Abstract. This contribution examines the capabilities of the Python ecosystem to solve nonlinear energy minimization problems, with a particular focus on transitioning from traditional MATLAB methods to Python's advanced computational tools, such as automatic differentiation. We demonstrate Python's streamlined approach to minimizing nonlinear energies by analyzing three problem benchmarks - the p-Laplacian, the Ginzburg-Landau model, and the Neo-Hookean hyperelasticity. This approach merely requires the provision of the energy functional itself, making it a simple and efficient way to solve this category of problems. The results show that the implementation is about ten times faster than the MATLAB implementation for large-scale problems. Our findings highlight Python's efficiency and ease of use in scientific computing, establishing it as a preferable choice for implementing sophisticated mathematical models and accelerating the development of numerical simulations.

Keywords: nonlinear energy minimization, autograd, p-Laplacian, Ginzburg-Landau model, hyperelasticity, finite elements.

1 Introduction

Solving problems posed by partial differential equations can often be accomplished using the variational approach, which is based on finding a minimum of

^{*} J. Valdman was supported by the project grant 24-10366S (GAČR) on Coupled dissipative processes and deformation mechanisms in metastable titanium alloys.

the corresponding energy functional

$$J(u) = \min_{v \in V} J(v), \qquad (1)$$

where V is a space of test functions defined in a domain Ω and includes Dirichlet boundary conditions on $\partial \Omega$. Problems of this nature appear in various applications in physics and are mathematically studied within the calculus of variations. The energy functionals are then described by integrals over domains in two- or three-dimensional space. The finite element method [4] can be utilized as an approximation of (1) and results in a minimization problem

$$J(u_h) = \min_{v \in V_h} J(v) \tag{2}$$

formulated in the finite-dimensional subspace V_h of V.

This contribution is based on recent MATLAB implementations [9–11], which use the simplest linear nodal basis functions to enable an efficient solution of (2). It extends the implementation to Python and exploits the new computational tools available therein, namely automatic differentiation, efficient graph coloring, and algebraic multigrid solvers. Our goal remains consistent with that of the MATLAB implementation: to achieve efficient and vectorized computations without the need for manual gradient implementation.

We reimplement and compare three problems: the p-Laplace problem, the Ginzburg-Landau model in superconductivity [1], and the Neo-Hookean hyperelastic model in solid mechanics [7].

Solution times were obtained using an AMD Ryzen 9 7940HS processor with 64 GB of memory, running MATLAB R2023b or Python 3.11.8 with packages (jax=0.4.26, numpy=1.26.4, scipy=1.13.0, igraph=0.11.4, pyamg=5.1.0).

The source code for the Python implementation is available on GitHub:

https://github.com/Beremi/nonlinear_energies_python/tree/PPAM2024

2 Method description

We provide an overview of the Python and MATLAB implementations, highlighting their differences. Since both implementations are based on the Finite Element Method (FEM) and use linear nodal elements, they share many similarities and common requirements for some precomputed values on the grid.

For a grid in 2D or 3D with n - the number of elements, we will use the following data as input to our energy functional implementations:

- u: Vector of minimized values for non-fixed degrees of freedom.
- u_0: Vector containing Dirichlet boundary values and zeros for non-fixed degrees of freedom.
- freedofs: Vector of indices for nonfixed degrees of freedom.
- elems: Matrix of indices for the corresponding nodes for each element (triangle in 2D $n \times 3$, tetrahedron in 3D $n \times 4$).

dvx/dvy/dvz: Matrices of the corresponding partial derivatives $\frac{\partial v}{\partial x}, \frac{\partial v}{\partial y}, \frac{\partial v}{\partial z}$ of a

test function for each degree of freedom in each element (triangle in 2D - $n \times 3$, tetrahedron in 3D - $n \times 4$).

vol: Vector of areas or volumes of each element.

Outside of these inputs to the energy functional implementation, there is also a sparsity pattern incidence matrix computed specifically from the grid. The sparsity pattern describes connections between vertices (degrees of freedom) based on their support on elements; i.e. a zero occurs only if there are no elements where both vertices have support. An example of a coarse 2D triangular mesh together with its sparsity pattern is shown in Fig. 1. It has 24 elements and 21 nodes. We aim for minimizations with up to 1 milion nodes on finer meshes. The sparsity pattern clearly corresponds to the sparsity pattern of Hessian $\nabla^2 J(v)$ for scalar problems discretized by linear nodal functions.

Fig. 1: Discretization of a rectangular domain (left) and the corresponding sparsity pattern (right).

2.1 Overview of Matlab approach

We briefly outline the main properties of the current MATLAB implementation.

- The gradient $\nabla J(v)$ is computed either analytically or via central differences approximation using energy densities [10].
- The minimization is fully performed by the MATLAB Optimization Toolbox in the form of the fminunc function:
 - It accepts the energy functional J(v) and its gradient $\nabla J(v)$ along with the Hessian sparsity pattern.
 - It uses SFD (Sparse Hessian via Finite Gradient Differences [6]) for the finite difference approximation of the Hessian $\nabla^2 J(v)$.

- 4 Michal Béreš, Jan Valdman
 - * The coloring of the sparsity pattern needed for SFD is done using greedy graph coloring and needs to be recomputed with each fminunc function call. Additionally, the MATLAB implementation is very slow for larger meshes.
 - It employs a Trust Region with diagonally preconditioned CG (Conjugate Gradient) solver, which is very inefficient for badly conditioned matrices and can scale poorly with matrices whose conditional number deteriorates with increasing grid size, which is typical for FEM.

2.2 Python approach and implementation

We present the Python implementation, highlighting mainly its differences from MATLAB's. We start by stating that the energy functional is implemented almost identically. The Python implementations will be showcased in subsequent sections. We used the JAX library with 64-bit floats. JAX is a Python library for accelerator-oriented array computation and program transformation, designed for high-performance numerical computing and large-scale machine learning. Our Python implementation can be summarized as follows:

- The gradient is computed via the JAX library [3]. This is an automatic process; no additional code is needed, as everything is handled by the jax.grad function. Note that the gradient computed this way is the exact analytical gradient.
- The Hessian is computed similarly to the SFD [6] approach with one major difference: Instead of using finite differences, the exact Jacobian dot product is used in the form of the call to the jax.jvp function. Note that the Hessian computed in this way is the exact analytical Hessian.
- Graph coloring is performed by the efficient package iGraph [5]. As this is our implementation of the minimizer procedure, the coloring can be reused if the same grid is used to solve multiple problems.
- All costly operators, such as energy, its gradient and Hessian evaluations, are compiled into XLA (Accelerated Linear Algebra) using jax.jit, resulting in faster execution.
 - This operation takes approximately 1.3 seconds across tested problems and grids and is a one-time operation; there is no need to recompute it for different grids.
- An energy minimization is performed using a basic textbook implementation of the Newton method with line search using the Golden section method; see [12].
- The solution of linear systems is accomplished using the Algebraic Multigrid solver (AMG), employing the PyAMG package [2], or using SciPy's direct solver. The choice of solver is determined by the size of the sparse system; systems with up to 15,000 unknowns (degrees of freedom) are solved directly, whereas larger systems are addressed using AMG.

3 Model problems and results

We present three benchmark problems, showcase their implementation in Python, and compare the complexity of the solutions to the current MATLAB implementation. For the Python implementation, we measure the setup time only once per mesh, which can be reused for multiple problems with different settings. This is not possible in the Matlab implementation. The expectation for the performance of all problems is as follows:

- automatically derived and compiled Jacobians and Hessians will be slightly faster in evaluation than their MATLAB counterparts,
- analytical Jacobians and Hessians can accelerate the convergence of Newton minimization (or trust region) methods compared to energy density and SFD approximations,
- algebraic multigrid solvers will be faster and, for increasingly worse conditioned problems with increasing grid size will have better scaling (compared to diagonally preconditioned CG).

3.1 p-Laplace 2D

The first benchmark problem is a (weak) solution of the p-Laplace equation [8]:

$$\begin{aligned} \Delta_p u &= f \quad \text{in } \Omega \,, \\ u &= g \quad \text{on } \partial \Omega \,, \end{aligned} \tag{3}$$

where the p-Laplace operator is defined as

$$\Delta_p u = \nabla \cdot \left(\|\nabla v\|^{p-2} \nabla u \right)$$

for some power p > 1. The domain $\Omega \in \mathbb{R}^d$ is assumed to have a Lipschitz boundary $\partial \Omega$, with $f \in L^2(\Omega)$ and $g \in W^{1-1/p,p}(\partial \Omega)$, where L and W denote the standard Lebesgue and Sobolev spaces, respectively. It is known that (3) represents an Euler-Lagrange equation corresponding to a minimization problem

$$J(u) = \min_{v \in V} J(v), \quad J(v) := \frac{1}{p} \int_{\Omega} \|\nabla v\|^p \,\mathrm{d}x - \int_{\Omega} f \, v \,\mathrm{d}x, \tag{4}$$

where $V = W_g^{1,p}(\Omega) = \{v \in W^{1,p}, v = g \text{ on } \partial\Omega\}$ includes Dirichlet boundary conditions on $\partial\Omega$. The minimizer $u \in V$ of (4) is known to be unique for p > 1.

6 Michal Béreš, Jan Valdman

Table 1: Performance comparison for the p-Laplace benchmark

Fig. 3: Performance comparison for the p-Laplace benchmark

Assume f = -10 for $x \in \Omega$, where $\Omega = \langle 0, 2 \rangle^2 \setminus \langle 1, 2 \rangle^2 \subset \mathbb{R}^2$ is a Lshaped domain, p = 3, and homogeneous Dirichlet boundary conditions on the boundary $\partial \Omega$. The exact solution u of (4) is unknown but can be approximated numerically; see Figure 2. The FEM approximation for this setting serves as a computational benchmark.

The complete implementation of the energy operator of (4) in JAX can be seen in the Listing 1.1. The corresponding gradient and Hessian are then evaluated exactly and automatically. The additional parameters are the power p = pand the vector $\mathbf{f} = [f_1, \ldots, f_n]$, where $f_i = \int f v_i \, dx$ with each $v_i \in V_h$. The vector f represents the linear functional f in terms of the FEM basis $v_i \in V_h$.

The resulting times and their comparison to the original MATLAB implementation can be seen in Table 1 and Figure 3. The observations align with the expectation that the Python implementation is faster, albeit with a fixed cost incurred by assembling and compiling functions for gradient and Hessian evaluation.

```
1 def J(u, u_0, freedofs, elems, dvx, dvy, vol, p, f):
\mathbf{2}
      v = u_0.at[freedofs].set(u)
3
      v_elems = v[elems]
4
      F_x = jnp.sum(v_elems * dvx, axis=1)
\mathbf{5}
6
      F_y = jnp.sum(v_elems * dvy, axis=1)
7
8
      intgrds = (1 / p) * (F_x**2 + F_y**2)**(p / 2)
9
      return jnp.sum(intgrds * vol) - jnp.dot(f, v)
```

Listing 1.1: Evaluation of the p-Laplace energy

Ginzburg-Landau problem 3.2

We consider the Ginzburg-Landau minimization problem [1] for a scalar test function $v \in V$. The energy functional is given by

$$J(v) = \int_{\Omega} \left(\frac{\varepsilon}{2} \|\nabla v\|^2 + \frac{1}{4} (v^2 - 1)^2 \right) \, \mathrm{d}x,\tag{5}$$

where $\Omega \subset \mathbb{R}^d$ is a given domain and ε is a given small positive parameter.

_

_

The benchmark problem consists of $\Omega = \langle -1, 1 \rangle^2 \subset \mathbb{R}^2$ and $\varepsilon = 0.01$. The Python implementation that allows for automatic differentiation of the energy functional (5) can be found in Listing 1.2. Additional non-grid parameters are

$$ip = \begin{bmatrix} \frac{2}{3} & \frac{1}{6} & \frac{1}{6} \\ \frac{1}{6} & \frac{2}{3} & \frac{1}{6} \\ \frac{1}{6} & \frac{1}{6} & \frac{2}{3} \end{bmatrix}, \quad w = \begin{bmatrix} \frac{1}{3} \\ \frac{1}{3} \\ \frac{1}{3} \\ \frac{1}{3} \end{bmatrix}, \quad eps = \varepsilon,$$

8 Michal Béreš, Jan Valdman

where ip is the matrix of coefficient of integration points and w is the vector of their weights. The integration rule used here is the same as in the corresponding MATLAB code. Note that it is accurate only up to the second degree of the polynomial, but $(v^2 - 1)^2$ requires the exact integration of fourth-order polynomials. This "variational crime" is acceptable, as linear convergence is expected with the linear elements considered.

Fig. 4: Numerical approximation of the solution u of the G-L benchmark.

```
def J(u, u_0, freedofs, elems, dvx, dvy, vol, ip, w, eps):
1
\mathbf{2}
       v = u_0.at[freedofs].set(u)
3
       v_elems = v[elems]
4
       F_x = jnp.sum(v_elems * dvx, axis=1)
\mathbf{5}
6
       F_y = jnp.sum(v_elems * dvy, axis=1)
7
8
       e_1 = (1 / 2) * eps * (F_x**2 + F_y**2)
       e_2 = (1 / 4) * ((v_elems @ ip)**2 - 1)**2 @ w
9
       return jnp.sum((e_1 + e_2) * vol)
10
```

Listing 1.2: Evaluation of the Ginzburg-Landau energy

The resulting comparison with the Matlab implementation is presented in Table 2 and Figure 5. We observed faster solution times; however, this was the only scenario in which the number of iterations for the analytical gradient and Hessian matched those of their numerical approximations. This behavior was primarily attributed to the choice of methods, as the diagonally regularized matrices in the trust-region approach yielded improved descent directions. Despite

	Pyt	Matlab				
dofs	time [s]	iters	$J\left(oldsymbol{u} ight)$	time [s]	iters	$J(\boldsymbol{u})$
49	0.01 / 0.18	6	0.3867	0.07	8	0.3867
225	0.02 / 0.18	8	0.3547	0.04	6	0.3547
961	0.03 / 0.24	7	0.3480	0.13	7	0.3480
3,969	0.10 / 0.20	7	0.3462	0.27	6	0.3462
16, 129	0.40 / 0.26	6	0.3458	0.60	7	0.3458
65,025	1.47 / 0.51	6	0.3457	4.65	8	0.3457
261, 121	6.04 / 1.56	6	0.3456	64.68	8	0.3456
1,046,529	26.63 / 5.76	6	0.3456	653.08	9	0.3456

this, the differences in performance were minimal and the computation times were nearly identical for both the line-search and trust-region methods. Consequently, we opted to present only one method in the Python implementation.

Table 2: Performance comparison for the G-L benchmark

Fig. 5: Performance comparison for the G-L benchmark

3.3 Hyperelasticity in 3D

The last benchmark is based on minimization of the energies of hyperelastic materials in mechanics of solids [7]. The trial space is chosen as $V = W_D^{1,p}(\Omega, \mathbb{R}^{\dim})$, that is, the (vector) Sobolev space of L^p integrable functions with the first weak derivative also being L^p integrable and satisfying (in the sense of traces) Dirichlet boundary conditions $v(x) = u_p(x)$ at the domain boundary $x \in \partial\Omega$, for a prescribed function $u_p : \partial\Omega \to \mathbb{R}^{\dim}$. A primary variable is the deformation mapping $v \in V$, which describes the relocation of any point $x \in \Omega$ during the deformation process.

10 Michal Béreš, Jan Valdman

The gradient deformation tensor $F \in L^p(\Omega, \mathbb{R}^{\dim \times \dim})$ is defined as

$$F(v) = \nabla v = \begin{bmatrix} \frac{\partial v^{(1)}}{\partial x_1} & \cdots & \frac{\partial v^{(1)}}{\partial x_{\dim}} \\ \vdots & \ddots & \vdots \\ \frac{\partial v^{(\dim)}}{\partial x_1} & \cdots & \frac{\partial v^{(\dim)}}{\partial x_{\dim}} \end{bmatrix}$$
(6)

The energy functional is given by

$$J(v) = \int_{\Omega} W(F(v(x))) \,\mathrm{d}x - \int_{\Omega} f(x) \cdot v(x) \,\mathrm{d}x,\tag{7}$$

where $W : \mathbb{R}^{\dim \times \dim} \to \mathbb{R}$ defines a strain-energy density function, and $f : \Omega \to \mathbb{R}^{\dim}$ is a loading functional. We assume the compressible Neo-Hookean density

$$W(F) = C_1(I_1(F) - \dim - 2\log(\det F)) + D_1(\det F - 1)^2,$$
(8)

where $I_1(F) = |F|^2$ uses the Frobenius norm $|\cdot|$, and $\det(\cdot)$ is the matrix determinant operator.

As a benchmark in $\dim = 3$, we consider a bar domain

$$\Omega = (0, l_x) \times \left(-\frac{l_y}{2}, \frac{l_y}{2}\right) \times \left(-\frac{l_z}{2}, \frac{l_z}{2}\right), \quad \text{where } l_x = 0.4, l_y = 0.01,$$

defined by the equivalent pairs of material parameters

-
$$E = 2 \cdot 10^8$$
 (Young's modulus), $\nu = 0.3$ (Poisson's ratio),
- $\mu = \frac{E}{2(1+\nu)}$ (the shear modulus), $K = \frac{E}{3(1-2\nu)}$ (the bulk modulus),
- $C_1 = \frac{\mu}{2}, D_1 = \frac{K}{2}.$

No loading is assumed, f = 0. The bar undergoes a deformation characterized by prescribed deformations at the right end of the bar, involving clockwise rotations up to 4 full turns across 24 iterations. The left end of the bar remains intact.

Fig. 6: Solution of hyperelasticity benchmark with underlying Neo-Hook densities

The Python implementation that facilitates automatic differentiation can be found in Listing 1.3. Additional non-grid parameters are $C1 = C_1$ and $D1 = D_1$.

The comparative analysis with the MATLAB implementation is detailed in Table 3 and Figure 7. Additionally, the Python setup times are as follows:

11

```
1 def J(u, u_0, freedofs, elems, dvx, dvy, dvz, vol, C1, D1):
\mathbf{2}
       v = u_0.at[freedofs].set(u)
3
       vx_elem = v[0::3][elems]
4
       vy_elem = v[1::3][elems]
\mathbf{5}
       vz_elem = v[2::3][elems]
\mathbf{6}
7
       F11 = jnp.sum(vx_elem * dvx, axis=1)
8
       F12 = jnp.sum(vx_elem * dvy, axis=1)
9
       F13 = jnp.sum(vx_elem * dvz, axis=1)
10
       F21 = jnp.sum(vy_elem * dvx, axis=1)
       F22 = jnp.sum(vy_elem * dvy, axis=1)
11
       F23 = jnp.sum(vy_elem * dvz, axis=1)
12
13
       F31 = jnp.sum(vz_elem * dvx, axis=1)
14
       F32 = jnp.sum(vz_elem * dvy, axis=1)
15
       F33 = jnp.sum(vz_elem * dvz, axis=1)
16
       I1 = (F11 * * 2 + F12 * * 2 + F13 * * 2 +
17
             F21**2 + F22**2 + F23**2 +
18
             F31**2 + F32**2 + F33**2)
19
20
       det = jnp.abs(+ F11 * F22 * F33 - F11 * F23 * F32
21
                      - F12 * F21 * F33 + F12 * F23 * F31
                      + F13 * F21 * F32 - F13 * F22 * F31)
22
23
       W = C1 * (I1 - 3 - 2 * jnp.log(det)) + D1 * (det - 1)**2
24
       return jnp.sum(W * vol)
```

Listing 1.3: Evaluation of the hyperelastic energy

- -0.42 s for 2,133 degrees of freedom (dofs),
- -1.69 s for 11,925 dofs, and
- -4.86 s for 77, 517 dofs.

These setup durations are almost negligible for this particular problem, given that the solution process—which encompasses all 24 iterations—is significantly more computationally demanding by comparison. The speedups are particularly notable for this benchmark, ranging from around $10 \times$ to $20 \times$ faster than the MATLAB computations. It is critical to note that MATLAB failed to converge with the same precision as the Python code. For comparison purposes, we maintain the original settings of the MATLAB code. Achieving the same level of convergence could be possible by increasing the tolerance; however, this adjustment would substantially extend the computation times.

4 Conclusions

We have presented a comparison of the MATLAB and Python implementations to solve a class of complex minimization problems. Our findings highlight several key advantages of using Python in scientific computing:

Table 3: Performance comparison for the hyperelasticity benchmark

Fig. 7: Performance comparison for the hyperelasticity benchmark

Firstly, the Python framework facilitates the implementation of new nonlinear functionals with remarkable ease, often requiring only a few lines of code. This simplicity significantly enhances the flexibility and speed of development in research settings.

Second, we have identified that custom solvers for linear systems, particularly those involving Hessians, are highly preferable. Unfortunately, MATLAB's fminunc function, with its trust region approach that uses only a sparse pattern and diagonally preconditioned conjugate gradients, does not support custom linear solvers. This limitation would require MATLAB implementations to rewrite the minimizer routine to their own implementations that facilitate these options. However, there are still no easily obtainable and efficient implementations for things such as algebraic multigrid solvers or efficient graph coloring algorithms.

Lastly, our benchmarks demonstrate that the current Python framework is more than ten times faster than MATLAB for larger problems.

These observations suggest that the current Python environment provides a more flexible and efficient computational environment for handling sophisticated mathematical models and large-scale problems.
