Abstract

Background

We propose a novel method to identify who may likely have clonal hematopoiesis of indeterminate potential (CHIP), a condition characterized by the presence of somatic mutations in hematopoietic stem cells without detectable hematologic malignancy, using deep learning techniques.

<u>Methods</u>

We developed a convolutional neural network (CNN) to predict CHIP status using 4 different views from standard delayed gadolinium-enhanced cardiac magnetic resonance imaging (CMR). We used 5-fold cross validation on 82 cardio-oncology patients to assess the performance of our model. Different algorithms were compared to find the optimal patient-level prediction method using the image-level CNN predictions.

Results

We found that the best model had an area under the receiver operating characteristic curve of 0.85 and an accuracy of 82%.

Conclusions

We conclude that a deep learning-based diagnostic approach for CHIP using CMR is promising.

1. Introduction

Clonal hematopoiesis of indeterminate potential (CHIP) is an age-related premalignant condition, characterized by the presence of clonally expanded hematopoietic stem cells caused by a leukemogenic mutation in individuals without evidence of hematologic malignancy (Marnell et al., 2021). CHIP is an independent risk factor for cardiovascular diseases (CVDs), such as atherosclerosis, myocardial infarction, and congestive heart failure (Mooney et al., 2021). We previously showed that CHIP is more prevalent in cancer patients compared to noncancer patients and CHIP is an independent risk factor for development of cardiomyopathy in this cohort (Leveille E, et al 2024). Cardiovascular disease is one of the leading causes of morbidity and mortality worldwide; thus, being able to augment the identification of CHIP beyond DNA sequencing is imperative. Further, although CHIP independently increases the risk of heart disease and heart failure, not all CHIP patients develop these adverse cardiovascular events. Thus, use of machine learning approaches can potentially identify imaging features that can risk stratify who may develop CVD amongst CHIP patients.

Traditionally, CHIP is diagnosed through next-generation sequencing (NGS), a technique that can determine a person's DNA sequence. For this, however, the patient's blood or bone marrow sample must be acquired, almost always through invasive means. As NGS can take hours to days to return a result as well, a quicker, non-invasive method for evaluation of CHIP becomes more desirable.

Our preliminary data shows that CHIP is associated with increased fibrosis pathways in human engineered heart tissue and increased burden of delayed gadolinium enhancement (DGE) in cardiac magnetic resonance imaging (CMR). DGE is the method of choice for detecting myocardial fibrosis in magnetic resonance imaging. Of note, most cardio-oncology patients undergo routine clinical CMR to evaluate for cardiotoxicity. Thus, we sought to explore whether

3

fibrosis burden and fibrosis features on CMR via DGE signatures could indicate if the patient had CHIP in our cardio-oncology population.

2. Methods

We consented and enrolled patients from the cardio-oncology service or clinic in an IRB approved study at Yale, and collected blood samples to determine CHIP status. CHIP status was determined by whole exome sequencing of genomic DNA from peripheral blood with targeted primers against known CHIP genes with a median sequencing depth of 1000x coverage. To evaluate radiomic features associated with CHIP, we pulled the CMR images from 98 patients who also had clinical CMRs done. An anonymized collection of DGE CMR images from these patients were pulled. After filtering out for missing data, 82 patients with a complete set of DGE images with multiple-views were included in subsequent analysis. Chart review was performed to determine demographic and co-morbidity data.

CMR was performed on 1.5T, with DGE evaluation performed 8-10 minutes after administration of contrast. Each patient had up to 4 different views in their collection of CMRs: short-axis view (SAS); 4-chamber view (4CH); vertical long axis (VLA); and left ventricular outflow view (LVOT). Multiple views were incorporated into the prediction model so that we could capture a more complete overview of the heart. Each patient had up to 5-7 SAS views for their CMRs, but only one CMR image for the other 3 views; some patients had fewer SAS images and/or were missing one or more of the other 3 views. Missing views were replaced by images with all 0s.

The CHIP identification model was a CNN designed for binary classification (Fig. 1), with 4 convolutional layers and 3 max pooling layers. Uniquely, we incorporated all 4 CMR views as inputs to the model. Each view underwent processing by the convolutional layers, and features from the final convolutional layer were concatenated and processed by fully connected layers. The output of the model gave the probability of CHIP based on the 4-view CMR sample.

4

The model was trained using a 5-fold cross validation framework in order to assess the performance of the model. Each fold contained between 14 and 15 patients; we ensured that all CMR images belonging to the same patient were in the same fold. Each of the 5 folds were used once as a test set, while the other 4 folds were combined to be the training set. In addition to standard image data augmentation techniques, as the SAS view included multiple image slices, random combinations of the 4 views were used to augment the number of samples. The model for each fold was trained using binary cross-entropy loss for 300 epochs and then evaluated on the test set. The evaluation profiles were then combined to give an overview of the model architecture's performance in the binary classification task using receiver operating characteristic (ROC) curve analysis, including measuring area under the curve (AUC) and accuracy.

Note the model classification is on an "image-level" - that is, it is classifying each of the image sets (one CMR from each of the 4 views) into one of the two categories, "CHIP" or "NO CHIP". To extend this to the "patient-level" - that is, combining the predictions for all the images belonging to a patient to make a single classification for the patient themselves - we tested different thresholding approaches for combining the image-level predictions to make a prediction for the patient. Specifically, two approaches were explored: 1) the ratio thresholding method, which took the portion of the image sets belonging to a patient that were classified in the CHIP category, and if the ratio was greater than the threshold (=0.4), the patient was classified as CHIP; and 2) the max thresholding method, which classified a patient as CHIP if the patient's 4-view image set with maximum probability of CHIP was greater than the threshold.

3. Results

The mean age of the cohort was 65 years old +/- 13 years. 66% were female. 24% had arrhythmias, 61% had CAD, 13% had diabetes, 41% had cardiomyopathy and 46% had

5

hypertension. The most common cancer type was breast cancer (41%), followed by lung (19%), followed by genitourinary (10%), skin (9%), and renal (6%). Patients were previously on anthracyclines (31%), HER2 inhibitors (16%) and immune checkpoint inhibitors (49%) with no significant difference between those with CHIP or no CHIP (p=0.828, 0.179, 0.100 respectively). 42% of patients were found to have CHIP in this cohort. The most common CHIP gene variant was DNMT3A (40%), followed by TET2 (18%) and PPM1D (15%).

The model classification results are shown in Fig. 2. We found that between the two thresholding methods, the ratio-thresholding approach performed much better than the max-thresholding method (AUC=0.85 vs. AUC=0.63). In addition, using the ratio-thresholding method, our approach was able to predict the patient's CHIP status with an accuracy of 82%.

4. Conclusions

In conclusion, we proposed a novel approach for determining CHIP from multi-view DGE CMR in cardio-oncology patients. Our promising early results suggest non-invasive, routine imaging may show who is likely to have CHIP in this high risk population. Future work will extend validation of our approach on large public datasets (e.g., TOPMed and UK Biobank) and apply model interpretation techniques (Adebayo et al., 2018) to identify CMR biomarkers for CHIP as well as imaging features that can predict adverse cardiovascular outcomes in CHIP patients with or without cancer.
