(Dated: July 2, 2024)

The electronic structure and phonon dispersion of XS_2 with X = Co, Tc, Ti, Ru, Nb, and Rh in the monolayer MoS_2 structure with trigonal-prismatic coordination are studied from first principles. Although each XS_2 is dynamically unstable, CoS_2 , TcS_2 , RuS_2 , and RhS_2 can be stabilized by developing charge density waves in the (2×2) supercell, leading to metal-insulator transitions. Without really needing the metal-insulator transitions and large atomic distortions, additional energy may be gained in the total energy by mixing transition metal elements to create high-entropy combinations for X, presenting a wide range of high-entropy XS_2 compounds that exhibit a variety of band structures, including direct- and indirect-gap semiconductors, metals, and semimetals.

The high-entropy alloy, also known as the multicomponent alloy, is a single-phase solid-solution mixture of metal elements, with each element contributing a significant percentage to the composition [1-5]. Most high-entropy alloys tend to crystallize in simple FCC, BCC, and HCP structures, similar to typical metal structures. The high-entropy alloy gains energy from the high configurational entropy of mixing by lowering the Gibbs free energy [6, 7]. The pioneering research conducted by Yeh *et al.*[6] and Cantor *et al.*[8] has shown that highly mixed equiatomic alloys can exhibit exceptional mechanical strength with excellent ductility, surpassing the fracture toughness achievable in conventional alloys [1-5]. Specifically, Cantor *et al.* fabricated a highentropy alloy consisting of a five-component alloy, Fe-CrMnNiCo, and Yeh et al. synthesized an equimolar mixture of $CuCoNiCrAl_x$ Fe with varying Al concentrations. The high-entropy alloys have also shown promising performance in electrocatalysis^[9] and can exhibit superconductivity, with the potential to further increase superconducting transition temperatures through proper mixing of various types of metal elements [7, 10, 11].

Contrary to the expectation that the entropy of mixing is the primary factor in stabilizing high-entropy alloys, Senkov et al.[3] found that simply increasing the configurational entropy doesn't guarantee stability in highentropy alloys after analyzing over 130,000 alloys using the calculated phase diagram method, suggesting that it's crucial to understand the role played by the total energy responsible for determining the formation enthalpy. First-principles approaches based on density functional theory [12, 13] have also been applied to study magnetic properties, phase stability, elastic properties, and local lattice distortions of high-entropy alloys [14-16]. Samolyuk et al. [16] argued that configurational entropy has minimal impact on stabilizing one crystal structure over another and the total energy gain from atomic displacement may be more important in eliminating dynamic instabilities in high-entropy alloys. Recently, two-

dimensional van der Waals materials with a variety of possible heterostructures through stacking and twisting have become popular and promising for next-generation technology[17–20]. High-entropy van der Waals compounds have also been extensively researched and produced experimentally, including metal dichalcogenides, halides and phosphorus trisulphides [21–26]. Among the layered compounds, MoS_2 is an interesting semiconductor that undergoes an indirect-direct gap transition as the structure changes from bulk to monolayer [27, 28], useful for electronic and optoelectronic applications. The monolayer MoS_2 has a trigonal-prismatic structure [29], which will be simply dubbed as $1H-MoS_2$. It is then pertinent to ask whether highly mixed transition metal elements formed in the "1H-MoS₂" structure can still be dynamically stable, able to engineer the band structure, and

gain energy at the level of total energy without the assistance of the configurational entropy of mixing, given that most of the pristine $1H-XS_2$ compounds, where X denotes the transition metal elements, are unstable unless charge density waves are developed in larger supercells[30, 31].

In this study, we performed first-principles calculations within the generalized gradient approximation [32] using the OpenMX code[33], where norm-conserving pseudopotentials and optimized pseudoatomic basis functions were adopted[34]. Phonon dispersion was obtained based on supercell force-constant calculations, and the force constants were properly partitioned [35]. More details can be found in Supplemental Material[36]. To investigate the potential two-dimensional high-entropy XS₂ compounds having the $1H-MoS_2$ structure, we first relaxed the lattice parameters by considering X to be each of the transition metal elements in the fourth and fifth rows of the periodic table. The optimized lattice constants are depicted in Fig. 1 (a). The result indicates that the values of two lattice constants, for instance, 4.2022 Å for Cd and 3.0345 Å for Cr, could differ by more than one angstrom. Even though a phase containing a mixed combination of all the explored transition metal elements could be stable, a good choice is to select the elements giving similar lattice constants, which can help maintain a structure that still closely resembles the $1H-MoS_2$ structure. While MoS_2 does not exhibit magnetism, we have discovered that several XS_2 compounds can be magnetic, such as MnS_2 , FeS_2 , and VS_2 . The total spin moments calculated for these pristine XS_2 compounds are shown in Fig. 1 (b). To better understand energy gain without considering the influence of magnetism, we will focus on non-magnetic XS_2 compounds with similar lattice constants. Specifically, we will examine the properties of XS_2 compounds with X = Mo, Co, Tc, Ti, Ru, Nb, and Rh in the following paragraphs.

The XS_2 compounds with X = Co, Tc, Ti, Ru, Nb, andRh have been less studied in the $1H-MoS_2$ structure. This is because of the existing dynamical instability, which can be seen in the phonon dispersions with imaginary frequencies, as demonstrated in Figs. 2 (a) and (b). The phonon instability is evident at the M point in all six compounds, indicating that charge density waves could be developed to stabilize the systems in the (2×2) supercell. As shown in Figs. 2 (c) to (h), CoS_2 , RuS_2 , TcS_2 , and Rh₂ become dynamically stable in the (2×2) supercell due to the developed charge density waves. However, this is not the case for TiS_2 and NbS_2 . As listed in Table I, all six compounds can gain energy in the (2×2) supercell compared to the corresponding energies calculated from the (1×1) unit cells. We have not observed the development of a charge density wave in MoS_2 , which is consistent with the stable dynamical behavior in the phonon dispersion of (1×1) 1H-MoS₂. Even with the development of charge density waves, the crystal structures of (2×2) TcS₂, (2×2) TiS₂, and (2×2) NbS₂ can

FIG. 2. Phonon dispersions of primitive-cell (1×1) (a) CoS₂, TcS₂, and TiS₂ and (b) RuS₂, NbS₂, and RhS₂. All the cases possess imaginary frequencies, which are presented by negative values. The phonon dispersions of the charge-densitywave structures of (c) CoS₂, (d) RuS₂, (e) TcS₂, (f) NbS₂, (g) TiS₂, and (h) RhS₂ obtained in the (2×2) supercell. Electronic density of states (DOS) of (i) CoS₂ and TcS₂ and (j) RuS₂ and RhS₂ in units of eV⁻¹ per atom. The Fermi level is shifted to 0 eV.

still remain hexagonal, in contrast to the case of (2×2) CoS₂, (2×2) RuS₂, and (2×2) RhS₂, where both lattice and atomic distortions can be found. We want to emphasize that the small energy gain of 0.2 meV per atom in (2×2) NbS₂ is genuine, as the imaginary frequencies along other paths can be stabilized. The more complete phonon dispersions of all the studied compounds can be found in Supplemental Material[36].

The charge density waves in (2×2) XS₂ involve both atomic distortion and charge order. Based on Mulliken population analysis, the largest charge difference in the X atom for X = Co, Tc, Ti, Ru, Nb, and Rh is 0.028,

TABLE I. The band-gap type of each monolayer XS_2 is listed together with the total energy difference from the corresponding energies of (1×1) XS_2 and (2×2) XS_2 with X = Mo, Co, Tc, Ti, Ru, Nb, and Rh in units of eV per atom, denoted as $E-(1\times1)$ and $E-(2\times2)$, respectively. The lattice parameters can be found in Supplemental Material[36].

Monolayer 1H-XS ₂	Gap type	E-(1×1)	$E-(2\times 2)$

0.030, 0.000, 0.015, 0.009, and 0.067 electrons, respectively. The largest charge difference in the S atom with the same sequence is 0.077, 0.035, 0.008, 0.110, 0.001, and 0.051 electrons, respectively. The negligible charge transfer in TiS_2 and NbS_2 are consistent with the slight energy gain and phonon instability in the (2×2) supercell. The important role played by the electronic structure in stabilizing CoS_2 , RuS_2 , TcS_2 , and Rh_2 in the (2×2) supercell can also be revealed in the density of states with the presence of a gap at the Fermi level. As demonstrated in Figs. 2 (i) and (j), CoS₂, TcS₂, RuS₂, and RhS₂ all encounter metal-insulator transitions. In contrast, TiS₂ is already an insulator in the (1×1) unit cell, and (2×2) NbS_2 remains metallic. This aligns with the finding that there is insufficient energy gain through the charge transfer and atomic distortion in these two compounds. This is because the band gap is already open in one case, while it is still not open in the other case.

The commonly considered energy gain of high-entropy alloys from mixing different elements in thermodynamics is through the TS term in the Gibbs free energy, G = U + PV - TS, where U, P, V, T, and S denote the total energy, pressure, volume, temperature, and entropy, respectively. Instead of exploring how to increase the disorder in contributing to the entropy, we intend to investigate the energy gain of highly mixed transition metal elements in the 1H-MoS₂ structure by examining the impact of mixing on the total energy, rather than focusing on increasing randomness to contribute to the entropy of mixing. The density functional theory is effective for delivering such total energy and it is generally not expected to gain total energy in a multi-element system with high disorder. Otherwise, predicting the groundstate structures would become more challenging if introducing higher-entropy combinations could easily lower the total energy and still keep the system dynamically stable. In the paragraph below, we will demonstrate that while the XS₂ compounds with X = Co, Tc, Ti, Ru, Nb, and Rh are unstable in the (1×1) unit cell, they become dynamically stable when they are mixed in the (2×2) supercell. Furthermore, in some combinations, the total energy gain can be greater than the sum of the individual energy gains of the corresponding (2×2) XS₂ compounds.

We have investigated 9 combinations involving 4 out of the 7 transition metal elements: Mo, Co, Tc, Ti, Ru, Nb, and Rh in the (2×2) supercell. These combinations are MoCoTcTiS₈, MoCoTiRuS₈, MoCoTiNbS₈, MoTiNbRhS₈, $MoTiRuNbS_8$, MoRuNbRhS₈, CoTcTiNbS₈, CoTcRuRhS₈, and TiRuNbRhS₈. Despite the mixing, both $MoTiNbRhS_8$ and $MoTiRuNbS_8$ can still keep the lattice hexagonal, and the atomic distortions compared to the perfect (2×2) 1H-MoS₂ structure are tiny. The structures of MoTiNbRhS₈, CoTcRuRhS₈, and TiRuNbRhS₈ are presented in Fig. 3 (a). The other structures can be found in Supplemental Material[36]. Note that even with the significant distortion of S atoms in $CoTcRuRhS_8$, the structure can still be recognized as closely related to the $1H-MoS_2$ structure. As shown in Table I, all 9 compounds possess total energies lower than the total-energy sum of the corresponding (1×1) XS_2 compounds. By further examining the total energy difference from the total-energy sum of the corresponding (2×2) XS₂ compounds, MoCoTcTiS₈, MoCoTiRuS₈, $MoTiRuNbS_8$, $MoTiNbRhS_8$, $CoTcTiNbS_8$, and $TiRuNbRhS_8$ can gain more energy than the individual XS_2 compounds in the (2×2) supercell. This suggests that mixing different transition metal elements can more efficiently develop charge density waves than the individual XS_2 compounds in gaining energy at the level of total energy, without the assistance of the TS term in the Gibbs free energy.

It is interesting to further examine the dynamical stability of these 9 compounds, including $MoCoTiNbS_8$, $MoRuNbRhS_8$, and $CoTcRuRhS_8$, where the total energies are lower than the summed total energy of the related (1×1) XS₂ compounds but the energy gain is less efficient compared to arranging the same elements in the (2×2) supercell. We have found that all the 9 compounds are dynamically stable without the presence of imaginary frequencies in the phonon dispersion. For illustration, the dispersions of MoTiNbRhS₈, CoTcRuRhS₈, and TiRuNbRhS₈ are shown in Figs. 3 (c)-(e), respectively. The other phonon disperions can be found in Supplemental Material [36]. Note that neither TiS_2 nor NbS₂ is dynamically stable in the (2×2) supercell, and MoS_2 does not develop a charge density wave. However, the combination of MoTiNb with Co, Ru, or Rh

FIG. 3. (a) Structures of MoTiNbRhS₈, CoTcRuRhS₈, TiRuNbRhS₈, and Mo₅CoTiRuRhS₁₈ and (b) the Brillouin zone. The phonon dispersions of (c) MoTiNbRhS₈, (d) CoTcRuRhS₈, (e) TiRuNbRhS₈, and (f) Mo₅CoTiRuRhS₁₈ along the paths shown in (b). The electronic band structures with the inclusion of spin-orbit coupling along the same paths are shown in (g), (h), (i), and (j), respectively.

can stabilize the phonon instability. The phonon instability can also be removed by combining TiNb with CoTc or RuRh. As presented in Table I, the metal-insulator transition is not really needed to stabilize these high-entropy compounds in general. This is especially true given that $MoCoTiRuS_8$, $MoTiRuNbS_8$, $CoTcTiNbS_8$, and $CoTcRuRhS_8$ are metallic.

Here, we extend the (2×2) supercell to the

 (3×3) supercell and investigate two examples with more significant mixing: Mo₅CoTiRuRhS₁₈ and $Mo_3CoTcTiRuNbRhS_{18}$. We aim to determine if the mixing-stabilized phonon instability can still be identified in a larger supercell. According to Table I, the compound $Mo_3CoTcTiRuNbRhS_{18}$, containing all the elements Mo, Co, Tc, Ti, Ru, Nb, and Rh, exhibits a lower total energy compared to both the total-energy sums obtained from the (1×1) and the (2×2) XS₂ compounds. On the other hand, $Mo_5CoTiRuRhS_{18}$ only has a lower total energy than the sum of the corresponding (1×1) XS₂ compounds. However, both compounds are dynamically stable without exhibiting imaginaryfrequency branches in the phonon dispersion. The structure and phonon dispersion of $Mo_5CoTiRuRhS_{18}$ are shown in Figs. 3 (a) and (f), respectively, and the results for Mo₃CoTcTiRuNbRhS₁₈ can be found in Supplemental Material[36]. The findings suggest that more stable high-entropy XS_2 compounds, where X represents a highly mixed combination of Mo, Co, Tc, Ti, Ru, Nb, and Rh, may be realized in larger supercells and gain energy at the level of total energy.

Finally, concerning the applications for nextgeneration devices, the high-entropy semiconductors are expected to be realized in the investigated XS₂ compounds through the mixing of transition metal elements with different supercell sizes or even without a short range of periodicity. The high-entropy XS_2 compounds offer a variety of band structures with different gap sizes and types, such as indirect-gap semiconductors, metals, semimetals, and direct-gap semiconductors, as illustrated in Figs. 3 (g)-(j) by MoTiNbRhS₈, CoTcRuRhS₈, $TiRuNbRhS_8$, and $Mo_5CoTiRuRhS_{18}$, respectively. The band-gap types, which describe the electrical conductivity properties, of all the studied compounds are listed in Table I. It's worth mentioning that even though (2×2) RuS₂ and (2×2) RhS₂ are categorized as indirect-gap semiconductors, the band structures suggest that they are close to direct-gap semiconductors, indicating the possible tunability through, for example, external strain. Furthermore, the band structure of MoRuNbRhS₈ indicates that it is close to a zero-gap semimetal, and the sign of the gap can be easily tuned by strain and temperature. The band structures of all the studied compounds can be found in Supplemental Material[36].

In conclusion, mixing transition metal elements to create high-entropy combinations in the 1H-MoS₂ structure may eliminate the phonon instability dictated in CoS₂, TcS₂, TiS₂, RuS₂, NbS₂, and RhS₂ and gain energy at the level of total energy without the help of the TS term in the Gibbs free energy. The high-entropy XS₂ compounds do not really need the metal-insulator transitions and large atomic distortions to stabilize the systems in general. This is because the different atomic species already provide, to some extent, the effect of structural distortions in the charge density waves. The illustrated cases obtained in the (2×2) and (3×3) supercells exhibit a rich set of band structures, including the directand indirect-gap semiconductors, metals, and semimetals, useful for electronic, optoelectronic, and other industrial applications.

The calculations were carried out using the facilities in JAIST and Tamkang University. C.-C.L. thanks Professor Giulia Galli for a fruitful discussion.
