](#page-2-1)

- Fully separable states. This kind of states corresponds to one vertex of $\Lambda_{\mathcal{S}} = (\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3) = (0, 0, 0);$
- Biseparable states (BS). In addition to rearranging the parties and applying local unitary transformations, the three classes of states can be exemplified by the state $|\psi\rangle_{\mathcal{BS}} = |0\rangle(\alpha|00\rangle + \beta|11\rangle),$ where $|\alpha|^2 + |\beta|^2 = 1$. Focus on one of these cases, as the other two are obtained through simple label permutations. This defines the entanglement polytope, characterized by $0 \leq \mathcal{E}_2 + \mathcal{E}_3 \leq 1$. These polytopes are depicted by the thick straight lines in Fig. [3,](#page-2-1) originating at the vertex $(0,0,0)$. Three vertices, $(0, \frac{E}{2}, \frac{E}{2})$, $(\frac{E}{2}, 0, \frac{E}{2})$ and $(\frac{E}{2}, \frac{E}{2}, 0)$, are for three kinds of biseparable states $|BS\rangle$ = $\frac{1}{2}$ $\frac{1}{2}(|00\rangle + |11\rangle) \otimes |0\rangle$ and its permutations.

FIG. 3. (Color online). The EMPS polytopes of three-qubit pure states.

• The W-class states (the orange tetrahedron). These states can be represented by

$$
|W\rangle = a_1|001\rangle + a_1|010\rangle + a_2|100\rangle \tag{10}
$$

with $\sum_i |a_i|^2 = 1$. For any W-type entanglement [\(10\)](#page-2-2), the vector $(\lambda_{\max}^{(1)}, \lambda_{\max}^{(2)}, \lambda_{\max}^{(3)})$, representing the set of local maximal eigenvalues, resides within the W-type entanglement polytope [\[24\]](#page-6-9). This implies that

$$
\lambda_{\max}^{(1)} + \lambda_{\max}^{(2)} + \lambda_{\max}^{(3)} \ge 2.
$$
 (11)

Assume that the local Hamiltonian $H = E|1\rangle\langle 1|$. Combining with the inequality (11) and Eq. (3) , it follows that the EMPS vector satisfies the following relation as

$$
\mathcal{E}_1 + \mathcal{E}_2 + \mathcal{E}_3 \le E. \tag{12}
$$

• The GHZ-class state (the entire polytope). The entire polytope is for the generalized GHZ states:

$$
|GHZ\rangle = \cos\theta|000\rangle + \sin\theta|111\rangle, \theta \in (0, \frac{\pi}{4}).
$$
 (13)

The inequality [\(12\)](#page-2-4) provides a new classification method for three-qubit pure states under the SLOCC, as shown in Fig[.3.](#page-2-1) Violating the inequality [\(12\)](#page-2-4) by the EMPS witnesses the GHZ-type entanglement. Howbeit, an EMPS vector may fail to fully distinguish different entanglement classes. This can be further resolved by using the following energy indicator as

$$
\eta_E(\ket{\Psi}) = \min_j \left\{ \sum_{k \neq j, k=1}^n \mathcal{E}_k(\ket{\Psi}) - \mathcal{E}_j(\ket{\Psi}) \right\}, \quad (14)
$$

The quantity $\eta_E(|\Psi\rangle)$ characterizes the genuine tripartite entanglement, i.e., it cannot be decomposed into biseparable states in terms of any bipartition S and \overline{S} as $|\Psi\rangle =$ $|\psi\rangle_S \otimes |\phi\rangle_{\overline{S}}$. Otherwise, it is biseparable state.

Proposition 1 Let each qubit be governed by the Hamiltonian $H_i = E|1\rangle\langle 1|$. A three-qubit pure state $|\Psi\rangle$ is genuine tripartite entangled if $\eta_E(|\Psi\rangle) \neq 0$.

Proof. Assume that the quantum state $|\Psi\rangle$ on the Hilbert space $\mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \mathcal{H}_3$ is not genuinely tripartite entangled, i.e., it can be decomposed as follows:

$$
|\Psi_{ijk}\rangle = |\varphi_i\rangle \otimes |\varphi_{jk}\rangle, \tag{15}
$$

$$
|\Psi_{ijk}\rangle = |\phi_i\rangle \otimes |\phi_j\rangle \otimes |\phi_k\rangle, \tag{16}
$$

where $i \neq j \neq k \in \{1, 2, 3\}, \, |\varphi_i\rangle$ and $|\phi_j\rangle$ represent the states of systems i and j, respectively, and $|\varphi_{ik}\rangle$ denotes the state of the joint system jk. In the case of Eq.[\(15\)](#page-3-0), it follows from Eq.[\(3\)](#page-1-0) that $\mathcal{E}_i = 0$, and $\mathcal{E}_j = \mathcal{E}_k$ from the pure state $|\varphi_{jk}\rangle$. Moreover, we can show that $\mathcal{E}_j = \mathcal{E}_i + \mathcal{E}_k$ for all $i \neq j \neq k \in \{1, 2, 3\}$, where \mathcal{E}_j represents the average extracted energy of the marginal passive state for the subsystem j. This implies $\eta_E(|\Psi\rangle) = 0$ for any $j \in \{1, 2, 3\}$. A similar result holds for the case [\(16\)](#page-3-0). \Box

Proposition [1](#page-3-1) provides a method to verify the genuine tripartite entanglement. To show the main idea we consider the generalized GHZ states $|\psi_g\rangle = \cos\theta_1|000\rangle +$ $\sin \theta_1 |111\rangle$, where $\theta_1 \in [0, \pi/4]$, each qubit is governed by the bare Hamiltonian $H = E|1\rangle\langle 1|$. It is easy to check that $\tau(|\psi_g\rangle) = \sin^2 2\theta_1 \neq 0$ if and only if $\theta_1 \neq 0$. Here, τ is a genuine tripartite entanglement measure [\[32\]](#page-6-18). On the other hand, we obtain that $\eta_E(|\psi_g\rangle) = \sin^2 \theta_1 E \neq 0$ if and only if $\theta_1 \neq 0$. This implies that $|\psi_q\rangle$ is a genuine tripartite entanglement.

As a complement to Theorem 1, the indicator $\eta_E(|\Psi\rangle)$ provides a finer criterion for classifying multi-qubit pure states under the LOCC.

IV. EXAMPLES

Example 1. Considering a generalized *n*-qubit W state on the Hilbert space $\otimes_{i=1}^n \mathcal{H}_i$ given by:

$$
|W_n\rangle = \sum_{i=1}^n \sqrt{a_i} |\vec{1}_i\rangle_{1\cdots n},\tag{17}
$$

where $\vec{1}_i$ denotes all zeros except for the *i*-th component being 1, and a_i satisfies $\sum_{i=1}^n a_i = 1$ with $a_1 \geq \cdots \geq a_n$. Let's assume that each qubit i is governed by the bare Hamiltonian $H_i = E|1\rangle\langle 1|$ for $1 \leq i \leq n$. From Eq.[\(3\)](#page-1-0), if there exists an $a_i > 1/2$, it implies that $\mathcal{E}_i(|W_n\rangle) =$ $(1 - a_i)E$ and $\mathcal{E}_j(|W_n\rangle) = a_jE$ for $j \neq i$. Conversely, for all $a_i < \frac{1}{2}$, we obtain that $\mathcal{E}_i(|W_n\rangle) = a_i E$ for any $1 \leq i \leq n$. This further implies that

$$
\mathcal{E}^{\text{ToI}}(|W_n\rangle) = \begin{cases} 2(1-a_i)E < E, \quad \exists i, a_i > \frac{1}{2}, \\ E, & \forall i, a_i < \frac{1}{2}. \end{cases} \tag{18}
$$

Hence, we obtain that $\mathcal{E}^{\text{ToI}}(|W_n\rangle) \leq E$ for any *n*-qubit W state. This means that the generalized W state with $a_i < 1/2$ for any *i* lies on the facet of $\mathcal{E}^{\text{tol}}(|W_n\rangle) = E$.

Example 2. Consider a generalized *n*-qubit GHZ state on Hilbert space $\otimes_{i=1}^n \mathcal{H}_i$ given by

$$
|GHZ_n\rangle = (\cos\theta|0\rangle^{\otimes n} + \sin\theta|1\rangle^{\otimes n})_{1\cdots n} \qquad (19)
$$

with $\theta \in (0, \frac{\pi}{4}]$. For each qubit the bare Hamiltonian is given by $H = E|1\rangle\langle 1|$. According to Eq.[\(3\)](#page-1-0), the EMPS for the subsystem i is given by $\mathcal{E}_i(|GHZ_g\rangle) = \sin^2 \theta E$. This implies that

$$
\mathcal{E}^{\text{Tol}}(|GHZ_n\rangle) = n\sin^2\theta E \le nE,\tag{20}
$$

where the maximum EMPS is obtained from the maximally entangled *n*-qubit GHZ state, i.e., $\theta = \pi/4$. Moreover, we have

$$
\mathcal{E}^{\text{Tol}}(|GHZ_n\rangle) > E\tag{21}
$$

for $\theta > \arcsin \sqrt{1/n}$. The generalized GHZ state with $\theta > \arcsin \sqrt{1/n}$ does not belong to the facet determined by the generalized n -qubit W state in Example 1. This provides a way to distinguish two entanglement classes by using the facet of $\mathcal{E}^{\text{tol}} = E$.

For the case of $\theta < \arcsin \sqrt{1/n}$, we obtain that

$$
\mathcal{E}^{\text{Tol}}(|GHZ_n\rangle) < E. \tag{22}
$$

According to Eqs. [\(22\)](#page-3-2) and [\(18\)](#page-3-3), the presence of overlapping regions fails to distinguish W-type entanglement from GHZ-type entanglement. The indicator η_E in Eq.[\(14\)](#page-2-5) may be used to certify the entanglement as

$$
\eta_E(|W_n\rangle) = 0, \exists i, a_i > \frac{1}{2},\tag{23}
$$

$$
\eta_E(|GHZ_n\rangle) = (n-2)\sin^2\theta E > 0, \quad \forall i. \quad (24)
$$

Moreover, for the case of $\theta = \arcsin \sqrt{1/n}$, we obtain

$$
\eta_E(|GHZ_n\rangle) = \frac{(n-2)E}{n}.\tag{25}
$$

Meanwhile, for the generalized W state we obtain

$$
\eta_E(|W_n\rangle) = (1 - 2a_i)E, \forall i, a_i < \frac{1}{2}.\tag{26}
$$

This implies $\eta_i(|GHZ_n\rangle) \neq \eta_i(|W_n\rangle)$ for any one a_i satisfying $a_i \neq 1/n$. This means the generalised GHZ state can be distinguished from all the almost generalized W states except for the maximally entangled W state beyond recent result [\[24\]](#page-6-9).

Example 3. Consider an *n*-qubit Dicke state with l excitations [\[34\]](#page-6-19) :

$$
|D_n^{(l)}\rangle_{12\cdots n} = \frac{1}{\sqrt{\binom{n}{l}}} \sum_{\mathsf{g}\in S_n} \mathsf{g}(|0\rangle^{\otimes n-l}|1\rangle^{\otimes l}),\tag{27}
$$

where $1 \leq l \leq n-1$. Here, the summation is taken over every possible permutation on $g \in S_n$ of the product states containing $n - l$ number of $|0\rangle$ and l number of

 $|1\rangle$, S_n denotes the permutation group on *n* items, and $\binom{n}{l}$ denotes the combination number of choosing l items from n items. For each qubit the bare Hamiltonian is given by $H = E|1\rangle\langle 1|$. Due to the symmetry of the *n*qubit symmetric Dicke states, the reduced density matrix of any subsystem i is:

$$
\varrho_i = \frac{n-l}{n} |0\rangle\langle 0| + \frac{l}{n} |1\rangle\langle 1|.
$$
 (28)

Using Eq. (3) , we find:

$$
\mathcal{E}_i(|D_n^{(l)}\rangle) = \frac{lE}{n} \quad \text{for } l \le \frac{n}{2},\tag{29}
$$

and for $l > \frac{n}{2}$:

$$
\mathcal{E}_i(|D_n^{(l)}\rangle) = \frac{nE - lE}{n}.\tag{30}
$$

According to Eq.[\(6\)](#page-1-4), the total energy follows a general polytope facet:

$$
\mathcal{E}^{\text{Tol}}(|D_n^{(l)}\rangle) = \begin{cases} lE, & \text{if } l \leq \frac{n}{2};\\ nE - lE, & \text{if } l > \frac{n}{2}. \end{cases}
$$
(31)

In particular, when $l = 1$ and $n \geq 3$, the *n*-qubit Dicke state reduces to the n -qubit W state, leading to $\mathcal{E}^{\text{ToI}}(|W\rangle) = E$. For any generalized Dicke states:

$$
|\hat{D}_n^{(l)}\rangle = \sum_{\mathsf{g}\in S_n} \alpha_{\mathsf{g}} \mathsf{g}(|0\rangle^{\otimes n-l}|1\rangle^{\otimes l})_{12\cdots n},\tag{32}
$$

where the coefficients α_{g} depend on the permutation $g \in$ S_n and satisfy $\sum_{g}^{n \choose l} \alpha_g^2 = 1$. Due to symmetry, $\mathcal{E}_i(|\hat{D}_n^{(l)}\rangle)$ is maximized when $\alpha_{\mathsf{g}} = 1/\sqrt{\binom{n}{l}}$ for each α_{g} , leading to:

$$
\mathcal{E}^{\text{Tol}}(|\hat{D}_n^{(l)}\rangle) \le \begin{cases} lE, & \text{if } l \le \frac{n}{2};\\ nE - lE, & \text{if } l > \frac{n}{2}. \end{cases}
$$
(33)

This shows that generalized Dicke states are below the facet of $\mathcal{E}^{\text{Tol}}(|\hat{D}_n^{(l)}\rangle) < lE$, while *n*-qubit Dicke states $|D_n^{(l)}\rangle$ lie on the facet of $\mathcal{E}^{\text{Tol}}(|D_n^{(l)}\rangle) = lE$. This observation provides a method for distinguishing Dicke states with different excitations that are inequivalent under the $SLOCC$, indicating that *n*-qubit Dicke states with different excitations lie on different facets.

Example 4. Consider a noisy W state as

$$
\varrho_W = (1 - v_1)|W\rangle\langle W| + \frac{v_1}{8} \mathbb{1}_8,\tag{34}
$$

and the noisy GHZ state

$$
\varrho_{GHZ} = (1 - v_2)|GHZ\rangle\langle GHZ| + \frac{v_2}{8}1_8,\tag{35}
$$

where $\mathbb{1}_8$ denotes the identity matrix of rank 8, $|W\rangle$ and $|GHZ\rangle$ are maximally entangled states which are respectively defined as $|W\rangle = \frac{1}{\sqrt{2}}$ $\frac{1}{3}(|100\rangle + |010\rangle + |001\rangle)$ and

 $|GHZ\rangle = \frac{1}{\sqrt{2}}$ $\frac{1}{2}(|000\rangle + |111\rangle)$. Here, each qubit *i* is governed by the Hamiltonian $H_i = E|1\rangle\langle 1|$ for $1 \leq i \leq 3$. These states are genuinely multipartite entangled for $v_1 < 9/17$ [\[35\]](#page-6-20) and $v_2 < 4/7$ [\[36\]](#page-6-21), respectively.

Consider any subsystem $i \in \{A, B, C\}$, the spectrum of reduced state ϱ_i for ϱ_W are given by $\{(4$ $v_1/6$, $(2+v_1)/6$. The extremal energy of the subsystem $i \in \{A, B, C\}$ is shown as $\mathcal{E}_i(\varrho_W) = (2E + v_1E)/6$. From Eq.[\(6\)](#page-1-4) we obtain that

$$
\mathcal{E}^{\text{ToI}}(\varrho_W) = \sum_i \mathcal{E}_i(\varrho_W) = \frac{2E + v_1 E}{2} < \frac{43E}{34} \tag{36}
$$

for $0 < v_1 < 9/17$. For noisy GHZ states, the reduced states of single qubit are completely mixed state $\frac{1}{2}\mathbb{I}$. This implies that $\mathcal{E}_i(\varrho_{GHZ}) = E/2$, which further follows that

$$
\mathcal{E}^{\text{ToI}}(\varrho_{GHZ}) = \frac{3E}{2} > \mathcal{E}^{\text{ToI}}(\varrho_W). \tag{37}
$$

So, the quantity of \mathcal{E}^{ToI} can be used to distinguish the noisy W states from the noisy GHZ states.

Using the average extracted energy of the passive state for the subsystem allows distinguishing the W-type entanglement from the GHZ-type entanglement. This is going beyond the capabilities of entanglement polytopes [\[24\]](#page-6-9). The following example shows that the energy indicator can be applied to characterize the genuine multipartite entanglement.

Example 5 Consider a chain of N spins, where each spin can be either up $(+1)$ or down (-1) . The Hamiltonian is given by

$$
H_0 = -J\sum_{i=1}^{N-1} s_i s_{i+1} - h\sum_{i=1}^{N} s_i,
$$
 (38)

Here, J represents the coupling constant that signifies the intensity of interaction among adjacent spins, h is the external magnetic field, and s_i represents the spin at site i . In this model, the spins tend to align with their neighbors to minimize the energy of the system. This model can be rewritten in terms of Pauli matrices into

$$
H = -J \sum_{i=1}^{N-1} s_i^z s_{i+1}^z - h \sum_{i=1}^N s_i^z,
$$
 (39)

where $s_z = \frac{1}{2}\sigma_z$. The simulation of η defined in Eq.[\(14\)](#page-2-5) is shown in Fig[.4.](#page-5-3) Here, the genuine multipartite entanglement can be verified by using a simple standard from the additive of von Neumann entropy, i.e., it is genuinely multipartite entangled pure state if $\min_{i,j} |S(\rho_{ij})-S(\rho_i) S(\rho_i) > 0$, where S denotes the von Neumann entropy and ρ_i , ρ_{ij} denote the reduced matrices. This kind of the nearest-correlated system can generate the genuine multipartite entanglement. Moreover, we consider another system with long-range correlations. The Hamiltonian is given by

$$
H = H_0 + 4\sigma_2^x \sigma_3^x \sigma_4^x + 3\sigma_1^x \sigma_3^x \sigma_4^x \sigma_5^x + 3\sigma_1^x \sigma_2^x \sigma_4^x \sigma_5^x. (40)
$$

FIG. 4. (Color online). Genuinely multipartite entanglement of Ising chain model. In simulation, the Hamiltonian 1 is de-fined in Eq.[\(39\)](#page-4-0) with $N = 5$, the coupling constant $J = 1$ and external magnetic field $h = 1$. The Hamiltonian 2 is de-fined in Eq.[\(40\)](#page-4-1) with long-range correlations. Energy (η_E/E) denotes the energy indicator of the marginal passive states with bare Hamiltonian $H = E|1\rangle\langle 1|$. Entropy denotes the entanglement measure $\min_{i,j} |S(\rho_{ij}) - S(\rho_i) - S(\rho_j)|$, where S denotes the von Neumann entropy and ρ_i , ρ_{ij} denote the reduced matrices.

Both entanglement measure can be used to characterize the genuine multipartite entanglement. Although it is difficult to characterize all the genuine multipartite entanglement, the present energy indicator is useful for pure states. It is valuable for further exploration of entanglement classification and entanglement measure.

Conclusion. We have established a correspondence between the geometric measure of entanglement and EMPS. We proved a polygon inequality for arbitrary n qubit pure states in terms of the EMPS. Associated with these inequalities, we have shown that the possible sets of all marginal passive state energies form a convex polytope. This reveals a physical interpretation of the entanglement polytopes, as well as provides a tool to detect entanglement in multi-qubit systems. Moreover, a set of multipartite EMPS indicators has been introduced

to distinguish the overlapping polytope of different entanglements in ref.[\[24\]](#page-6-9). This provides new insights of entanglement classifications going beyond the one-body quantum marginal quantities.

Given the profound analogies between thermodynamic quantities and entanglement, the passive-state energy provides a good entanglement measure for the pure bipartite states [\[19\]](#page-6-4). This may lead to the possibility of capturing the signature of genuineness in multipartite entanglement from the passive state energy. Furthermore, it is still unknown whether the set of EMPS for multipartite mixed states forms a convex polytope.
