Abstract—Sparsely-activated Mixture-of-Expert (MoE) layers have found practical applications in enlarging the model size of large-scale foundation models, with only a sub-linear increase in computation demands. Despite the wide adoption of hybrid parallel paradigms like model parallelism, expert parallelism, and expert-sharding parallelism (i.e., MP+EP+ESP) to support MoE model training on GPU clusters, the training efficiency is hindered by communication costs introduced by these parallel paradigms. To address this limitation, we propose Parm, a system that accelerates MP+EP+ESP training by designing two dedicated schedules for placing communication tasks. The proposed schedules eliminate redundant computations and communications and enable overlaps between intra-node and inter-node communications, ultimately reducing the overall training time. As the two schedules are not mutually exclusive, we provide comprehensive theoretical analyses and derive an automatic and accurate solution to determine which schedule should be applied in different scenarios. Experimental results on an 8-GPU server and a 32-GPU cluster demonstrate that Parm outperforms the state-of-the-art MoE training system, DeepSpeed-MoE, achieving $1.13\times$ to $5.77\times$ speedup on 1296 manually configured MoE layers and approximately $3\times$ improvement on two real-world MoE models based on BERT and GPT-2.

Index Terms—Large Language Models, Distributed Training, Mixture-of-Experts, Task Scheduling

I. INTRODUCTION

The generalization performance of foundation models is predominantly influenced by their scale [1] (e.g., GPT-2 [2] with 1.5 billion parameters and GPT-3 [3] with 175 billion parameters). However, the immense size of these models inevitably demands substantial computing resources. For instance, training GPT-3 requires 3.14×10^{23} FLOPs [3], which is a daunting amount of computation. This has raised concerns about the feasibility of expanding these models further. In recent years, sparsely-activated Mixture-of-Experts (MoE) layers have gained significant attention for increasing model size while demanding only a sub-linear increase in computation [4]–[7]. An MoE layer incorporates multiple experts, each typically a feed-forward block trained for specific subtasks. It employs a gating mechanism, often implemented using softmax activation [7], to dynamically determine which experts are trained with which samples. As a result, it enables scaling up

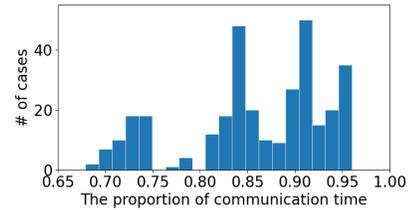

Figure 1: The communication time ratio varies across different configurations, ranging from 67.92% to 96.02% when using 32 Nvidia GeForce RTX 2080Ti GPUs. Detailed configurations for test cases can be found in Table III.

the model size while requiring a relatively smaller computing cost. For example, Switch Transformer [8] scales to 1.5 trillion parameters with MoE.

As the scale of foundation models continues to grow, various parallel paradigms are emerging to meet the growing computational demands. For traditional models, three commonly used parallel paradigms (also known as 3D parallelism [9]) are: *Data Parallelism* (DP) [10], *Model Parallelism* (MP) [10], and *Pipeline Parallelism* (PP) [11]. For MoE-based models, two additional parallel paradigms are involved: *Expert Parallelism* (EP) [6] and *Expert-Sharding Parallelism* (ESP) [12]. EP places experts across multiple devices when a single device cannot accommodate all experts. It dynamically assigns each input to particular experts using an AlltoAll collective communication known as *AlltoAll Dispatch*. Another AlltoAll collective communication, named *AlltoAll Combine*, then gathers the computed results from experts. On the other hand, ESP further divides a single expert into multiple shards and executes across multiple devices in parallel when a single expert cannot be stored on one device. EP and ESP are commonly used in conjunction to distribute the workload of an MoE layer across multiple devices, thereby enabling efficient parallel computing [12,13] in large-scale training scenarios.

Nevertheless, the training performance of MoE-based models in GPU or TPU clusters is hampered by the communication time introduced by various parallel paradigms. As reported in [7,13,14], the AlltoAll communication time occupies 30% to 60% of the overall time of the MoE layers on high-end GPU

*Corresponding author.

or TPU clusters. This situation worsens when using multiple parallel paradigms such as MP, EP, and ESP (MP+EP+ESP) simultaneously. To delve deeper into this issue, we measured the communication time (including communication introduced by DP, MP, EP, and ESP) for 324 different configurations of MoE layers using 32 Nvidia GeForce RTX 2080Ti GPUs, as shown in Fig. 1. Our findings reveal that the communication time significantly dominates the training time of an MoE layer. In summary, training large MoE-based models on GPU clusters poses a significant performance challenge.

Prior research has endeavored to tackle the performance challenges in training MoE-based foundation models from three distinct directions. First, algorithm-level innovations, exemplified by works like [7] and [8], aim to design load-balancing gates that ensure more balanced network traffic across GPUs. Second, system-level studies, such as [15] and [16], focus on devising AlltoAll algorithms that are tailored to specific network topological architectures. Lastly, scheduling techniques [12,17]–[19] have been proposed to explore the overlap of AlltoAll communications and computing tasks in the MoE layer to enhance GPU utilization. However, these studies have primarily concentrated on mitigating AlltoAll communication costs incurred in EP alone, while largely neglecting the other communication costs arising from MP and ESP.

In this paper, we propose two dedicated and complementary schedules (say S_1 and S_2) for placing communication tasks specifically tailored for the MP+EP+ESP scenario. The highlights of the proposed schedules are: 1) they eliminate redundant computations to reduce computation time, 2) they decrease the overall communication volume to reduce communication time, and 3) they enable overlapping between intra-node and inter-node communications to optimize bandwidth utilization. However, S_1 and S_2 have distinct communication volumes, which depend on the model and environment configurations, making them suitable for different scenarios. Hence, we develop an automatic and accurate solution to determine which schedule applies during training. To achieve this, we conduct thorough theoretical analyses for the time performance of the baseline schedule, S_1 , and S_2 . Based on these analyses, we derive a closed-form solution for choosing S_1 or S_2 to achieve shorter training time. Integrating the two designed schedules and the automatic schedule decision scheme, we develop a prototype system named Parm atop PyTorch for training large MoE models.

We perform extensive experiments on an 8-GPU server and a 32-GPU cluster to compare Parm with DeepSpeed-MoE [12], the current state-of-the-art MoE training system. The experimental results show that our Parm outperforms DeepSpeed-MoE significantly. Specifically, when evaluated on the configured 1296 valid runnable MoE models, Parm achieves $1.13\times$ to $5.77\times$ speedups over DeepSpeed-MoE on our testbeds. For two real-world MoE models based on BERT and GPT-2, Parm trains the models $2.98\times$ – $3.15\times$ faster than DeepSpeed-MoE.

II. BACKGROUND AND PRELIMINARIES

For ease of presentation, we summarize the key notations used throughout the paper in Table I.

Table I: Notations.

| Name | Description |
|------|--|
| P | # of workers (or GPUs) in the cluster |
| B | # of samples per GPU (or local mini-batch size) |
| L | # of tokens per sample (or sequence length) |
| T | # of assigned tokens per expert |
| E | total number of experts |
| M | embedding size of a token |
| H | hidden size of the feed-forward layer in experts |
| k | top- k experts should be selected for each token |
| f | factor to control expert’s maximum token count |

A. Mixture-of-Experts Layer

Mixture-of-experts (MoE) layers offer a cost-effective approach by selectively activating specific experts for particular inputs, resulting in a sub-linear increase in computational costs when adding more parameters.

Specifically, the MoE layer consists of two primary components: a gating function and a set of E experts. MoE models inherit the dense model and use the MoE layer to replace the dense feed-forward layer (FFN). During training, the input tensor I for the MoE layer has a shape of (B, L, M) , i.e., $I \in \mathbb{R}^{B \times L \times M}$, where B represents the mini-batch size, L represents the sequence length per sample, and M represents the embedding size of a token.

Gating Function. The gating function determines which tokens should be processed by each expert. It takes the input tensor I and applies a gating function g , which typically consists of a small feed-forward neural network (usually with one linear layer) and a routing function (with a softmax layer and top- k selection). The output tensor $G \in \mathbb{R}^{E \times T \times M}$ is generated, where T is the maximum number of tokens assigned to an expert. The softmax function’s dynamic nature may lead to an imbalanced workload across different GPUs, with some experts processing more tokens than others. To address this, a capacity factor f is used to limit the maximum number of tokens assigned to an expert, that is $T := k \times f \times B \times L/E$. Each row of G ($G[i, :, :]$) corresponds to the data that should be dispatched to expert i ($i = 1, 2, \dots, E$) for computation. Formally, $G = g(I)$.

Experts. An MoE layer consists of E experts, and each expert (say expert i) only processes the data in the tensor $G[i, :, :]$ at each iteration during training or inference. All experts have an identical structure and can be executed in parallel with different input tokens. Typically, each expert is a small neural network consisting of two FFN layers followed by an activation function [7]. The FFN layer has a weight matrix of shape (M, H) , and the second layer has a shape of (H, M) , where H is the size of the hidden layer. We denote the expert i as e_i , and its output as $Q_i = e_i(G[i, :, :])$. To generate the MoE output, the outputs of different experts are combined into a single tensor $[Q_1, Q_2, \dots, Q_E]$, which can be reshaped as (B, L, M) for further processing in subsequent layers.

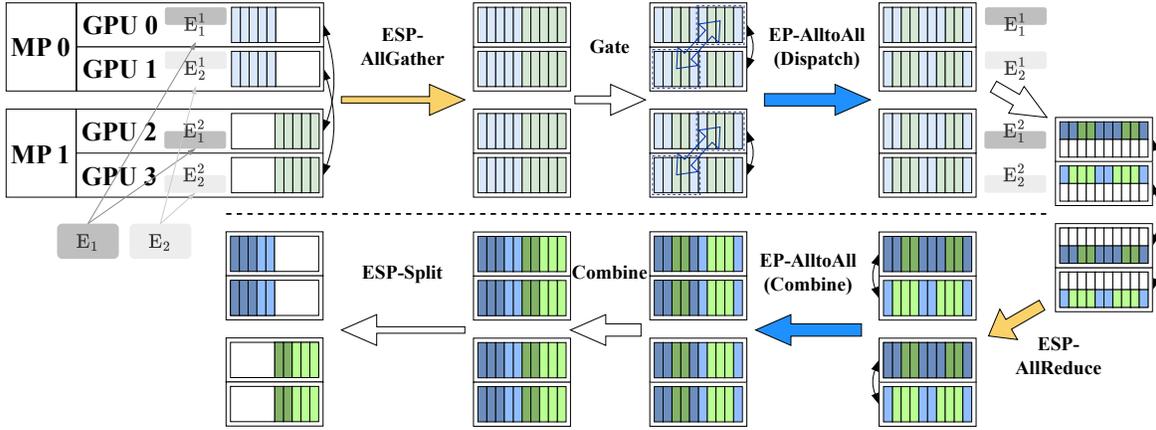

Figure 2: An example of $N_{MP} = N_{EP} = N_{ESP} = 2$. The two experts (E_1 and E_2) are distributed to the two EP groups in EP, and each expert is further partitioned into two shards across the ESP group, that is $E_1 \rightarrow [E_1^1, E_1^2]$ are distributed to GPU 0 and GPU2 respectively and $E_2 \rightarrow [E_2^1, E_2^2]$ are distributed to GPU 2 and GPU 4 respectively. The blue and green rectangles indicate the data tensors and the partially colored part represents a partial sum.

B. Paradigms of Parallelism

DP, PP, MP, EP, and ESP are the five popular parallel paradigms in training large sparse models with a large-scale cluster. As our work focuses on optimizing MP+EP+ESP, and the proposed optimizations can also be integrated with DP and PP, we mainly introduce MP, EP, and ESP.

Model Parallelism. Model Parallelism (MP) [10] (also known as Tensor Parallelism [9] or Operator Parallelism [20]) partitions model parameters across multiple workers to execute computations in parallel. For example, consider a model with two linear layers, W_1 and W_2 , and an activation function f . The computation, $Y = W_2 f(W_1 X)$, is parallelized in P -way MP by dividing W_1 's columns and W_2 's rows. This results in $Y = \sum_{p=1}^P W_2^{(p)} f(W_1^{(p)} X)$, allowing parallel execution of each segment. The segments are then aggregated across GPUs using AllReduce.

Expert Parallelism. A standard implementation of MoE suffers from the issue of a shrinking batch [6]. When the gating function selects k out of E experts for each token, each expert receives only $T = k \times f/E \times B \times L$ tokens, which is usually much smaller than the local token size $B \times L$. To address this issue, expert parallelism (EP) [6] is employed, as shown in Fig. 2. With EP, each device retains only a subset of experts. After passing through the gating function, each row of G ($G[i, :, :]$) on each device corresponds to data that should be dispatched to expert i ($i = 1, 2, \dots, E$). Since the experts may reside on different devices, the dispatch operation is implemented using the AlltoAll collective, known as *AlltoAll Dispatch*. Following the AlltoAll Dispatch, the tokens are subsequently fed to their corresponding experts for computation (i.e., FFNs). Afterward, the outputs from all experts are aggregated using another AlltoAll operation, which is referred to as *AlltoAll Combine*, to be processed for its following layer. We use N_{EP} to denote the number of GPUs in an EP group.

Expert-Sharding Parallelism. In training large-scale MoE

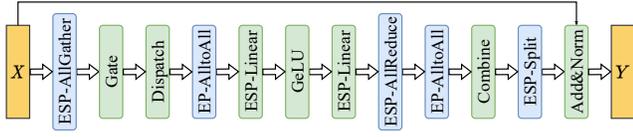

models, the number of workers P would be possibly larger than E . In such a scenario, Expert-Sharding Parallelism (ESP) [12,13] can be used to balance the workload of all workers. In ESP, an ESP group partitions the experts uniformly to all GPUs in the group, which is similar to MP. In such a way, all workers in the ESP group can compute the outputs of the expert in parallel. However, for one MoE layer with EP and ESP, it also introduces some additional operators including an AllGather operation, an AllReduce operation, and a Split operation in the ESP group, which are denoted as ESP-AllGather, ESP-AllReduce, and ESP-Split respectively. ESP-AllGather is to ensure the input is uniformly sharded to all workers, ESP-AllReduce is required to aggregate the outputs of the expert shards among the ESP group, and ESP-Split is to split the combined outputs to the original structure of the input in MP+EP+ESP. We use N_{ESP} to denote the number of GPUs in an ESP group. An example with a two-node cluster, each of which has two GPUs, that uses two-way EP and two-way ESP using two experts, is shown in Fig. 2, where $N_{MP} = N_{EP} = N_{ESP} = 2$ (details in §IV-A).

III. PARM: DEDICATED SCHEDULES

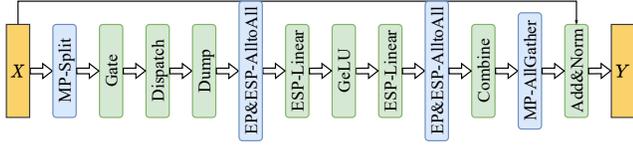

A. Observations: Inefficiency of the Baseline Schedule

In MP+EP+ESP training, an example with $N_{MP} = N_{EP} = N_{ESP} = 2$ using the default schedule has been demonstrated in Fig. 2 and it can be generalized as Fig. 3(a). In the baseline schedule, the input tensor duplication occurs within each MP group, resulting in identical input tokens being processed by the same expert and performing fully identical computations by N_{MP} times. It means that the default schedule causes three main inefficient operations including two communication operations (ESP-AllGather and ESP-AllReduce in Fig. 3(a)) and one redundant computing operation (the same expert calculates the same input data by N_{MP} times).

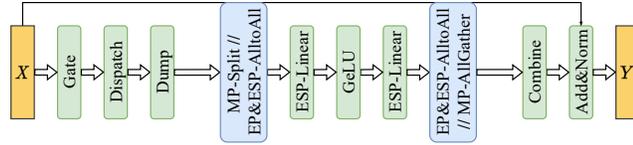

Observation 1. As shown in Fig. 3(a), the baseline schedule first needs to conduct an intra-node ESP-AllGather and fol-

(a) The baseline schedule in existing systems.

(b) S_1 : Disable MP before *Gate* and enable it after *Combine*.

(c) S_2 : Disable MP after *Gate* and enable MP before *Combine*.

Figure 3: Three schedules in MP+EP+ESP including (a) the default schedule, (b) our proposed S_1 schedule, and (c) our proposed S_2 schedule. The yellow color indicates input or output data, the blue color indicates communication operations, and the green color indicates computation operations. Note that the split operations have no communication workload in feed-forward propagation, but they introduce the AllGather communication in backpropagation. That two blue rectangles are overlapped indicates the two operations can be executed in parallel and can be overlapped with each other.

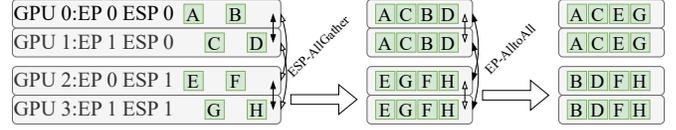

lowed by an inter-node EP-AlltoAll. Note that the inter-node EP-AlltoAll can only start after the intra-node ESP-AllGather. It means during the communication of each operation, either the intra-node connect or the inter-node connect is idle, making the network resources under-utilized. An example with $N_{EP} = N_{ESP} = 2$ is demonstrated in Fig. 4(a).

Observation 2. Similarly, before executing the inter-node EP-AlltoAll operation, an intra-node ESP-AllReduce operation is required for result aggregation. The sequential execution of these two communication operations prevents the overlap of intra-node and inter-node communication, leading to suboptimal utilization. This problem becomes evident when training on GPU clusters without NVLink or NVSwitch. Unfortunately, most researchers do not have access to high-end GPU servers with NVLinks or NVSwitches, making it a common challenge to address. An example of demonstrating how the two operations work is shown in Fig. 4(b).

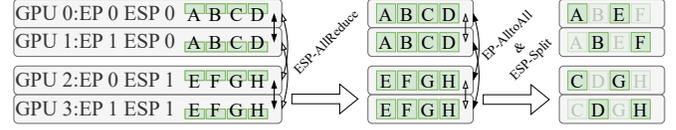

Therefore, based on the above observations that cause inefficient communications and duplicate computations, our design goal is to eliminate these three inefficient operations in MP+EP+ESP training.

B. Dedicated Schedules

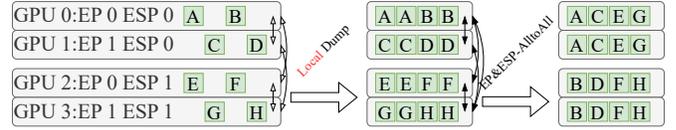

Our dedicated schedules revolve around the key idea of temporarily disabling MP (PauseMP) in MoE layers, which

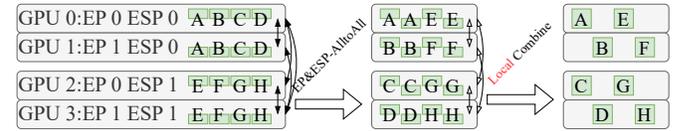

(a) An ESP-AllGather followed by an EP-AlltoAll.

(b) An ESP-AllReduce followed by simultaneous EP-AlltoAll and ESP-Split operations.

(c) A local data dump followed by an EP&ESP-AlltoAll.

(d) An EP&ESP-AlltoAll followed by a local data combine.

Figure 4: Examples of communication patterns with $N_{EP} = N_{ESP} = 2$ under different schedules. The solid arrows indicate requiring communications and the hollow arrow indicates no communications.

brings several benefits: 1) elimination of duplicate computations, 2) significant reduction in communication volume, and 3) replacement of inefficient continuous communications with highly parallel communications, allowing for the overlap of intra-node and inter-node communications. To achieve this, we introduce a Split operation within the MP group (MP-Split) to divide the input tensor of the MoE layer into N_{MP} parts along the column dimension. After the MoE layer, we utilize an AllGather operation within the MP group (MP-AllGather) to restore the original input shape. This ensures that each expert processes a unique set of input tokens, thereby optimizing computing resource utilization without redundant operations. In PauseMP, we use a Dump operation to virtually duplicate the data for the expert computation. Thus, the original EP-AlltoAll becomes EP&ESP-AlltoAll which is a AlltoAll operation (details in §III-C) within both the EP and ESP groups.

To implement PauseMP in MoE layers, there are two potential schedules. The first schedule involves disabling MP the gate function and enabling it again after combining, as illustrated in Fig. 3(b). The second schedule entails disabling MP after the gate function and enabling it again before combining as shown in Fig. 3(c). For clarity, we refer to the above two schedules as S_1 and S_2 , respectively.

S_1 Schedule: With MP disabled before the gate function, we partition the input data for the gating function, resulting

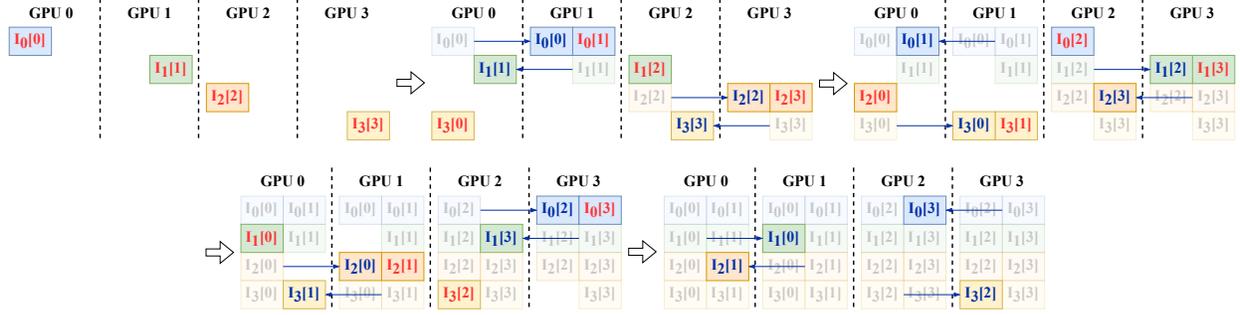

Figure 5: Example of SAA (4-way AlltoAll and 2-way AllGather). Red slices represent data received from AlltoAll at the current turn and blue slices represent the data received from AllGather. Blue arrow represents data transfer using AllGather.

in a reduced size of input data dispatched to experts by N_{MP} times. Consequently, for the EP&ESP-AlltoAll collective, the input size becomes $O(BLM \times N_{ESP}/N_{MP})$. In comparison to the baseline schedule, S_1 effectively reduces both the computation workload and the overall communication volume by N_{MP} times. While S_1 introduces an additional intra-node MP-AllGather, its overhead is significantly smaller than the benefits gained.

S_2 Schedule: In the S_2 schedule, we move the MP-Split operation before the first EP&ESP-AlltoAll and place the MP-AllGather after the second EP&ESP-AlltoAll. Similar to S_1 , S_2 also achieves computation reduction benefits. The communication volume in S_2 becomes $O(ETM)$, which is also better than the baseline. Moreover, in S_2 , the EP&ESP-AlltoAll operation and the MP-AllGather operation are inter-node communication dominant and intra-node communication dominant operations respectively. This allows us to design a simultaneous AlltoAll and AllGather (SAA) collective to enhance the bandwidth utilization (details in §III-D).

The two schedules share identical communication collectives, but they differ in their input dimensions, making them suitable for distinct scenarios. To this end, we devise an automatic strategy which will be elaborated in §V.

C. EP&ESP-AlltoAll: One Collective to Replace Two

As shown in Fig. 4(c)(d), EP&ESP-AlltoAll performs an AlltoAll operation with both the EP and ESP groups, allowing simultaneous execution of intra-node and inter-node communications. To enable this feature in PauseMP, a local dump operation is necessary to virtually duplicate the data locally before the AlltoAll operation, as shown in Fig. 4(c). Compared to the sequential execution of ESP-AllGather and EP-AlltoAll in the baseline schedule, EP&ESP-AlltoAll reduces communication volume and utilizes network resources more efficiently. Similarly, EP&ESP-AlltoAll also replaces ESP-AllReduce, EP-AlltoAll, and ESP-Split by performing a local combine operation after AlltoAll, as shown in Fig. 4(d).

D. Simultaneous AlltoAll and AllGather (SAA)

In our S_2 schedule, as depicted in Fig. 3(c), the EP&ESP-AlltoAll operation can be overlapped with MP-AllGather. The time cost of EP&ESP-AlltoAll is mainly influenced by the

inter-node communication, while MP-AllGather is an intra-node operation that occurs within a single node and is faster in practice. By executing EP&ESP-AlltoAll and MP-AllGather simultaneously (referred to as SAA), we can better utilize both the intra-node and inter-node communication bandwidths. We implement SAA using NCCL `ncclSend` and `ncclRecv` primitives with multiple CUDA streams to enable concurrent communications. An example with a 4-way EP&ESP-AlltoAll and 2-way MP-AllGather is shown in Fig.5. We divide AlltoAll into four phases, with each phase receiving one data slice from another GPU, indicated in red. The red-marked data slice in one phase becomes the source for the blue-marked AllGather in the next phase. This configuration allows efficient overlapping of data transfers between AlltoAll and AllGather operations, enhancing S_2 's performance.

IV. ANALYSIS AND PROBLEM FORMULATION

To ensure the applicability of our analysis to a broad range of physical network topologies, we adopt minimal and practical assumptions. Specifically, we assume that the cluster consists of multiple homogeneous nodes, each equipped with multiple homogeneous devices. We use β_{intra} and β_{inter} to denote two distinct communication speeds for intra-node and inter-node communications, respectively. Without loss of generality, we assume $\beta_{intra} > \beta_{inter}$.

A. Time Cost of the Baseline Schedule

The baseline schedule in existing state-of-the-art MoE training systems [12,13] contains four collective communication operations per MoE layer, as shown in Fig. 3(a). To enable ESP, the first step is the ESP-AllGather operator, which takes $AG_{ESP}(BLM \times N_{ESP})$ time. Next, the input is dispatched using an EP-AlltoAll primitive, whose time cost is $A2A_{EP}(ETM \times N_{ESP})$. After the expert layers execute their computations, an ESP-AllReduce primitive synchronizes the computation results, and it costs $AR_{ESP}(ETM \times N_{ESP})$ time. Finally, another EP-AlltoAll primitive is used to gather the output, which also takes $A2A_{EP}(ETM \times N_{ESP})$ time. Note that the ESP-Split operation does not involve communication workload during forward propagation, but it requires an ESP-AllGather operation during backpropagation. Summing it up,

the total communication time consumption of the baseline schedule at each training iteration can be formulated as:

$$t_B := \text{AG}_{\text{ESP}}(BLM \times N_{\text{ESP}}) + \text{AR}_{\text{ESP}}(ETM \times N_{\text{ESP}}) + 2 \times \text{A2A}_{\text{EP}}(ETM \times N_{\text{ESP}}). \quad (1)$$

B. Time Costs of S_1 and S_2 Schedules

Although our proposed Parm schedules are designed for distributed training with MP+EP+ESP, they are also effective in scenarios with EP+ESP alone. In order to demonstrate their effectiveness, we analyze the two schedules separately for the cases when $N_{\text{MP}} = 1$ and $N_{\text{MP}} > 1$, showing that both schedules outperform the baseline.

$N_{\text{MP}} = 1$. Let's first consider the scenario when $N_{\text{MP}} = 1$, meaning that no MP is used in the distributed training. In this case, pausing MP (i.e., PauseMP) does not directly reduce the communication and computation complexities compared to the baseline schedule. However, it still offers the advantage of enabling communication fusion of ESP-AllGather and EP-AlltoAll into a single communication collective, EP&ESP-AlltoAll, which is more efficient. Formally, the time cost for dedicated S_1 and S_2 schedules with EP&ESP-AlltoAll can be represented as:

$$t_D := 2 \times \text{A2A}_{\text{EP\&ESP}}(ETM \times N_{\text{ESP}}). \quad (2)$$

Our primary objective is to demonstrate the advantages of overlapping ESP-AllGather and EP-AlltoAll, i.e., proving

$$\text{A2A}_{\text{EP\&ESP}}(x) \leq \text{AG}_{\text{ESP}}(x) + \text{A2A}_{\text{EP}}(x), \quad (3)$$

where x represents the number of elements in the input tensor. To achieve this, we consider four different cases based on the placements of EP and ESP groups.

Case 1: Single Node GPU Configuration. Here, each GPU exchanges tensors with all other P GPUs, resulting in $(x \times N_{\text{ESP}})$ tensors for EP&ESP-AlltoAll. Similarly, in the baseline, each GPU communicates with N_{EP} GPUs, also totaling $(x \times N_{\text{ESP}})$ tensors in EP-AlltoAll. Given the equal communication volume $(x \times N_{\text{ESP}})$ and speed β_{intra} , both EP-AlltoAll and EP&ESP-AlltoAll exhibit identical communication times, expressed as:

$$\text{A2A}_{\text{EP\&ESP}}(ETM \times N_{\text{ESP}}) = \text{A2A}_{\text{EP}}(ETM \times N_{\text{ESP}}). \quad (4)$$

This clearly indicates Equation (3) is satisfied for this case.

Case 2: Place ESP groups in the same node. If all GPUs within the same ESP group are located on the same node, the performance bottleneck of the EP-AlltoAll primitive in the baseline schedule is that some GPU receive/send tensors of dimension $(x \times N_{\text{ESP}}/N_{\text{EP}})$ from/to another GPUs within the same EP group at a lower speed β_{inter} . By contrast, in our S_1 or S_2 , the EP&ESP-AlltoAll operation can be divided into two components: intra-node ESP communication and inter-node ESP communication. The former exhibits the same communication workload and speed as ESP-AllGather. The latter requires each GPU to receive/send tensors with dimensions of (x/N_{EP}) from/to all other GPUs in the other ESP groups, where each group has $(N_{\text{EP}} - 1) \times N_{\text{ESP}}$ GPUs.

Compared to the EP-AlltoAll operation, EP&ESP-AlltoAll can be viewed as simultaneously processing N_{ESP} ESP-AlltoAll operations, where each tensor is N_{ESP} times smaller than that of EP-AlltoAll. Due to the fact that ESP groups are placed in the same node, EP&ESP-AlltoAll is always faster or equal to EP-AlltoAll, which also makes Equation (3) satisfied.

Case 3: Place EP in the same node. Similarly, if the GPUs within the EP group are located on the same node, the time cost of the ESP-AllGather operation is dominated by the inter-node communication in the baseline schedule, as some GPUs receive/send data (say x dimension) from/to another GPUs within the same ESP group. By contrast, in our S_1 or S_2 , the EP&ESP-AlltoAll operation can be divided into two components: intra-node EP communication and inter-node EP communication. The former exhibits the same communication workload and speed as EP-AlltoAll. The latter entails each GPU receiving/sending tensors with dimensions of (x/N_{EP}) from/to all GPUs in other ESP groups, totaling $(N_{\text{ESP}} - 1) \times N_{\text{EP}}$ GPUs in total. Compared to an ESP-AllGather operator, the latter can be viewed as simultaneously processing N_{EP} ESP-AllGather, where each tensor is N_{EP} times smaller than the ESP-AllGather. Due to the fact that expert-parallel groups are placed in the same node, the latter operator is always faster or equal to ESP-AllGather.

Case 4: Others. The time taken by a collective communication depends on the slowest transmission, which is influenced by the uniform workloads among all the participating GPUs in the collective. Given that $\beta_{\text{intra}} > \beta_{\text{inter}}$, it is advantageous to place either each ESP group or each EP group in the same node. This ensures that the slowest transmission time for both ESP-AllGather and EP-AlltoAll operations is minimized. Placing them differently would cause an increased slowest transmission time, making the collective less efficient.

Integrating all the above cases, which contain all scenarios in MP+EP+ESP, we prove that Equation (3) always holds. Similarly, by replacing ESP-AllGather with an ESP-ReduceScatter, we also can derive

$$\text{A2A}_{\text{EP\&ESP}}(x) \leq \text{RS}_{\text{ESP}}(x) + \text{A2A}_{\text{EP}}(x) \quad (5)$$

since AllReduce can be implemented by an AllGather followed with a ReduceScatter (RS) operator [21,22]. Thus, we have:

$$\begin{aligned} & t_B - t_D \\ & := \text{AG}_{\text{ESP}}(BLM \times N_{\text{ESP}}) + \text{AR}_{\text{ESP}}(ETM \times N_{\text{ESP}}) \\ & \quad + 2 \times \text{A2A}_{\text{EP}}(ETM \times N_{\text{ESP}}) \\ & \quad - 2 \times \text{A2A}_{\text{EP\&ESP}}(ETM \times N_{\text{ESP}}) \\ & = \text{AG}_{\text{ESP}}(BLM \times N_{\text{ESP}}) + \text{AG}_{\text{ESP}}(ETM \times N_{\text{ESP}}) \\ & \quad + \text{A2A}_{\text{EP}}(ETM \times N_{\text{ESP}}) \\ & \quad - \text{A2A}_{\text{EP\&ESP}}(ETM \times N_{\text{ESP}}) \\ & \quad + \text{RS}_{\text{ESP}}(ETM \times N_{\text{ESP}}) + \text{A2A}_{\text{EP}}(ETM \times N_{\text{ESP}}) \\ & \quad - \text{A2A}_{\text{EP\&ESP}}(ETM \times N_{\text{ESP}}) \\ & \geq \text{AG}_{\text{ESP}}(BLM \times N_{\text{ESP}}), \end{aligned} \quad (6)$$

which concludes that our dedicated schedules (S_1 or S_2) always run faster than the baseline schedule in the scenario of $N_{MP} = 1$.

$N_{MP} > 1$. For $N_{MP} > 1$, the communication time of the S_2 schedule (denoted as t_{D2}) is always smaller than the non-overlapping variant, that is,

$$\begin{aligned} t_{D2} &:= A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad + \text{Overlap} (ETM \times N_{ESP}/N_{MP}) \\ &\leq 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad + AG_{MP} (ETM), \end{aligned} \quad (7)$$

where $\text{Overlap}(\cdot)$ denotes the overlap between EP&ESP-AlltoAll and MP-AllGather. An AllGather operator can be viewed as a special AlltoAll operator, which sends the same data to each GPU. We can obtain:

$$AG_{MP} (x) \leq A2A_{MP} (x). \quad (8)$$

Because model parallel are placed in the same node whenever possible, we can derive:

$$AG_{MP} (x) \leq A2A_{MP} (x) \leq A2A_{EP\&ESP} (x). \quad (9)$$

We can calculate the improvement $t_B - t_{D2}$:

$$\begin{aligned} &t_B - t_{D2} \\ &:= 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}) \\ &\quad - 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad - AG_{MP} (ETM) \\ &\geq 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}) \\ &\quad - 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad - A2A_{EP\&ESP} (ETM) \\ &\geq A2A_{EP\&ESP} \left(2ETMN_{ESP} \frac{N_{MP} - 1}{N_{MP}} \right) \\ &\quad - A2A_{EP\&ESP} (ETM) \\ &\geq A2A_{EP\&ESP} (ETM) (\because N_{ESP} \geq 1, N_{MP} \geq 2) \\ &\quad - A2A_{EP\&ESP} (ETM) \\ &\geq 0. \end{aligned} \quad (10)$$

Combine Equation (6) and Equation (10), we can conclude that the S_2 schedule is always better than the baseline schedule.

When comparing the S_1 and S_2 schedules, the communication times differ as they depend on the MoE configurations. Specifically, t_{D1} can be formalized as follows:

$$\begin{aligned} t_{D1} &:= 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad + AG_{MP} (BLM). \end{aligned} \quad (11)$$

For instance, when $N_{ESP} = 1$ and $T \rightarrow 0$, the S_2 schedule performs better than S_1 , as $t_{D2} \rightarrow 0$ while $t_{D1} \rightarrow AG_{MP} (BLM)$. Conversely, when $T \rightarrow \infty$, the S_1 schedule becomes advantageous because $AG_{MP} (BLM)$ does not increase as $T \rightarrow \infty$. This nature of these two schedules leads us to derive how to determine which one should be applied.

Algorithm 1 Find the Better Schedule from S_1 and S_2

Input: $\alpha_{MP}^{AG}, \beta_{MP}^{AG}, \alpha_{EP\&ESP}^{A2A}, \beta_{EP\&ESP}^{A2A}, \alpha_o, \beta_o, B, L, E, M, k, f, N_{ESP}, N_{MP}$

Output: Better schedule from S_1 and S_2

```

1:  $x = B \times L \times M$ ;
2:  $T = k \times f \times B \times L \times M/E$ ;
3:  $y = E \times T \times M \times N_{ESP}$ ;
4:  $t_{D1} = 2 \times (\alpha_{EP\&ESP}^{A2A} + \beta_{EP\&ESP}^{A2A} \times y/N_{MP}) + \alpha_{MP}^{AG} + \beta_{MP}^{AG} \times x$ ;
5:  $t_{D2} = \alpha_{EP\&ESP}^{A2A} + \beta_{EP\&ESP}^{A2A} \times y/N_{MP} + \alpha_o + \beta_o \times y$ ;
6: if  $t_{D1} \leq t_{D2}$  then
7:   Return  $S_1$ ;
8: else
9:   Return  $S_2$ ;

```

V. SOLUTION

A. Performance Models

To automatically choose a better schedule from S_1 and S_2 , we employ the α - β time performance model [18,23]–[25], which represents the communication cost for performing collective communication among a group of workers. In this model, α indicates the startup time to perform the collective operation, and β is the transmission time per element. Therefore, we formalize the communication time of collectives by $\alpha + \beta \times x$, where x represents the length of the tensor being transmitted. For example, the time cost of the MP-AllGather operation $AG_{MP}(x)$ can be represented as:

$$AG_{MP}(x) := \alpha_{MP}^{AG} + \beta_{MP}^{AG} \times x, \quad (12)$$

where α_{MP}^{AG} and β_{MP}^{AG} are two value related to the specific network topology in the MP group. To measure α_{MP}^{AG} and β_{MP}^{AG} , we can determine the elapsed time using various sizes for the AG_{MP} primitives and employ a least square fitting method to estimate them. The collective $A2A_{EP\&ESP}$ in different parallel groups has the same form as Equation (12) but different $\alpha = \alpha_{EP\&ESP}^{A2A}$ and $\beta = \beta_{EP\&ESP}^{A2A}$ terms. This performance model primarily addresses homogeneous GPU setups.

B. Automatic Selection Solution

To derive the automatic selection from S_1 and S_2 , we should quantitatively measure the time difference between t_{D1} and t_{D2} . Formally, according to the time performance of each communication collective, t_{D1} can be represented as

$$\begin{aligned} t_{D1} &:= 2 \times A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad + AG_{MP} (BLM) \\ &= 2 \times (\alpha_{EP\&ESP}^{A2A} + \beta_{EP\&ESP}^{A2A} \times ETM/N_{MP}) \\ &\quad + (\alpha_{MP}^{AG} + \beta_{MP}^{AG} \times BLM). \end{aligned} \quad (13)$$

Similarly, the time cost of schedule S_2 can be represented as

$$\begin{aligned} t_{D2} &:= A2A_{EP\&ESP} (ETM \times N_{ESP}/N_{MP}) \\ &\quad + \text{Overlap} (ETM \times N_{ESP}/N_{MP}) \\ &\quad + AG_{MP} (ETM) \\ &= (\alpha_{EP\&ESP}^{A2A} + \beta_{EP\&ESP}^{A2A} \times ETM \times N_{ESP}/N_{MP}) \\ &\quad + (\alpha_o + \beta_o \times ETM \times N_{ESP}/N_{MP}) \\ &\quad + (\alpha_{MP}^{AG} + \beta_{MP}^{AG} \times ETM), \end{aligned} \quad (14)$$

Table II: The server configurations in our testbeds.

| Name | Testbed A | Testbed B |
|---------|---|--|
| CPU | Dual AMD EPYC™ 7402 CPU @ 2.80GHz | Dual Intel(R) Xeon(R) Gold 6230 CPU @ 2.10GHz |
| GPU | 8x Nvidia RTX4090 @2.23GHz and 24GB Mem | 4x Nvidia RTX2080Ti @1.35GHz and 11GB Mem |
| Memory | 512GiB DDR4 | 512GB DDR4 |
| PCIe | 4.0 (x16) | 3.0 (x16) |
| Network | - | Mellanox MT27800 Family (ConnectX-5) @ 100Gb/s |

Table III: Configurations of MoE layers.

| | Candidate Values |
|---------------------------|--------------------|
| P | {8, 16, 32} |
| N_{MP} and N_{ESP} | {1, 2, 4} |
| B | {2, 4, 8} |
| L | {512, 1024, 2048} |
| H/N_{ES} and M/N_{ES} | {1024, 2048, 4096} |
| f | {1.2, 2.4} |

where α_o and β_o are the α and β terms of the overlapped version of EP&ESP-AlltoAll. Note that the α and β terms can be measured in the real-world clusters (§VI-B). Our strategy is to dynamically compare t_{D1} and t_{D2} online to determine which schedule should be used during training. The algorithm to find the better schedule is shown in Algorithm 1.

VI. EVALUATION

A. Experimental Settings

Testbeds. We conduct experiments on two testbeds: Testbed A, an 8-GPU node featuring eight Nvidia GeForce RTX4090 GPUs linked through PCIe 4.0x16, and Testbed B, a 32-GPU cluster. Detailed server configurations are provided in Table II. Due to hardware constraints, notably the absence of NVLink or NVSwitch-equipped GPU servers, our experiments primarily utilized PCIe environments. We compare our Parm with the baseline schedule in DeepSpeed-MoE¹.

MoE configurations. Similar to [13,18], we choose a combination of input parameters whose ranges are shown in Table III to cover a variety of typical configurations of MoE layers. Note that some cases that require memory larger than the capacity of GPU memory cannot run on our testbeds are excluded, so we runs totally 1296 valid cases. The time for the allreduce of gradients is excluded from the training time, as this part does not benefit from improvements under Amdahl’s Law.

B. Performance Models

To develop performance models for collective communications, we measure their elapsed time over various message sizes in different parallel groups and collectives. Some partial results are shown in Fig. 6, which shows that the linear model well fits the time cost of collectives and $\alpha_{MP}^{AG} = 6.64 \times 10^{-4}$ and $\beta_{MP}^{AG} = 5.38 \times 10^{-10}$ on the 8-GPU server and $\alpha_{MP}^{AG} = 1.09 \times 10^{-4}$ and $\beta_{MP}^{AG} = 7.14 \times 10^{-10}$ on the 32-GPU cluster. We use these parameters for Parm in running Algorithm 1 to determine the best schedule.

¹<https://github.com/microsoft/DeepSpeed> at version v0.8.1.

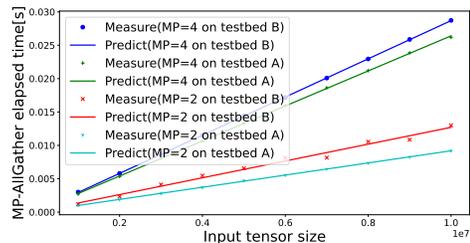

Figure 6: Time performance of collectives on two testbeds.

C. Performance Comparison on Configured MoE Layers

Table IV: Averaged speedups of our schedules over the baseline schedule on testbed A (T-A) and testbed B (T-B) with configured MoE layers in Table III. For each MoE layer, we measure the average iteration time of 30 iterations and 10 warmup iterations.

| Schedule | N_{MP} | N_{ESP} | Speedup (T-A) | Speedup (T-B: 8-GPU//16-GPU//32-GPU) | | |
|----------|----------|-----------|---------------|--------------------------------------|-----------|--------|
| | | | | | | |
| S_1 | 2 | 2 | 2.10× | 2.62 × // | 2.46 × // | 2.72 × |
| | | 4 | 2.24× | 3.37 × // | 2.85 × // | 2.85 × |
| | 4 | 2 | 3.72× | 4.18 × // | 4.12 × // | 3.92 × |
| | | 4 | 4.19× | 5.77 × // | 5.08 × // | 4.57 × |
| S_2 | 2 | 2 | 1.99× | 2.42 × // | 2.20 × // | 2.57 × |
| | | 4 | 2.41× | 3.05 × // | 2.44 × // | 2.75 × |
| | 4 | 2 | 3.21× | 3.58 × // | 3.81 × // | 4.10 × |
| | | 4 | 4.12× | 5.38 × // | 4.82 × // | 4.91 × |
| Parm | 2 | 2 | 2.10× | 2.62 × // | 2.46 × // | 2.57 × |
| | | 4 | 2.41× | 3.37 × // | 2.85 × // | 2.85 × |
| | 4 | 2 | 3.70× | 4.18 × // | 4.12 × // | 4.06 × |
| | | 4 | 4.20× | 5.77 × // | 5.08 × // | 4.91 × |

We compare our Parm with DeepSpeed-MoE under a wide range of configurations based on Table III. Experimental results show that S_1 , S_2 , and Parm outperform the baseline schedule in all tested cases, which verifies our theoretical analysis in §IV-B. The average speedups of our schedules over the baseline schedule are shown in Table IV.

S_1 vs. baseline. Comparing S_1 with the baseline schedule, it is seen that S_1 runs 2.1× to 4.19× faster on testbed A, and 2.46× to 5.77× faster on testbed B. With an increased N_{MP} or N_{ESP} , the improvement of S_1 over the baseline becomes larger. It is mainly because larger N_{MP} or N_{ESP} allows S_1 to eliminate more duplicate computations and to overlap more communications.

S_2 vs. baseline. Similarly, S_2 runs 1.99× to 4.12× faster on testbed A, and 2.2× to 5.38× faster on testbed B than the baseline. It is seen that S_1 and S_2 may be better than each other under different scenarios. For example, under the setting of $N_{MP} = 4$ and $N_{ESP} = 2$, S_1 achieves 3.72× faster than the baseline, which is larger than the improvement of S_2 over the baseline (3.21×) on testbed A. However, on testbed B, the improvement of S_1 is smaller than S_2 under the same configuration. Note that S_2 is also accelerated with SAA (§III-D). Compared with executing AlltoAll and AllGather sequentially (AAS), SAA achieves 1.09% and 1.12% improvements over SAA on our two testbeds, respectively.

Parm vs. baseline. As Parm is expected to choose the better one from S_1 and S_2 , Parm achieves higher average speedups over the baseline than S_1 and S_2 , which are $2.1\times$ to $4.2\times$ on testbed A and $2.46\times$ to $5.77\times$ on testbed B. Since Parm selects S_1 or S_2 automatically, Parm achieves 8% and 10.5% improvements over the worse case of S_1 and S_2 on testbed A and B, respectively.

Statistics on a cluster. We also demonstrate the speedup statistics of Parm over DeepSpeed-MoE under the configured MoE layers on our 32-GPU cluster when $N_{MP} = 4$ and $N_{ESP} = 4$ as shown in Fig. 7. The results show that Parm can outperform DeepSpeed-MoE by $4.91\times$ on average and the speedup is larger than $4\times$ in around 89% cases.

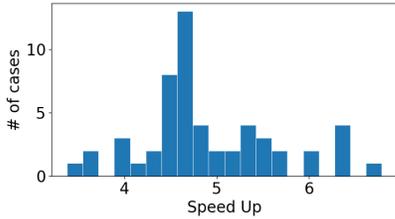

Figure 7: Speedup statistics of Parm over DeepSpeed-MoE on 32 GPUs under $N_{MP} = 4$ and $N_{ESP} = 4$.

D. Training Time on Real-world MoE Models

Table V: Time performance (average iteration time in milliseconds) and the speedup of Parm over DeepSpeed-MoE on real-world MoE models based on BERT-Base and GPT-2.

| Base Model | Testbed | DeepSpeed-MoE | Parm | Speedup |
|------------|---------|---------------|-------------|--------------|
| BERT-Base | A | 1733 ± 4 | 567 ± 2 | $3.06\times$ |
| | B | 1920 ± 6 | 645 ± 3 | $2.98\times$ |
| GPT-2 | A | 1790 ± 4 | 581 ± 3 | $3.08\times$ |
| | B | 2187 ± 47 | 695 ± 7 | $3.15\times$ |

To test Parm’s performance in real-world MoE models, we conducted experiments with MoE versions of BERT-Base [26] and GPT-2 [2], using $N_{MP} = N_{ESP} = 4$. The number of experts is set to 2 and 8 on testbed A and B respectively. The average iteration time of training is shown in Table V, which indicates that Parm outperforms DeepSpeed-MoE by around 3 times.

VII. RELATED WORK

There are three main orthogonal directions in optimizing the training performance of MoE models: 1) MoE algorithms to choose experts for input tokens to balance workloads for different GPUs [6,7,27]–[30] and gating functions for improving the model generalization [31]–[33]. 2) AlltoAll algorithms to improve data dispatch and combine efficiency [12,13,16,34]–[36]. 3) Scheduling algorithms to overlap communications with computations [13,18,19,25,37]. Our work mainly focuses on task scheduling, so we mainly introduce the related studies in the third direction.

Tutel [13] is a dedicated optimized system for training MoE models with different aspects of optimizations including task scheduling. For pipelining MoE layers, Tutel supports

a manually set degree of pipelining or a heuristic search under limited searching space, which may be sub-optimal. FasterMoE [25] only allows to partition the input tokens into two groups for pipelining expert computations and AlltoAll communications, which cannot support finer-grain scheduling of these tasks. PipeMoE [18] proposes an optimal partition of input tokens with performance modeling of expert computation and AlltoAll communication. SmartMoE [37] proposes to use a hybrid optimization (i.e., static pools offline and choices to pick within a pool online) by exploring the space of hybrid parallelism with awareness of heterogeneous workloads. Lina [19] also studies the communication scheduling and it tries to avoid the network contention of AllReduce and AlltoAll during backpropagation. DeepSpeed-TED [38] also reduces data movement but is limited to cases where ESP equals MP. In summary, existing MoE training systems mainly consider the scenario with only DP and EP and optimize its efficiency. They may not be suitable to existing MoE-based large model training as it typically requires to enable multiple dimensions of parallelism including MP, EP, and ESP.

VIII. CONCLUSION

In this paper, we first proposed two dedicated schedules (say S_1 and S_2) for improving the communication efficiency in distributed training of MoE models under commonly used parallelisms (MP+EP+ESP). The two dedicated schedules not only eliminate redundant computations and communications, but also enable the overlapping between intra-node and inter-node communications. We then provided theoretical analyses for the two schedules and concluded that they are not mutually exclusive. To this end, we further derived an efficient solution to adaptively choose the smaller one from S_1 and S_2 . Integrating the two designed schedules and the automatic schedule decision scheme, we develop a prototype system named Parm atop PyTorch for training large MoE models. We conduct extensive experiments on two testbeds (an 8-GPU server and a 32-GPU cluster) to compare Parm with the state-of-the-art MoE training system DeepSpeed-MoE. Experimental results show that our Parm outperforms DeepSpeed-MoE by $1.13\times$ to $5.77\times$ on 1296 configured MoE layers and by $2.98\times$ to $3.15\times$ two real-world MoE models based on BERT and GPT-2. The code of Parm can be found at <https://github.com/Fragile-azalea/Parm>.
