**Abstract.** The cosmological dispersion measure (DM) as a function of redshift, derived from localized fast radio bursts (FRBs), has been used as a tool for constraining the cosmic ionized fraction and cosmological parameters. For these purposes, the DM in a homogeneous cosmological model has typically been used, neglecting the inhomogeneity of matter distribution. In this study, we derive a bias in the ensemble average of the DM over many FRBs owing to gravitational lensing by the inhomogeneous matter distribution based on cosmological perturbation theory. We demonstrate that the ensemble average is 0.4%–1% smaller than the DM in the corresponding homogeneous model for a source redshift of  $z_{\rm s} = 1$ , according to recent cosmological hydrodynamic simulations of IllustrisTNG and BAHAMAS. This reduction occurs because light rays from FRBs tend to avoid high-density regions owing to lensing deflection. We also discuss another selection effect, magnification bias, where demagnified FRBs with low DMs, fainter than the detection threshold, are excluded from the observed sample, leading to a selective observation of magnified FRBs with high DMs. Lensing bias, including magnification bias, must be considered to achieve percent level accuracy in the DM–redshift relation.

## 1 Introduction

Fast radio burst (FRB) is a radio transient, with a typical duration of milliseconds, from a cosmological distance (e.g., recent reviews [1–4]). Many theoretical models for FRBs have been proposed, but their physical origin is still elusive (e.g., [4]). From a frequency dependence of the arrival time, the dispersion measure (DM) is measured, which is the column density of free electrons along the light path to the source. If its host galaxy is identified, it is called a localized FRB, and its redshift can be determined. Currently, at least 40 localized FRBs have been identified (e.g., [5–11]), with the highest redshift being  $z_s = 1.0$  [12]. The observed DM is influenced by contributions from the Milky Way (MW), the host galaxy, and cosmological objects such as the inter-galactic medium (IGM) and intervening galaxies. Because the cosmological contribution is dominant for relatively high source redshifts ( $z_s \gtrsim 0.5$ ), we focus solely on the cosmological DM in this study.

The DM-redshift relation, measured from localized FRBs, has been utilized to constrain the ionized fraction in the IGM ( $f_e$ ) [13–17], Hubble parameter ( $H_0$ ) [18–24], and cosmic baryon abundance ( $\Omega_b$ ) [5, 25, 26]. Because these parameters are completely degenerate (DM  $\propto H_0 f_e \Omega_b$ ), external constraints or assumptions are required to determine one of them. When many localized FRBs are available at high redshifts ( $z_s \gtrsim 0.5$ ), the DM–z relation can probe the properties of dark energy (e.g., [27–29]) and the history of cosmic reionization (e.g., [30–35]). In all previous works, the DM was calculated using a homogeneous cosmological model. In this study, we investigate the effects of matter inhomogeneity on the ensemble average of the DM over many FRBs.

The effects of inhomogeneous mass distribution on the luminosity distance  $D_{\rm L}$  have been extensively studied for supernova (SN) cosmology, utilizing second-order cosmological perturbation theory (e.g., [36–47]; also the recent review [48]). Matter inhomogeneity causes a scatter and a bias in  $D_{\rm L}$ . The bias arises from the second-order term of density fluctuations because the first-order term averages out over many sources. For high redshifts ( $z_{\rm s} \gtrsim 0.3$ ), the dominant contribution is gravitational lensing, while for low redshifts ( $z_{\rm s} \lesssim 0.3$ ), it is the peculiar motions of the observer and the source [39, 40]. In this study, we focus on the lensing contribution, with other second-order effects briefly discussed in Subsection 5.1. The ensemble average of  $D_{\rm L}$  in an inhomogeneous universe,  $\langle D_{\rm L} \rangle$ , and that in the corresponding homogeneous model,  $\bar{D}_{\rm L}$ , follow a simple relation:  $\langle D_{\rm L} \rangle = [1 + (3/2) \langle \kappa^2 \rangle] \bar{D}_{\rm L}$ , where  $\kappa$  is the convergence field (e.g., [44, 49]). Given that the variance of  $\kappa$  is estimated as  $\langle \kappa^2 \rangle \approx (2 8) \times 10^{-3} z_{\rm s}^2$  [50–53], the lensing bias increases  $D_{\rm L}$  by  $\mathcal{O}(0.1\%$ –1%) for  $z_{\rm s} \gtrsim 0.4$ . This bias will need to be accounted for in future SN cosmology analyses (e.g., [36, 54]).

Kaiser & Peacock (2016) [44] (hereafter KP16) evaluated the lensing bias in  $\langle D_{\rm L} \rangle$  using standard perturbation theory. By solving the null-geodesic equation, they demonstrated that light rays propagate through underdense regions on average because they tend to avoid matter clumps owing to lensing deflection. They also analytically derived that the average convergence  $\kappa$  is negative, satisfying the simple relation  $\langle \kappa \rangle = -2 \langle \kappa^2 \rangle$ . This originates from flux conservation<sup>1</sup> [55]. This relation is also confirmed by cosmological ray-tracing simulations [56] and for weak lensing of gravitational waves in wave optics (i.e., without the geometricaloptics approximation) [57, 58].

In this study, we calculate the lensing bias in the average of the DM,  $\langle DM \rangle$ , in an inhomogeneous universe where the total matter (dark matter and baryons) and free-electron distributions are inhomogeneous. A standard deviation of the DM caused by matter inhomogeneity has been previously studied (e.g., [59-63]), but the bias has not yet been examined. We use the standard cosmological perturbation theory following the KP16 procedure. Based on previous studies on  $\langle D_{\rm L} \rangle$ , we expect  $\langle {\rm DM} \rangle$  to be smaller than the prediction from the homogeneous model. Section 2 details our approach, where we integrate the free-electron density along null geodesics in curved spacetime to compute the DM and then expand it in terms of density fluctuations. We derive a leading correction term in  $\langle DM \rangle$  determined by the cross-power spectrum of matter and free electrons (Appendix A), utilizing data from recent hydrodynamic simulations of IllustrisTNG<sup>2</sup> and BAHAMAS<sup>3</sup>. Section 3 presents numerical results for  $\langle DM \rangle$ , comparing it with predictions from the homogeneous model. We also discuss the influence of baryonic feedback on (DM). Section 4 addresses another selection effect, magnification bias, and its impact on  $\langle DM \rangle$ . Section 5 discusses other second-order effects aside from lensing bias (Subsection 5.1) and provides insights into lensing bias in rotation measures (Subsection 5.2). Finally, Section 6 summarizes the findings of this study.

In this paper, for any arbitrary quantity f,  $\langle f \rangle$  denotes its ensemble average in an inhomogeneous universe, while  $\overline{f}$  represents its value in the corresponding homogeneous model. We adopt a spatially flat  $\Lambda$ CDM model consistent with the *Planck* 2015 best-fitting parameters [64]: matter density  $\Omega_{\rm m} = 1 - \Omega_{\Lambda} = 0.3089$ , baryon density  $\Omega_{\rm b} = 0.0486$ , Hubble parameter h = 0.6774, spectral index  $n_{\rm s} = 0.9667$ , and amplitude of matter density fluctuations on the scale of  $8 h^{-1}$ Mpc  $\sigma_8 = 0.8159$ . This model is identical to the one used in IllustrisTNG. All physical quantities such as length, wavenumber, and number density are

<sup>&</sup>lt;sup>1</sup>From flux conservation, the average lensing magnification is unity,  $\langle \mu \rangle = 1$ . Using  $\mu = 1/[(1 - \kappa)^2 - \gamma^2]$ ( $\gamma$  is the shear field, satisfying  $\langle \gamma^2 \rangle = \langle \kappa^2 \rangle$ ) with  $|\kappa|, |\gamma| \ll 1$ , one obtains  $\langle \kappa \rangle = -2\langle \kappa^2 \rangle$ . Similarly, the bias in  $D_{\rm L}$  is obtained as  $\langle D_{\rm L} \rangle = \langle \mu^{-1/2} \rangle \bar{D}_{\rm L} \simeq [1 + (3/2)\langle \kappa^2 \rangle] \bar{D}_{\rm L}$ .

**Figure 1.** The solid curve represents the path of a light ray toward the FRB, parameterized by the affine parameter (path length)  $\lambda$ :  $\lambda = 0$  at the observer and  $\lambda = \lambda_s$  at the source. The dashed line represents the radial coordinate r toward the source, and  $\boldsymbol{x}$  denotes a two-dimensional coordinate perpendicular to the r-axis.

expressed in comoving units.

### 2 Ensemble average of the DM

#### 2.1 Light ray path in an inhomogeneous universe

This subsection briefly explores the path of a light ray in an inhomogeneous universe (e.g., Appendices of KP16; a review [65]; a textbook [66]). Figure 1 illustrates the coordinate system used. The r axis represents the radial coordinate (comoving distance) connecting the observer and the FRB. The coordinate r is expressed as a function of redshift z:  $r(z) = c \int_0^z dz'/H(z')$ , where H(z) is the Hubble expansion rate. The distance to the source is  $r_s = r(z_s)$ . The two-dimensional coordinate  $\boldsymbol{x}$  is perpendicular to the r-axis. The spatial coordinate is denoted by  $\boldsymbol{r} = (r, \boldsymbol{x})$ .

In a homogeneous universe, a light ray from the source travels along the *r*-axis. In an inhomogeneous scenario, the propagation of a light ray is affected by gravitational deflections caused by matter clumps. The matter inhomogeneity generates a gravitational potential  $\phi = \phi(\mathbf{r}; z)$ , assuming weak gravity  $(|\phi|/c^2 \ll 1)$ . We adopt the Newtonian gauge for the metric perturbation and neglect the peculiar velocities of the observer and source. The path of a light ray is determined by the geodesic equation with the affine parameter  $\lambda$ :  $d^2\mathbf{r}/d\lambda^2 = -(2/c^2) \nabla_{\perp}\phi$  where  $\nabla_{\perp}$  is derivative in the direction perpendicular to the path. Here,  $\lambda$  is the path length from the observer. The geodesic equation is solved under the boundary condition that the positions at both endpoints are fixed to those of the observer and the source (Appendix E of KP16):

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}\lambda}(\lambda) = -\frac{2}{c^2} \int_0^{\lambda} \mathrm{d}\lambda' \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}'; \boldsymbol{z}') + \frac{2}{c^2} \frac{1}{\lambda_{\mathrm{s}}} \int_0^{\lambda_{\mathrm{s}}} \mathrm{d}\lambda' (\lambda_{\mathrm{s}} - \lambda') \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}'; \boldsymbol{z}'),$$

$$\boldsymbol{x}(\lambda) = -\frac{2}{c^2} \int_0^{\lambda} \mathrm{d}\lambda' (\lambda - \lambda') \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}'; \boldsymbol{z}') + \frac{2}{c^2} \frac{\lambda}{\lambda_{\mathrm{s}}} \int_0^{\lambda_{\mathrm{s}}} \mathrm{d}\lambda' (\lambda_{\mathrm{s}} - \lambda') \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}'; \boldsymbol{z}'),$$
(2.1)

where  $\mathbf{r}' = \mathbf{r}(\lambda') = (r(\lambda'), \mathbf{x}(\lambda')), \ z' = z(\lambda'), \ \text{and} \ \nabla_{\mathbf{x}} \ (\simeq \nabla_{\perp})$  is the gradient with respect to  $\mathbf{x}$ . Equation (2.1) includes terms up to the first order of  $\phi/c^2$ . Because the gravitational potential is weak, we obtain  $|\mathbf{x}| \ll r$ .

A light ray can also experience deflection by an inhomogeneous plasma density caused by spatial variations in the refractive index (plasma lensing). We have disregarded this effect because the deflection angle is typically negligible, except in cases involving high-density clumps at low radio frequencies  $\nu$ . For lensing by an intervening galaxy, the deflection angle is typically  $\approx 1 \operatorname{arcsec}$  for gravitational lensing and  $\approx 10^{-3} (\nu/400 \text{MHz})^{-2} \operatorname{arcsec}$  for plasma lensing (e.g., [67]).

#### 2.2 The DM in an inhomogeneous universe

The DM represents the column density of free electrons along the path to the source<sup>4</sup> (e.g., [30, 31, 70]):

$$DM(z_{s}) = \int_{0}^{\lambda_{s}} d\lambda \, n_{e}(\boldsymbol{r}; z) \, (1+z).$$
(2.2)

The integration is conducted along the geodesic (2.1). The free-electron density  $n_{\rm e}$  is separated into its spatial mean  $\bar{n}_{\rm e}$  and fluctuations  $\delta_{\rm e}$ :

$$n_{\rm e}(\boldsymbol{r};z) = \bar{n}_{\rm e}(z) \left[1 + \delta_{\rm e}(\boldsymbol{r};z)\right].$$
(2.3)

The spatial average of the second term vanishes,  $\langle \delta_{\rm e} \rangle = 0$ . The mean free-electron number density is expressed as (e.g., [71]):

$$\bar{n}_{\rm e}(z) = \frac{3H_0^2}{8\pi G} \frac{\Omega_{\rm b}}{m_{\rm p}} \left( X(z) + \frac{1}{2} Y(z) \right) f_{\rm e}(z), \tag{2.4}$$

where  $m_{\rm p}$  is the proton mass, X and Y are the mass fractions of hydrogen and helium  $(X \simeq 0.75 \text{ and } Y \simeq 0.25)$ , and  $f_{\rm e}$  is the ionized fraction  $(f_{\rm e} \approx 0.7-0.9)$ . In the homogeneous model, the DM simplifies to

$$\overline{\mathrm{DM}}(z_{\mathrm{s}}) = \int_{0}^{r_{\mathrm{s}}} \mathrm{d}r \, \bar{n}_{\mathrm{e}}(z) \, (1+z),$$
$$= \int_{0}^{z_{\mathrm{s}}} \frac{c \, \mathrm{d}z}{H(z)} \, \bar{n}_{\mathrm{e}}(z) \, (1+z).$$
(2.5)

The integration is done along the r-axis.

Next, we derive a leading correction term in the DM arising from second-order perturbations ( $\phi/c^2$  and  $\delta_e$ ). In Eq. (2.2), because  $|\boldsymbol{x}| \ll r$ ,  $n_e$  can be expanded up to the linear order of  $\boldsymbol{x}$ :

$$n_{\rm e}(\boldsymbol{r}; z) \simeq n_{\rm e}(\boldsymbol{r}; z)|_{\boldsymbol{x}=0} + \boldsymbol{x} \cdot \nabla_{\boldsymbol{x}} n_{\rm e}(\boldsymbol{r}; z)|_{\boldsymbol{x}=0},$$
  
=  $\bar{n}_{\rm e}(z) \left[ 1 + \delta_{\rm e}(\boldsymbol{r}; z)|_{\boldsymbol{x}=0} + \boldsymbol{x} \cdot \nabla_{\boldsymbol{x}} \delta_{\rm e}(\boldsymbol{r}; z)|_{\boldsymbol{x}=0} \right].$  (2.6)

<sup>&</sup>lt;sup>4</sup>The DM–z relation is sometimes referred to as the Macquart relation [25], although it had been developed earlier in previous studies (e.g., [30, 31, 68-71]).

The integral along the geodesic in Eq. (2.2) is replaced by integration along the r-axis:

$$d\lambda = \sqrt{1 + \left(\frac{d\boldsymbol{x}}{d\lambda}\right)^2} \bigg|_{\boldsymbol{x}=0} dr,$$
  

$$\simeq dr + \frac{1}{2} \left(\frac{d\boldsymbol{x}}{d\lambda}\right)^2 \bigg|_{\boldsymbol{x}=0} dr.$$
(2.7)

Using Eqs. (2.2), (2.6) and (2.7), we derive the ensemble average of the DM as

$$\langle \mathrm{DM} \rangle(z_{\mathrm{s}}) = \int_{0}^{r_{\mathrm{s}}} \mathrm{d}r \, \bar{n}_{\mathrm{e}}(z) \, (1+z) + \int_{0}^{r_{\mathrm{s}}} \mathrm{d}r \, \bar{n}_{\mathrm{e}}(z) \, (1+z) \, \left\langle \left. \mathbf{x} \cdot \nabla_{\mathbf{x}} n_{\mathrm{e}}(\mathbf{r}; z) \right|_{\mathbf{x}=0} \right\rangle$$

$$+ \frac{1}{2} \int_{0}^{r_{\mathrm{s}}} \mathrm{d}r \, \bar{n}_{\mathrm{e}}(z) \, (1+z) \left\langle \left. \left( \frac{\mathrm{d}\mathbf{x}}{\mathrm{d}\lambda} \right)^{2} \right|_{\mathbf{x}=0} \right\rangle.$$

$$(2.8)$$

The first term corresponds to the DM in the homogeneous model (2.5). The second and third terms represent the leading correction terms. Appendix A provides a detailed calculation of these terms; the second term is negative<sup>5</sup>, whereas the third is positive. Because the third term is  $\approx 10^{-7}$  (10<sup>-5</sup>) times smaller than the first (second) term for  $z_{\rm s} = 0$ -3, we disregard the third term in subsequent analysis.

In summary, the ensemble average of the DM is written as

$$\langle \mathrm{DM} \rangle(z_{\mathrm{s}}) = \overline{\mathrm{DM}}(z_{\mathrm{s}}) + \Delta \mathrm{DM}(z_{\mathrm{s}}),$$
 (2.9)

with

$$\Delta \mathrm{DM}(z_{\mathrm{s}}) = -\frac{3H_0^2 \Omega_{\mathrm{m}}}{2\pi c^2} \int_0^{z_{\mathrm{s}}} \frac{c \, \mathrm{d}z}{H(z)} \,\bar{n}_{\mathrm{e}}(z) \,(1+z)^2 \,\frac{r(z) \,(r_{\mathrm{s}} - r(z))}{r_{\mathrm{s}}} \int_0^\infty \mathrm{d}k_\perp k_\perp P_{\mathrm{me}}(k_\perp; z), \quad (2.10)$$

where  $P_{\rm me}$  is the cross-power spectrum of matter and free electrons (defined in Eq. (A.4)); therefore,  $\Delta DM$  originates from the cross-correlation between these two fields. The distributions of matter and free electrons determine  $\boldsymbol{x}$  and  $\nabla_{\boldsymbol{x}} n_{\rm e}$ , respectively, in Eq. (2.8). Our result (2.9) is consistent with the previous one for the average convergence,  $\langle \kappa \rangle = -2\langle \kappa^2 \rangle$ , when  $\kappa$  is used instead of the DM (see also Appendix A). According to Eq. (2.10), the density fluctuations approximately halfway to the source (i.e.,  $r(z) \approx r_{\rm s}/2$ ) contribute the most to  $\Delta DM$ .

### 2.3 The cross-power spectrum of matter and free electrons

This subsection discusses two theoretical models of  $P_{\rm me}$  in Eq. (2.10). The first one is our fitting function of  $P_{\rm me}$  based on the hydrodynamic simulations of IllustrisTNG [73–78]. The other is a numerical scheme of HMx<sup>6</sup> [72, 79] calibrated with another hydrodynamic simulation suite of BAHAMAS [80, 81]. A comparison of these different models helps to understand the baryonic feedback effect on  $P_{\rm me}$ .

We measure  $P_{\rm me}$  in the public IllustrisTNG data set [78] to make its fitting function, following the same procedure as in our previous work [63] (their Subsection 3.3). The simulations follow the gravitational clustering of matter (dark matter and baryons), as well as

<sup>&</sup>lt;sup>5</sup>The vector  $\boldsymbol{x}$  points from high to low density, whereas the direction of  $\nabla_{\boldsymbol{x}} n_{\rm e}$  is the opposite; thus, the second term is negative.

<sup>&</sup>lt;sup>6</sup>https://github.com/tilmantroester/pyhmcode

**Figure 2.** Cross-power spectrum of matter and free electrons at z = 0, 0.4, and 1. The blue and green symbols represent results from hydrodynamic simulations TNG300-1 and TNG100-1, respectively. The red curves depict our theoretical model based on the free-electron bias (2.12) fitted to the TNG results. The dashed orange curves show predictions from HMx [72], calibrated with BAHAMAS. The three orange curves differ in the AGN feedback temperature:  $\log_{10}(T_{AGN}/K) = 7.6$  (thin), 7.8 (average), and 8.0 (thick), where the higher temperature corresponds to the stronger feedback. In the middle and right panels, the amplitudes are multiplied by 2 and 5, respectively, to make the peak heights uniform.

astrophysical processes such as star and galaxy formation, and stellar and active galactic nucleus (AGN) feedback. The gravitational evolution and magneto-hydrodynamic processes were computed with the moving-mesh code AREPO [82]. We analyzed two simulations with different box sizes: TNG300-1 and TNG100-1. TNG300-1 (TNG100-1) comprises 2500<sup>3</sup> (1820<sup>3</sup>) dark matter particles and a nearly equivalent number of baryon particles in a cubic box with a side length of 205 (75)  $h^{-1}$ Mpc; thus, TNG100-1 offers higher spatial and mass resolutions. The baryon particles consist of gas, stars, and black holes, with free electrons included in the gas particles. To calculate the matter density contrast  $\delta_{\rm m}$ , we assign the masses of dark matter and baryon particles to regular grid cells using the cloud-in-cell interpolation with the interlacing scheme (e.g., [83–85]). Similarly, we calculate the free-electron density contrast  $\delta_{\rm e}$  by assigning the masses of free electrons to the grid cells. Fourier transform<sup>7</sup>. The power spectrum is then measured as

$$P_{\rm me}(k;z) = \frac{1}{N_{\rm mode}} \sum_{|\mathbf{k}'| \in k} \operatorname{Re}\left[\tilde{\delta}_{\rm m}(\mathbf{k}')\tilde{\delta}_{\rm e}^*(\mathbf{k}')\right], \qquad (2.11)$$

where the summation is performed in the spherical shell  $k - \Delta k/2 < |\mathbf{k}'| < k + \Delta k/2$  with a bin width of  $\Delta \log_{10} k = 0.1$ , and  $N_{\text{mode}}$  represents the number of Fourier modes in the shell. The power spectrum is reliable up to the particle Nyquist wavenumber  $k_{\text{Nyq}}$ , determined by

<sup>&</sup>lt;sup>7</sup>FFTW (Fastest Fourier Transform in the West) at http://www.fftw.org.

the mean separation of gas particles  $r_{\text{gas}}$ :  $k_{\text{Nyq}} = \pi/r_{\text{gas}} = 38.3 (76.2) h \text{ Mpc}^{-1}$  for TNG300-1 (TNG100-1). We measured  $P_{\text{me}}$  at z = 0, 0.2, 0.4, 0.7, 1, 2 and 3.

The TNG team also conducted dark matter-only (DMO) runs, where the box sizes and the number of dark matter particles matched those in TNG300-1 and TNG100-1, respectively. These runs include N-body particles representing dark matter and baryons, focusing solely on gravitational evolution. We measure the matter power spectra in the DMO runs, denoted as  $P_{\rm DMO}$ , using the identical procedure as for  $P_{\rm me}$ . Subsequently, we define the free-electron bias:

$$b_{\rm e}(k;z) \equiv \frac{P_{\rm me}(k;z)}{P_{\rm DMO}(k;z)}.$$
 (2.12)

The fitting function of  $b_{\rm e}$  is detailed in Appendix B. It is worth noting that the freeelectron bias (2.12) differs slightly from our previous definition [63], i.e.,  $b_{\rm e}^{(\rm prev)}(k;z) \equiv [P_{\rm e}(k;z)/P_{\rm DMO}(k;z)]^{1/2}$ , where  $P_{\rm e}(k;z)$  is the auto-power spectrum of free electrons. The discrepancy is noticeable only on small scales  $(k \gtrsim 1h {\rm Mpc}^{-1})$ , as discussed in Appendix B.

Moving on to HMx, the BAHAMAS simulations were conducted using the smoothedparticle hydrodynamic code GADGET-3 [86], incorporating subgrid models to simulate baryonic processes. The stellar and AGN feedback models were calibrated to match observations of the galaxy's stellar mass function and the hot gas fraction in galaxy groups and clusters. AGN feedback strength is specified by the heating temperature:  $\log_{10}(T_{\rm AGN}/\rm K) = 7.6, 7.8$ , and 8.0 where 7.8 is their fiducial value consistent with the observed hot gas fraction of groups and clusters [80]. There are  $1024^3$  dark matter particles and an equivalent number of baryon particles in a box volume of  $(400 h^{-1} \rm Mpc)^3$ . HMx utilizes the halo model framework (e.g., [87–90]), calibrated to reproduce auto- and cross-power spectra of five fields: total matter, cold dark matter, gas, stars, and electron pressure, measured in BAHAMAS. The calibration range is  $k = 0.015-7 h \rm Mpc^{-1}$  and z = 0-1. We derive  $P_{\rm me}$  from the cross-power spectrum of matter and gas in HMx, denoted as  $P_{\rm mg}^{\rm HMx}$ , assuming that free electrons exactly trace gas (i.e.,  $\delta_{\rm e} = \delta n_{\rm e}/\bar{n}_{\rm e} = \delta \rho_{\rm gas}/\bar{\rho}_{\rm gas}$ ). Because the normalization of  $P_{\rm mg}^{\rm HMx}$  differs from our  $P_{\rm me}$ , we rescale it<sup>8</sup>. Previously, the HMx power spectrum was used to calculate the covariance of the DM [91] and the angular cross-power spectrum of the DM and  $\kappa$  [92].

Figure 2 presents  $P_{\rm me}$  at z = 0, 0.4, and 1. The blue and green symbols denote TNG measurements. The TNG300-1 and TNG100-1 show consistent results for  $k \leq 10 h {\rm Mpc}^{-1}$ . However, the TNG100-1 gives slightly higher amplitudes for  $k \geq 10 h {\rm Mpc}^{-1}$ , probably owing to the finer spatial resolution. The red curves are our theoretical model,  $P_{\rm me}(k; z) = b_{\rm e}(k; z) P_{\rm DMO}(k; z)$ , using the fitting function of  $b_{\rm e}$  and HALOFIT [93, 94] for the non-linear matter power spectrum  $P_{\rm DMO}$ . The dashed orange curves are the HMX results. All TNG and HMX results agree at the largest scale  $(k < 1 h {\rm Mpc}^{-1})$  because the free electrons trace the underlying dark matter irrespective of baryonic physics [63]. The free-electron bias is almost unity at such a large scale (Appendix B). For  $k > 1 h {\rm Mpc}^{-1}$ ,  $P_{\rm me}$  shows suppression influenced by AGN feedback strength; higher  $T_{\rm AGN}$  leads to stronger suppression, consistent with trends seen in the matter power spectrum (e.g., [95]). From the peak of  $k^2 P_{\rm me}(k)$  in Fig. 2, the density fluctuations of  $k = 1-10 h {\rm Mpc}^{-1}$  contribute the most to  $\Delta {\rm DM}$  in Eq. (2.10).

Let us briefly summarize the current observational constraints on the  $T_{\text{AGN}}$  parameter. Chen et al. (2023) [96] detected baryon feedback suppression on the matter power spectrum

<sup>&</sup>lt;sup>8</sup>These two power spectra are related via  $P_{\rm me}(k;z) = (\bar{\rho}_{\rm m}/\bar{\rho}_{\rm gas}(z)) P_{\rm mg}^{\rm HMx}(k;z) = (\Omega_{\rm m}/\Omega_{\rm b}) [1 - (\Omega_{\rm m}/\Omega_{\rm b})(\bar{\rho}_{\rm star}(z)/\bar{\rho}_{\rm m})]^{-1} P_{\rm mg}^{\rm HMx}(k;z)$ , where  $\bar{\rho}_{\rm m}, \bar{\rho}_{\rm gas}$  and  $\bar{\rho}_{\rm star}$  are the mean densities of matter, gas, and stars, respectively ( $\bar{\rho}_{\rm m}$  is constant while the others are functions of z). The ratio  $\bar{\rho}_{\rm star}(z)/\bar{\rho}_{\rm m}$  is obtained by averaging the stellar fraction (Eq. (27) in [72]) over all halo masses.

Figure 3. The ensemble average of the DM in an inhomogeneous universe  $\langle DM \rangle$  normalized by that in the corresponding homogeneous model  $\overline{DM}$  as a function of source redshift  $z_s$ . These curves are distinguished by the  $P_{\rm me}$  model: the solid red curve uses the fitting function (2.12) for TNG, and the dashed orange curves use HMX with  $\log_{10}(T_{\rm AGN}/\rm K) = 7.6$  (thin), 7.8 (average) and 8.0 (thick). The dashed curves for  $z_s > 1$  are obtained from an extrapolation of HMX (which is calibrated up to z = 1).

using cosmic shear measurements from the Dark Energy Survey (DES) year 3 data. They found that the suppression was consistent with values of  $\log_{10}(T_{AGN}/K) = 7.8$  and 8.0 (their Fig. 8), which is consistent with other cosmic shear analyses [97, 98]. On the other hand, Terasawa et al. (2024) [99] performed a similar analysis using the Subaru Hyper Suprime-Cam three-year data, probing down to very small scales (0.28 arcmin). Their findings suggest a preference for weaker feedback with  $\log_{10}(T_{AGN}/K) = 7.6$  (their Fig. 11; also discussed in [100]). Tröster et al. (2022) [79] performed a combined analysis of cosmic shear from the Kilo-Degree Survey and the thermal Sunyaev–Zel'dovich data from Planck and the Atacama Cosmology Telescope. Their constraint is  $\log_{10}(T_{AGN}/K) = 7.96^{+0.20}_{-0.48}$ . Ferreira et al. (2024) [101] measured a cross-power spectrum of weak lensing in DES Y3 and the diffuse X-ray background in the Roentgensatellit (ROSAT), providing a very precise constraint of  $\log_{10}(T_{AGN}/K) = 7.998 \pm 0.008$ . In summary, the constraints do not converge well among the different measurements.

## 3 Results

This section presents our main results for  $\langle DM \rangle$  as described in Eq. (2.9). Figure 3 illustrates  $\langle DM \rangle$  normalized by  $\overline{DM}$  as a function of  $z_s$ . Here, we set  $f_e = 0.83$  and X = 1 - Y = 0.76 in Eq. (2.4), noting that the ratio  $\langle DM \rangle / \overline{DM}$  is independent of  $f_e$ , X and Y as long as these quantities are constant. The TNG results exhibit a stronger lensing bias owing to weaker baryon feedback. For TNG,  $\langle DM \rangle$  is 1% (0.6%) smaller than  $\overline{DM}$  at  $z_s = 1$  ( $z_s = 0.5$ ), with the bias becoming more pronounced at higher  $z_s$ . For HMX,  $\langle DM \rangle$  is 0.4% - 0.8% smaller than  $\overline{DM}$  at  $z_s = 1$ , depending on the value of  $T_{AGN}$ . Notably, HMX is calibrated only up to z = 1; thus, the results for  $z_s > 1$  are extrapolated. If the baryonic feedback is ignored (i.e.,  $b_e = 1$ ),  $\Delta DM$  becomes approximately twice the TNG result. In summary, the conventional

formula for  $\overline{\text{DM}}$  slightly overestimates the DM owing to the gravitational lensing effect, where light rays tend to avoid dense matter clumps.

We estimate the number of localized FRBs needed to detect the lensing bias in the DM– z relation for  $z_s = 0.5$  and 1. While the total DM comprises contributions from the MW, host galaxy, and cosmological sources, the lensing bias impacts the cosmological component. Referring to Fig. 3, the discrepancy between  $\langle DM \rangle$  and  $\overline{DM}$  is

$$\langle \mathrm{DM} \rangle(z_{\mathrm{s}}) - \overline{\mathrm{DM}}(z_{\mathrm{s}}) \approx -3.0 \,\mathrm{pc/cm^3} \left( \frac{\langle \mathrm{DM} \rangle / \overline{\mathrm{DM}}}{0.994} \right) \quad \text{for } z_{\mathrm{s}} = 0.5,$$
  
 $\approx -10 \,\mathrm{pc/cm^3} \left( \frac{\langle \mathrm{DM} \rangle / \overline{\mathrm{DM}}}{0.99} \right) \quad \text{for } z_{\mathrm{s}} = 1,$ 
(3.1)

for the TNG result. Here, we have used the approximate relation  $\overline{\text{DM}}(z_{\rm s}) \approx 1000 z_{\rm s} \text{ pc/cm}^3$ (e.g., [30]). The standard deviation of the measured DM ( $\sigma_{\rm DM}$ ) arises from cosmological contribution ( $\sigma_{\rm DM,cosmo}$ ) and host-galaxy contribution ( $\sigma_{\rm DM,host}$ ):  $\sigma_{\rm DM} = (\sigma_{\rm DM,cosmo}^2 + \sigma_{\rm DM,host}^2)^{1/2}$ . Using  $\sigma_{\rm DM,cosmo} \approx 200 z_{\rm s}^{1/2} \text{ pc/cm}^3$  (e.g., [59, 63, 102]) and  $\sigma_{\rm DM,host} \approx 100 (1 + z_{\rm s})^{-1} \text{ pc/cm}^3$  (e.g., [25, 103, 104]), the standard deviation is

$$\sigma_{\rm DM}(z_{\rm s}) \approx 160 \,\mathrm{pc/cm^3} \quad \text{for } z_{\rm s} = 0.5,$$
$$\approx 210 \,\mathrm{pc/cm^3} \quad \text{for } z_{\rm s} = 1. \tag{3.2}$$

Using many FRBs, the standard deviation decreases inversely proportional to the square root of their count. Therefore, according to Eqs. (3.1) and (3.2), when approximately 3000 and 400 localized FRBs are available for  $z_{\rm s} = 0.5$  and 1, respectively, the lensing bias will affect  $\langle \text{DM} \rangle$  at the 1 $\sigma$  error level. In the near future, instruments such as the Canadian Hydrogen Intensity Mapping Experiment FRB instrument (CHIME/FRB) outriggers, the Canadian Hydrogen Observatory and Radio-transient Detector (CHORD)<sup>9</sup>, and the Deep Synoptic Array (DSA)-2000<sup>10</sup> are expected to detect ~ 10<sup>4</sup> localized FRBs per year (e.g., [105–107]). With the many FRBs available, the lensing bias must be carefully considered in the DM–z relation.

There are two types of FRBs: repeaters and non-repeaters. Multiple signals from a repeater are consolidated into a single event when calculating  $\langle DM \rangle$  to prevent duplication. In contrast, multiple images of a single source resulting from strong lensing are treated as independent events because their light ray paths differ. However, the probability of such lensing occurrences is relatively low, e.g.,  $\approx 10^{-3}$  for lensing by a galaxy and  $\approx 10^{-5}$  for lensing by a galaxy cluster (e.g., [108]).

The numerical results in Fig. 3 can be fitted by a simple function:

$$\frac{\langle \mathrm{DM} \rangle(z_{\mathrm{s}})}{\overline{\mathrm{DM}}(z_{\mathrm{s}})} = 1 - \frac{1}{az_{\mathrm{s}}^{\gamma} + b},\tag{3.3}$$

where the second term corresponds to  $\Delta DM/\overline{DM}$ . The fitting parameters are  $(a, b, \gamma) = (37, 63, -1.2)$  for TNG and  $(a, b, \gamma) = (24, 136, -1.6)$  for HMx with  $\log_{10}(T_{AGN}/K) = 7.8$ . The relative difference between the numerical results and the fitting functions is less than  $2.2 \times 10^{-4}$  and  $3.8 \times 10^{-4}$  for TNG and HMx, respectively, over the range of  $z_s = 0-3$ .

# 4 Magnification bias

Gravitational lensing in an inhomogeneous universe magnifies (or demagnifies) the flux of a source by a magnification factor  $\mu$ . As a light ray traverses a higher (or lower) density region, both the DM and magnification increase (or decrease); thus, the DM correlates with magnification. Because sources fainter than the detection threshold cannot be observed, more demagnified sources are likely to be missed compared to magnified ones. Therefore, the observed sample includes brighter, magnified events with higher DMs (or excludes fainter, demagnified events with lower DMs). This observational selection bias is known as magnification bias (e.g., [65, 109, 110]). This section addresses this bias in  $\langle DM \rangle$ .

The observed (lensed) luminosity  $L_{obs}$  and the unlensed luminosity L are related as  $L_{obs} = \mu L$ . Because the number density of sources is conserved with and without lensing magnification, we have  $\Phi_{obs}(L_{obs}; z_s) dL_{obs} = \Phi(L; z_s) dL$ , where  $\Phi_{obs}(\Phi)$  is the luminosity function with (without) lensing. The lensed luminosity function is then expressed as

$$\Phi_{\rm obs}(L_{\rm obs}; z_{\rm s}) = \int_{\mu_{\rm min}}^{\infty} \frac{\mathrm{d}\mu}{\mu} P_{\mu}(\mu; z_{\rm s}) \Phi\left(\frac{L_{\rm obs}}{\mu}; z_{\rm s}\right), \qquad (4.1)$$

where  $P_{\mu}$  is the probability distribution function of  $\mu$ , satisfying  $\int d\mu P_{\mu} = 1$  and  $\int d\mu \mu P_{\mu} = \langle \mu \rangle = 1$ . The minimum magnification  $\mu_{\min}$  is given as  $\mu_{\min} = (1 - \kappa_{\min})^{-2}$  where the minimum convergence  $\kappa_{\min}$  is obtained in Eq. (A.7) with  $\delta_{\rm m} = -1$  (the empty beam). The ensemble average of the DM with the magnification bias is obtained from Eq. (4.1):

$$\langle \mathrm{DM} \rangle_{\mathrm{mag}}(z_{\mathrm{s}}) = \frac{\int_{\mu_{\mathrm{min}}}^{\infty} \mathrm{d}\mu \, \mu^{-1} \int_{L_{\mathrm{obs,thr}}}^{\infty} \mathrm{d}L_{\mathrm{obs}} \int_{0}^{\infty} \mathrm{d}\mathrm{DM} \, P_{\mu,\mathrm{DM}}(\mu,\mathrm{DM};z_{\mathrm{s}}) \, \mathrm{DM} \, \Phi(L_{\mathrm{obs}} \, \mu^{-1};z_{\mathrm{s}})}{\int_{\mu_{\mathrm{min}}}^{\infty} \mathrm{d}\mu \, \mu^{-1} \int_{L_{\mathrm{obs,thr}}}^{\infty} \mathrm{d}L_{\mathrm{obs}} \, P_{\mu}(\mu;z_{\mathrm{s}}) \, \Phi(L_{\mathrm{obs}} \, \mu^{-1};z_{\mathrm{s}})},$$

$$(4.2)$$

where  $P_{\mu,\text{DM}}$  is the joint probability distribution function of  $\mu$  and the DM. If there is no correlation between them (i.e.,  $P_{\mu,\text{DM}}(\mu,\text{DM}) = P_{\mu}(\mu) \times P_{\text{DM}}(\text{DM})$ ),  $\langle \text{DM} \rangle_{\text{mag}}$  reduces to  $\langle \text{DM} \rangle$  in Eq. (2.9). The threshold luminosity  $L_{\text{obs,thr}}$  is determined by the flux limit  $f_{\text{thr}}$  as  $L_{\text{obs,thr}} = 4\pi D_{\text{L}}^2 f_{\text{thr}}$ . To calculate  $\langle \text{DM} \rangle_{\text{mag}}$ , a theoretical model of  $P_{\mu,\text{DM}}$  and  $\Phi$  is necessary; however,  $P_{\mu,\text{DM}}$  has not yet been studied extensively (cosmological ray-tracing simulations would be required to obtain  $P_{\mu,\text{DM}}$ ). Instead, we will calculate  $\langle \text{DM} \rangle_{\text{mag}}$  under a few assumptions in the following.

Considering the luminosity function of a power-law form,  $\Phi \propto L^{-\alpha}$  ( $\alpha$  is a constant),  $(DM)_{mag}$  in Eq. (4.2) reduces to a simpler form:

$$\langle \mathrm{DM} \rangle_{\mathrm{mag}}(z_{\mathrm{s}}) = \frac{\int_{\mu_{\mathrm{min}}}^{\infty} \mathrm{d}\mu \int_{0}^{\infty} \mathrm{dDM} P_{\mu,\mathrm{DM}}(\mu,\mathrm{DM};z_{\mathrm{s}}) \,\mu^{\alpha-1} \,\mathrm{DM}}{\int_{\mu_{\mathrm{min}}}^{\infty} \mathrm{d}\mu \,P_{\mu}(\mu;z_{\mathrm{s}}) \,\mu^{\alpha-1}} ,$$

$$= \frac{\langle \mu^{\alpha-1}\mathrm{DM} \rangle}{\langle \mu^{\alpha-1} \rangle}.$$

$$(4.3)$$

This equation indicates that the magnification bias disappears when  $\alpha = 1$ . We further use the weak lensing approximation, in which the magnification can be expanded as  $\mu =$   $[(1-\kappa)^2 - \gamma^2]^{-1} \simeq 1 + 2\kappa + 3\kappa^2 + \gamma^2$  with  $|\kappa|, |\gamma| \ll 1$ . Using  $\langle \kappa^2 \rangle = \langle \gamma^2 \rangle$  and  $\langle \kappa \rangle = -2\langle \kappa^2 \rangle$ , the denominator of Eq. (4.3) is

$$\langle \mu^{\alpha-1} \rangle \simeq 1 + 2 \left( \alpha - 1 \right) \left( \alpha - 2 \right) \langle \kappa^2 \rangle.$$

Using Eqs. (2.9) and (A.6), the numerator is

$$\langle \mu^{\alpha-1} \mathrm{DM} \rangle \simeq \overline{\mathrm{DM}} + 2 (\alpha - 1) (\alpha - 2) \langle \kappa^2 \rangle \overline{\mathrm{DM}} + (2 - \alpha) \Delta \mathrm{DM}.$$

Here, we have neglected the third and higher order terms of the perturbative quantities ( $\kappa$ ,  $\gamma$ , and  $\Delta DM$ ). Finally,  $\langle DM \rangle_{mag}$  simplifies to

$$\langle \mathrm{DM} \rangle_{\mathrm{mag}}(z_{\mathrm{s}}) \simeq \overline{\mathrm{DM}}(z_{\mathrm{s}}) + \Delta \mathrm{DM}(z_{\mathrm{s}}) + (1 - \alpha) \Delta \mathrm{DM}(z_{\mathrm{s}}).$$
 (4.4)

The second term represents the primary correction discussed in Section 2, while the third accounts for magnification bias. Both terms introduce a comparable bias ( $\Delta$ DM). For larger values of  $\alpha$  (> 1), there are more faint sub-threshold sources than super-threshold ones. Some of these sub-threshold sources become detectable owing to magnification, thereby increasing  $\langle DM \rangle_{mag}$  (where  $\Delta DM < 0$ ). For  $\alpha = 2$ , this increase cancels out the lensing bias in the second term of Eq. (4.4). The opposite is true for smaller values of  $\alpha$  (< 1). Some of the many super-threshold sources are lost owing to demagnification; thus, the magnification bias decreases  $\langle DM \rangle_{mag}$ . A plot of  $\langle DM \rangle_{mag}/\overline{DM}$  as a function of  $z_s$  is the same as in Fig. 3, but the deviation from unity is multiplied by a factor of  $(2 - \alpha)$ .

The index  $\alpha$  of the FRB luminosity (or energy) function remains poorly constrained by current observations. Previous studies have predominantly explored either a single power-law function (e.g., [111, 112]) or a Schechter function<sup>11</sup> (e.g., [113–115]) to fit observational data, yielding best-fit values of  $\alpha$  ranging broadly from 0.4 to 1.8. A more precise determination of  $\alpha$  is needed to estimate  $\langle DM \rangle_{mag}$ .

### 5 Discussion

#### 5.1 The other second-order effects on (DM)

We have examined the lensing bias affecting  $\langle DM \rangle$ . However, other second-order terms in perturbation theory also affect  $\langle DM \rangle$ . According to previous studies concerning  $\langle D_L \rangle$ (e.g., [38–40, 46]), the lensing bias dominates over other second-order effects for  $z_s \gtrsim 0.3$ , suggesting a similar dominance for  $\langle DM \rangle$ . These additional factors include the Doppler effect from the peculiar motions of the observer and source, the integrated Sachs–Wolfe (ISW) effect owing to potential evolution along the photon path, and the SW effect arising from potential differences between the observer and source. The peculiar velocity is approximately  $v/c \approx 10^{-3} [v/(300 \text{ km/s})]$ , and the galactic potential is  $|\phi|/c^2 \approx 10^{-5}-10^{-6}$ , both of which are smaller than the lensing convergence  $|\kappa| \approx \langle \kappa^2 \rangle^{1/2} \approx 10^{-2} z_s$ . These effects introduce a slight bias on the source redshift of the order of  $(v/c)^2$  for the peculiar velocity,  $(\phi/c^2)^2$  for the potential term, and  $(v\phi/c^4)$  for their cross term (e.g., [46]). The quantitative assessment of all second-order effects on  $\langle DM \rangle$  is beyond the scope of this paper and remains a topic for future investigation.

<sup>&</sup>lt;sup>11</sup>A Schechter function is the same as the power-law model but incorporating an exponential cutoff at a high L.

#### 5.2 Rotation measure

The lensing bias can also be directly applied to the cosmological rotation measure (RM) (e.g., a review [116]). When a radio signal propagates through a magnetized plasma, its polarization angle undergoes Faraday rotation (e.g., [117]). The RM is derived from the frequency-dependent rotation angle. Similar to the DM, the RM is expressed as (e.g., [118])

$$\mathrm{RM}(z_{\rm s}) = \frac{e^3}{2\pi m_{\rm e}^2 c^4} \int_0^{\lambda_{\rm s}} \mathrm{d}\lambda \, n_{\rm e}(\boldsymbol{r}; z) \, B_{\parallel}(\boldsymbol{r}; z) \, (1+z)^2, \tag{5.1}$$

where e and  $m_{\rm e}$  are the electric charge and mass of the electron, respectively, and  $B_{\parallel}$  is the comoving magnetic field component along the line of sight. Because light rays propagate through underdense regions owing to lensing, we expect that the lensing bias also influences  $\langle |\text{RM}| \rangle^{12}$ . Estimating the lensing bias in  $\langle |\text{RM}| \rangle$  requires the cross-power spectrum of matter and  $n_{\rm e}B_{\parallel}$  fluctuations, which is beyond the scope of this study.

#### 6 Conclusions

We investigated the lensing effects on the ensemble average of the cosmological dispersion measure,  $\langle DM \rangle$ . Using the cosmological perturbation theory, we derived the primary correction term in  $\langle DM \rangle$  involving the cross-power spectrum of matter and free electrons. We found that  $\langle DM \rangle$  is 0.4 % - 1 % smaller than the DM in the homogeneous cosmological model at  $z_{\rm s} = 1$ , based on recent hydrodynamic simulations of IllustrisTNG and BAHAMAS. The impact of lensing bias becomes more pronounced for higher  $z_{\rm s}$  and in scenarios with weaker baryonic feedback models. Additionally, we discussed magnification bias, where brighter magnified sources with higher DM values are preferentially included in the observed sample. The magnification bias introduces a similar level of bias,  $\mathcal{O}(0.1\% - 1\%)$ , on  $\langle DM \rangle$  depending on the luminosity (or energy) function of FRBs.

Upcoming detectors, such as the CHIME/FRB outriggers, CHORD, and DSA-2000, are expected to detect  $\approx 10^4$  localized FRBs annually. During this era, it will be crucial to account for lensing bias, including magnification bias, to achieve accuracy at the percent level in the DM-z relation.

# A Derivation of the DM correction terms

This appendix provides a detailed calculation of the DM correction terms in Eq. (2.8). The second and third terms of Eq. (2.8) are written as  $\Delta DM_{2nd}(z_s)$  and  $\Delta DM_{3rd}(z_s)$ , respectively. Substituting  $\boldsymbol{x}$  in Eq. (2.1) into Eq. (2.8), the second term becomes

$$\Delta DM_{2nd}(z_{s}) = \frac{2}{c^{2}} \int_{0}^{r_{s}} \mathrm{d}r \, \bar{n}_{e}(z) \left(1+z\right) \left[-\int_{0}^{r} \mathrm{d}r' \left(r-r'\right) + \frac{r}{r_{s}} \int_{0}^{r_{s}} \mathrm{d}r' \left(r_{s}-r'\right)\right] \\ \times \left\langle \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}';z') \cdot \nabla_{\boldsymbol{x}} \delta_{e}(\boldsymbol{r};z) \right\rangle \Big|_{\boldsymbol{x}=\boldsymbol{x}'=0}.$$
(A.1)

Here, the integration is performed along the r-axis, and  $\lambda$ ,  $\lambda'$  and  $\lambda_s$  have been substituted with r, r' and  $r_s$ , respectively.

The Fourier transforms of  $\phi$  and  $\delta_{e}$  are

$$\phi(\boldsymbol{r};z) = \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \tilde{\phi}(\boldsymbol{k};z) \,\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}, \quad \delta_{\mathrm{e}}(\boldsymbol{r};z) = \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \tilde{\delta}_{\mathrm{e}}(\boldsymbol{k};z) \,\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}}. \tag{A.2}$$

The gravitational potential  $\phi$  is determined by the matter density fluctuations  $\delta_{\rm m}$  through the Poisson equation in Fourier space:  $-k^2 \tilde{\phi}(\mathbf{k}; z) = (3/2) H_0^2 \Omega_{\rm m}(1+z) \tilde{\delta}_{\rm m}(\mathbf{k}; z)$ . The cross correlation of  $\nabla_{\mathbf{x}} \phi$  and  $\nabla_{\mathbf{x}} \delta_{\rm e}$  in Eq. (A.1) is rewritten using the Fourier transforms (A.2):

$$\left\langle \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}'; \boldsymbol{z}') \cdot \nabla_{\boldsymbol{x}} \delta_{\mathbf{e}}(\boldsymbol{r}; \boldsymbol{z}) \right\rangle \Big|_{\boldsymbol{x}=\boldsymbol{x}'=0} = -\frac{3H_0^2 \Omega_{\mathrm{m}}}{2} (1+\boldsymbol{z}) \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \int \frac{\mathrm{d}^3 k'}{(2\pi)^3} \frac{\mathbf{k}_{\perp} \cdot \boldsymbol{k}'_{\perp}}{k'^2} \\ \times \left\langle \tilde{\delta}_{\mathrm{m}}(\boldsymbol{k}'; \boldsymbol{z}') \tilde{\delta}_{\mathbf{e}}^*(\boldsymbol{k}; \boldsymbol{z}) \right\rangle \mathrm{e}^{\mathrm{i}(\boldsymbol{k}'_{\parallel}\boldsymbol{r}'-\boldsymbol{k}_{\parallel}\boldsymbol{r})},$$
(A.3)

where  $k_{\parallel}$  and  $\mathbf{k}_{\perp}$  are the wave vectors parallel and perpendicular to the *r*-axis (i.e.,  $\mathbf{k} \cdot \mathbf{r} = k_{\parallel} \mathbf{r} + \mathbf{k}_{\perp} \cdot \mathbf{x}$ ), respectively. The cross-power spectrum between  $\delta_{\rm m}$  and  $\delta_{\rm e}$  is defined as

$$\left\langle \tilde{\delta}_{\rm m}(\boldsymbol{k}';z')\tilde{\delta}_{\rm e}^{*}(\boldsymbol{k};z) \right\rangle \equiv (2\pi)^{3} \delta_{\rm D}(\boldsymbol{k}-\boldsymbol{k}') P_{\rm me}(k;z,z'),$$
 (A.4)

where  $\delta_{\rm D}$  is the Dirac delta function. Using Eq. (A.4), Eq. (A.3) reduces to

$$\left\langle \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}'; z') \cdot \nabla_{\boldsymbol{x}} \delta_{\mathbf{e}}(\boldsymbol{r}; z) \right\rangle \Big|_{\boldsymbol{x}=\boldsymbol{x}'=0} = -\frac{3H_0^2 \Omega_{\mathbf{m}}}{2} (1+z) \int \frac{\mathrm{d}^3 k}{(2\pi)^3} \frac{k_\perp^2}{k^2} P_{\mathbf{me}}(k; z, z') \,\mathrm{e}^{\mathrm{i}k_{\parallel}(r'-r)},$$
$$= -\frac{3H_0^2 \Omega_{\mathbf{m}}}{2} (1+z) \int \frac{\mathrm{d}^2 k_\perp}{(2\pi)^2} P_{\mathbf{me}}(k_\perp; z) \,\delta_{\mathbf{D}}(r'-r). \quad (A.5)$$

In the second equality, we applied the Limber approximation:  $\int dk_{\parallel} e^{ik_{\parallel}(r'-r)} P_{\rm me}(k;z,z') = 2\pi \delta_{\rm D}(r'-r) P_{\rm me}(k_{\perp};z)$ , which neglects the cross-correlation of  $\phi(r';z')$  and  $\delta_{\rm e}(r;z)$  for the different redshifts  $z' \neq z$ . Substituting Eq. (A.5) into Eq. (A.1) yields the following:

$$\Delta \mathrm{DM}_{2\mathrm{nd}}(z_{\mathrm{s}}) = -\frac{3H_0^2\Omega_{\mathrm{m}}}{2\pi c^2} \int_0^{r_{\mathrm{s}}} \mathrm{d}r \,\bar{n}_{\mathrm{e}}(z) \,(1+z)^2 \frac{r(r_{\mathrm{s}}-r)}{r_{\mathrm{s}}} \int_0^\infty \mathrm{d}k_\perp k_\perp P_{\mathrm{me}}(k_\perp;z),$$
$$= -2 \,\left\langle \kappa \left(\mathrm{DM} - \overline{\mathrm{DM}}\right) \right\rangle. \tag{A.6}$$

Here, the convergence field for the source redshift  $z_s$  is defined as

$$\kappa(z_{\rm s}) = \frac{3H_0^2 \Omega_{\rm m}}{2c^2} \int_0^{r_{\rm s}} dr \, (1+z) \frac{r(r_{\rm s}-r)}{r_{\rm s}} \, \delta_{\rm m}(\boldsymbol{r};z). \tag{A.7}$$

Therefore, the correction term  $\Delta DM_{2nd}$  arises from a cross-correlation between  $\kappa$  and the DM. Equation (A.6) is consistent with the previous work (Section 2 of Ref. [119]) by replacing their f with the DM. Equations (A.6) and (2.9) agree with the previous result for the convergence [44, 56],  $\langle \kappa \rangle = -2 \langle \kappa^2 \rangle$ , by replacing  $\bar{n}_e \delta_e$  with  $(3H_0^2 \Omega_m/2c^2) [r(r_s - r)/r_s] \delta_m$  in Eqs. (2.2)–(2.3).

Next, we proceed to the third term of Eq. (2.8). This term arises from the difference in path length from the observer to the source between the straight line (along the *r*-axis) and the curved path (specified by  $\lambda$ ) in Fig. 1. Substituting  $d\mathbf{x}/d\lambda$  in Eq. (2.1) into Eq. (2.8), this term becomes

$$\Delta DM_{3rd}(z_{s}) = \frac{2}{c^{4}} \int_{0}^{r_{s}} dr \, \bar{n}_{e}(z) \, (1+z) \left[ \int_{0}^{r} dr' \int_{0}^{r} dr'' + \frac{1}{r_{s}^{2}} \int_{0}^{r_{s}} dr'(r_{s}-r') \int_{0}^{r_{s}} dr''(r_{s}-r'') - \frac{2}{r_{s}} \int_{0}^{r} dr' \int_{0}^{r_{s}} dr''(r_{s}-r'') \right] \left\langle \nabla_{\boldsymbol{x}'} \phi(\boldsymbol{r}';z') \cdot \nabla_{\boldsymbol{x}''} \phi(\boldsymbol{r}'';z'') \right\rangle \Big|_{\boldsymbol{x}'=\boldsymbol{x}''=0}.$$
(A.8)

Similar to Eq. (A.5), the correlation function of  $\nabla_{\boldsymbol{x}}\phi$  in Eq. (A.8) is obtained as follows:

$$\left\langle \nabla_{\boldsymbol{x}'}\phi(\boldsymbol{r}';z') \cdot \nabla_{\boldsymbol{x}''}\phi(\boldsymbol{r}'';z'') \right\rangle \Big|_{\boldsymbol{x}'=\boldsymbol{x}''=0} = \frac{9H_0^4\Omega_{\mathrm{m}}^2}{4}(1+z')^2 \int \frac{\mathrm{d}^2k_{\perp}}{(2\pi)^2} \frac{1}{k_{\perp}^2} P_{\mathrm{m}}(k_{\perp};z') \,\delta_{\mathrm{D}}(r'-r''), \tag{A.9}$$

where  $P_{\rm m}$  is the matter power spectrum defined as  $\langle \tilde{\delta}_{\rm m}(\mathbf{k}'; z) \tilde{\delta}_{\rm m}^*(\mathbf{k}; z) \rangle \equiv (2\pi)^3 \delta_{\rm D}(\mathbf{k} - \mathbf{k}') P_{\rm m}(k; z)$ . Using Eq. (A.9), Eq. (A.8) is rewritten as

$$\Delta DM_{3rd}(z_{s}) = \int_{0}^{r_{s}} dr \,\bar{n}_{e}(z) \left(1+z\right) \int_{0}^{r} dr' \,\frac{2r'-r_{s}}{r_{s}} J(z') + \overline{DM}(z_{s}) \int_{0}^{r_{s}} dr \left(\frac{r_{s}-r}{r_{s}}\right)^{2} J(z),$$
(A.10)

with

$$J(z) = \frac{9H_0^4 \Omega_{\rm m}^2}{4\pi c^4} (1+z)^2 \int_0^\infty \frac{\mathrm{d}k_\perp}{k_\perp} P_{\rm m}(k_\perp; z).$$
(A.11)

The function J(z) is the same as in KP16. The smallness of the dimensionless quantity rJ is discussed in Section 1.3 of KP16. The third term  $\Delta DM_{3rd}$  is orders of magnitude smaller compared to the first and second terms in Eq. (2.8).

Figure 4. The free-electron bias is defined as the ratio of the cross-power spectrum  $P_{\rm me}(k)$  to the matter power spectrum in the DMO run  $P_{\rm DMO}(k)$ :  $b_{\rm e}(k) \equiv P_{\rm me}(k)/P_{\rm DMO}(k)$ . The blue and green symbols represent measurements in TNG300-1 and TNG100-1, respectively. The solid red curve is the fitting function (B.1). The gray pluses are the bias in our previous work [63],  $b_{\rm e}^{\rm (prev)}(k;z) \equiv [P_{\rm e}(k;z)/P_{\rm DMO}(k;z)]^{1/2}$ , measured in TNG300-1.

Figure 5. The cross-correlation coefficient is defined as  $P_{\rm me}(k)/[P_{\rm m}(k)P_{\rm e}(k)]^{1/2}$ . The blue and green symbols represent measurements in TNG300-1 and TNG100-1, respectively.

### **B** Free-electron bias

This section introduces a fitting function for the free-electron bias, defined as  $b_{\rm e}(k;z) \equiv P_{\rm me}(k;z)/P_{\rm DMO}(k;z)$ , using TNG300-1 and TNG100-1. The fitting range is  $k < 38.3 h \,{\rm Mpc}^{-1}$ 

and 76.2 h Mpc<sup>-1</sup> for TNG300-1 and TNG100-1 (i.e., the Nyquist wavenumbers), respectively, in z = 0-3 (z = 0, 0.2, 0.4, 0.7, 1, 2 and 3). Figure 4 shows the bias for z = 0, 0.4, 1 and 2. The sample variance of the power spectrum, caused by the finite simulation volume, is canceled because the hydrodynamic run and the DMO run have the same initial seed of random Gaussian fluctuations. The bias is fitted as follows:

$$b_{\rm e}(k;z) = \frac{b_0(z)}{1 + [k/k_*(z)]^{\gamma}} + b_1(z), \tag{B.1}$$

with

$$b_0(z) = 0.86 - 0.20z,$$
  

$$b_1(z) = 0.11 + 0.19z,$$
  

$$k_*(z) = 5.4 - 2.9z + 2.0z^2 - 0.40z^3,$$
  

$$\gamma(z) = 2.4 + 0.2z - 0.2z^2,$$

where  $k_*$  is in unit of  $h \operatorname{Mpc}^{-1}$ . The fitting function agrees with both simulations (TNG300-1 and TNG100-1) to within 4.3% (9.5%) for  $k \leq 1$  (10)  $h \operatorname{Mpc}^{-1}$  and z = 0-3. The bias approaches unity on large scales ( $k \leq 1 h \operatorname{Mpc}^{-1}$ ), but is significantly reduced on small scales ( $k \geq 1 h \operatorname{Mpc}^{-1}$ ) owing to AGN and stellar feedback. The bias is slightly smaller than unity on the largest scales, especially for higher redshifts, because the fluctuations in baryons gradually catch up to the fluctuations in dark matter after the cosmological recombination (e.g., Subsection 3.3 of Ref. [63]).

It is worth noting that the free-electron bias differs slightly from the bias defined in our previous study [63] using the free-electron power spectrum  $P_{\rm e}$ :  $b_{\rm e}^{(\rm prev)}(k;z) = [P_{\rm e}(k;z)/P_{\rm DMO}(k;z)]^{1/2}$ . The gray pluses in Fig. 4 represent the previous bias. Both biases are nearly identical on large scales  $(k \leq 1 h \,\mathrm{Mpc}^{-1})$ , but the new one is slightly more suppressed at  $k \gtrsim 1 h \mathrm{Mpc}^{-1}$ . To view this difference from another perspective, the cross-correlation coefficient,

$$r(k;z) \equiv \frac{P_{\rm me}(k;z)}{\left[P_{\rm m}(k;z)P_{\rm e}(k;z)\right]^{1/2}},\tag{B.2}$$

is plotted in Fig. 5. Here,  $P_{\rm m}$  is the matter power spectrum of the hydrodynamic simulations (not the DMO simulations). The coefficient r quantifies the phase difference between the two fields. If the phases differ, such as when  $\arg(\tilde{\delta}_{\rm e}(\boldsymbol{k};z)) - \arg(\tilde{\delta}_{\rm m}(\boldsymbol{k};z)) = \theta$  where  $\theta$  is a constant, then  $r = \cos \theta$ . Alternatively, if  $\tilde{\delta}_{\rm e}(\boldsymbol{k};z) = b_1(k;z) \tilde{\delta}_{\rm m}(\boldsymbol{k};z)$  with a real function  $b_1$ , then r = 1. Figure 5 shows r = 1 for large scales  $(k \leq 1 h \,\mathrm{Mpc}^{-1})$ , but r < 1 for small scales  $(k \geq 1 h \,\mathrm{Mpc}^{-1})$ . Here, r < 1 leads to additional small-scale suppression of  $b_{\rm e}$  compared to  $b_{\rm e}^{(\mathrm{prev})}$ , as shown in Fig. 4.
