# Beyond Image Prior: Embedding Noise Prior into Conditional Denoising Transformer

Yuanfei Huang, *Member, IEEE*, and Hua Huang, *Senior Member, IEEE*

**Abstract**—Existing learning-based denoising methods typically train models to generalize the image prior from large-scale datasets, suffering from the variability in noise distributions encountered in real-world scenarios. In this work, we propose a new perspective on the denoising challenge by highlighting the distinct separation between noise and image priors. This insight forms the basis for our development of conditional optimization framework, designed to overcome the constraints of traditional denoising framework. To this end, we introduce a Locally Noise Prior Estimation (LoNPE) algorithm, which accurately estimates the noise prior directly from a single raw noisy image. This estimation acts as an explicit prior representation of the camera sensor's imaging environment, distinct from the image prior of scenes. Additionally, we design an auxiliary learnable LoNPE network tailored for practical application to sRGB noisy images. Leveraging the estimated noise prior, we present a novel Conditional Denoising Transformer (Condformer), by incorporating the noise prior into a conditional self-attention mechanism. This integration allows the Condformer to segment the optimization process into multiple explicit subspaces, significantly enhancing the model's generalization and flexibility. Extensive experimental evaluations on both synthetic and real-world datasets, demonstrate that the proposed method achieves superior performance over current state-of-the-art methods. The source code is available at [https://github.com/YuanfeiHuang/Condformer.](https://github.com/YuanfeiHuang/Condformer)

# <span id="page-0-2"></span>**1 INTRODUCTION**

I MAGE denoising, a fundamental aspect of low-level vision, is garnering increased interest due to its significant<br>applications in computational photography and computer MAGE denoising, a fundamental aspect of low-level viapplications in computational photography and computer vision. The primary goal of image denoising is to mitigate the impact of unwanted noise in noisy observations, thereby enhancing image quality for either aesthetic enhancement or to facilitate subsequent processing tasks.

In general, natural images embody strong priors for visual perception [\[1\]](#page-14-0), [\[2\]](#page-14-1), such as repetitive textures and continuous edges, which are more readily inferred than the seemingly random presence of noise. Thus, a prevailing strategy among many existing learning-based denoising methods [\[3\]](#page-14-2), [\[4\]](#page-14-3), [\[5\]](#page-14-4), [\[6\]](#page-14-5), [\[7\]](#page-14-6), [\[8\]](#page-14-7), [\[9\]](#page-14-8) involves developing a unified model capable of generalizing from a vast collection of noisy-clean pairs. This process typically formulates optimization as:

$$
\hat{\theta} = \arg\max_{\theta} \mathbb{E}_x \log P(y|x; \theta)
$$
 (1)

where  $\theta$  represents the model parameters, x and y denote the noisy observation and clean target, respectively. In this context, the noise map is treated as an additive mask over the clean image, with the ultimate aim of deducing the underlying image prior. However, the noise prior, which is crucial for distinguishing between various noise distributions, is often overlooked.

This framework faces limitations in real-world scenarios due to two primary challenges:

1) The difficulty and cost associated with gathering largescale noisy-clean image datasets. Learning sophisticated image priors necessitates a model with substantial capacity,

• *(Corresponding author: Hua Huang.)*

<span id="page-0-0"></span>

<span id="page-0-1"></span>Fig. 1: Illustration of denoising model optimization: (a) unconditional optimization space with image prior [\[8\]](#page-14-7), [\[9\]](#page-14-8); (b) conditional optimization with noise prior and image prior in this work.

which is hindered by the challenges of acquiring clean images. Clean image acquisition typically requires long exposures in static scenes [\[10\]](#page-14-9), [\[11\]](#page-14-10), [\[12\]](#page-14-11) or involves complex alignment procedures [\[10\]](#page-14-9).

2) The inefficiency and incompleteness of an unconditional optimization space. Conventional learning-based denoising methods, which focus solely on image priors, are inherently unconditional. However, as illustrated in Fig. [1a,](#page-0-0) these methods attempt to learn and generalize the image prior from numerous noisy-clean samples, resulting in an optimization space that is both overly broad, encompassing unnecessary scenarios, and simultaneously incomplete, missing critical outlier cases.

To address these issues, we propose segmenting the singular unconditional optimization space into multiple subspaces by incorporating reliable noise priors alongside the complicated image priors, as illustrated in Fig. [1b.](#page-0-1)This

<sup>•</sup> *The authors are with the School of Artificial Intelligence, Beijing Normal University, Beijing, 100875, China. E-mail: yfhuang@bnu.edu.cn; huahuang@bnu.edu.cn.*

approach recognizes that a noisy observation is influenced both by the scene (image prior) and the imaging environment (noise prior), making it logical to infer the noise prior for optimizing the denoising process. Consequently, the optimization space for a conditional denoising model should comprise various independent and complete subspaces, each conditioned on specific priors, and can be represented as:

<span id="page-1-1"></span>
$$
\hat{\theta} = \arg \max_{\theta} \sum_{i=1}^{n} \mathbb{E}_{x_i} \log P(y | x_i, z_i; \theta)
$$
 (2)

where  $\{z_i\}_{i=1}^n$  represents the noise prior.

Distinct from traditional models that rely on given conditional embeddings (*e.g*., cGAN [\[13\]](#page-14-12), cVAE [\[14\]](#page-14-13) and DnCNN [\[15\]](#page-14-14)) or implicit noise prediction (*e.g*., VDN [\[16\]](#page-14-15) and CVF-SID [\[17\]](#page-14-16)), a conditional denoising model must adeptly estimate an explicit noise prior from a single noisy observation and distinctly address the noise and image priors based on their independence. In essence, as depicted in Fig. [1b,](#page-0-1) the principle of a conditional denoising model lies in its ability to navigate the generation of pixels by harnessing implicit natural image priors to shape the optimization landscape, while also leveraging explicit sensor noise priors to precisely target the optimization's focus.

Building upon this concept, we introduce a novel approach for explicit noise prior estimation from a single noisy observation, termed **Lo**cally **N**oise **P**rior **E**stimation (**LoNPE**), and develop a **Con**ditional **d**enoising Trans**former** (**Condformer**) that incorporates this noise prior. This integration allows for the segmentation of the entire optimization space into distinct, explicit optimization subspaces. Our main contributions are summarized as follows:

- By rethinking the imaging mechanism in physics, we offer a new perspective on image denoising, highlighting the independence between noise and image priors. This distinction is crucial for conditional optimization, particularly within the context of real-world scenarios.
- We introduce an innovative LoNPE algorithm for estimating noise prior from raw noisy image. This method effectively captures the characteristics of sensor noise, providing an explicit prior for conditional optimization. Additionally, we present a learnable LoNPE network, tailored for practical application with only single sRGB noisy observation.
- By exploring the noise statistics concealing in the latent space, we propose a novel Condformer that leverages the estimated noise prior within a conditional selfattention module. This design represents a pioneering effort to incorporate prior knowledge into a Transformerlike architecture for denoising.
- Quantitative and qualitative experiments demonstrate the superior performance of our LoNPE algorithm and Condformer model across various real and synthetic noise analysis and image denoising tasks.

The rest of this paper is organized as follows: Section [2](#page-1-0) reviews related work. Section [3](#page-2-0) presents our noise prior estimation and conditional image denoising methods. Qualitative and quantitative experiments are reported and analyzed in Section [4.](#page-6-0) Finally, Section [5](#page-13-0) concludes our work and discusses the limitation and future work.

## <span id="page-1-0"></span>**2 RELATED WORK**

As the core goal of this paper is to explore a conditional denoising Transformer with explicit noise prior, we next mainly introduce the advances in the fields of noise modeling, image denoising, and vision Transformer, respectively.

#### **2.1 Noise Modeling**

In general, the signal-independent Gaussian distribution is regarded as a theoretically common hypothesis of noise modeling, and has derived numerous supervised image denoising methods to handle the widely-used additive white Gaussian noise (AWGN). However, the real noise model is more sophisticated. Particularly, due to the characteristics of imaging sensor, the practical noise could be explicitly modeled on raw sensors, and the corresponding raw sensor noise commonly consists of the signal-dependent shot noise and the signal-independent read noise. Typically, the Poisson-Gaussian noise model [\[18\]](#page-14-17) was employed to characterize the distribution of this raw sensor noise and has inspired numerous advances in realistic noise synthesis and real image denoising [\[17\]](#page-14-16), [\[19\]](#page-14-18), [\[20\]](#page-14-19), [\[21\]](#page-14-20). Beyond the hypothesis on building the distribution of noise, to match the noise model in more complex imaging environment on various devices, multi-frame calibration [\[18\]](#page-14-17), [\[21\]](#page-14-20), [\[22\]](#page-14-21) and variance-stabilizing transformations [\[23\]](#page-14-22), [\[24\]](#page-14-23) technologies were presented to refine the noise model for different sensors. Furthermore, some works attempt to employ the calibrated noise parameter of sensor to explicitly synthesize noisy samples [\[21\]](#page-14-20), [\[25\]](#page-14-24), [\[26\]](#page-14-25), or guide the network optimization [\[16\]](#page-14-15), [\[17\]](#page-14-16), [\[27\]](#page-14-26), [\[28\]](#page-14-27) for training a denoising model. Instead of explicitly modeling noise from a certain distribution, learnble noise modeling methods recently have been raised with the development of generative models, such as variational bayes [\[29\]](#page-14-28), generative adversarial networks [\[30\]](#page-14-29), [\[31\]](#page-14-30), and normalizing flows [\[32\]](#page-14-31), [\[33\]](#page-14-32), [\[34\]](#page-14-33).

## **2.2 Image Denoising**

After decades of development, image denoising methods are generally divided into model-based and learning-based. Model-based denoising methods aim to model the characteristics of natural images as a regularization prior to iteratively optimize a well-designed model. The representative regularization priors include total variation [\[35\]](#page-14-34), sparsity [\[36\]](#page-14-35), non-local self-similarity [\[37\]](#page-14-36), [\[38\]](#page-14-37), and external statistical priors [\[39\]](#page-14-38). On the other hands, learning-based methods attempt to reconstruct a clean image from the noisy observation with an end-to-end learnable model, which is trained from large-scale noisy-clean pairs. Initially, with the development of convolutional neural networks (CNN), CNN-based denoising methods [\[3\]](#page-14-2), [\[4\]](#page-14-3), [\[5\]](#page-14-4), [\[15\]](#page-14-14), [\[40\]](#page-14-39), [\[41\]](#page-14-40) have received significant advances in learning an end-to-end mapping from the noisy observations to clean targets. In essence, due to the nature of CNN in local visual perception, the key of these CNN-based denoising methods is to learn how a pixel is generated from a corrupted one and its neighbors in local perception region, namely, to learn the image prior in local perceptions, such as details in texture, smoothness in flat. Nevertheless, some contextual image priors are difficult to capture in local perceptions, *e.g*., objects,

structural information, edges and repeated textures. Recently, considering these image priors in non-local or global visual perception, several Transformer-based [\[6\]](#page-14-5), [\[7\]](#page-14-6), [\[42\]](#page-14-41), MLPbased [\[43\]](#page-14-42), [\[44\]](#page-14-43), [\[45\]](#page-14-44) and Mamba-based [\[46\]](#page-14-45), [\[47\]](#page-14-46) denoising methods have attracted increasing attentions and achieved remarkably superior performances against other existing CNN-based methods. In particular, to capture long-range feature dependencies, pyramid [\[48\]](#page-14-47), rectangle-window [\[49\]](#page-14-48), chaotic-window [\[50\]](#page-15-0), sparse [\[51\]](#page-15-1) and anchored-stripe [\[52\]](#page-15-2) self-attention mechanisms have been explored. Yet capturing spatial correspondence commonly causes quadratically increasing computational loads as the resolution increases, then efficient Transformer-based denoisers recently achieve growing concerns. Specifically, hierarchical U-shape architecture [\[8\]](#page-14-7) and channel-wise self-attention mechanism [\[9\]](#page-14-8) were proposed to reduce the unbearable computational loads from increasing spatial resolutions.

Except for the evolution of denoiser architectures, a blind denoising strategy with stronger generalization is essential for practical applications due to the unknowability and the diversity of noise in real scene. In the type of aforementioned supervised learning-based methods, numerous noisy-clean pairs with various noise levels are employed to train an unified denoiser [\[9\]](#page-14-8), [\[15\]](#page-14-14), [\[53\]](#page-15-3), [\[54\]](#page-15-4). Besides, to adapt for real scenes with only noisy observations, self-supervised denoising methods [\[2\]](#page-14-1), [\[17\]](#page-14-16), [\[55\]](#page-15-5) have been raised by learning implicit representation from image priors. However, they often fall short in scenarios requiring high accuracy, complex noise handling, and stable convergence.

## **2.3 Vision Transformer**

The self-attention mechanism [\[42\]](#page-14-41) in Transformers facilitates learning long-range dependencies, leading to significant success in natural language processing [\[42\]](#page-14-41), [\[56\]](#page-15-6) and computer vision tasks [\[57\]](#page-15-7), [\[58\]](#page-15-8). For high-level vision, ViT [\[57\]](#page-15-7) demonstrated the Transformer's effectiveness in non-local visual perception and high-accuracy object recognition, sparking the development of more effective and efficient Transformer architectures for various vision tasks like object detection [\[58\]](#page-15-8), [\[59\]](#page-15-9), semantic segmentation [\[60\]](#page-15-10), [\[61\]](#page-15-11), and low-level vision [\[6\]](#page-14-5), [\[9\]](#page-14-8).

Especially in low-level vision, self-attention mechanism was firstly utilized to transfer relevant textures in referencebased super-resolution [\[62\]](#page-15-12). More generally, IPT [\[6\]](#page-14-5) later introduced a multi-task image processing model using standard Transformer architecture with tokenized inputs. By integrating the advantage of local attention mechanism of CNN and long-range dependency of Transformer, Swin Transformer [\[58\]](#page-15-8) was proposed by introducing the shifted window scheme and was applied into image restoration tasks [\[7\]](#page-14-6). To alleviate the limitation of Swin Transformer in receptive fields, cross aggregation Transformer (CAT) [\[49\]](#page-14-48) was proposed by aggregating features cross different windows to expand the receptive field. Despite their effectiveness, these Transformers are computationally intensive as calculating the spacial cross-covariance of large-scale tokens. To address this, Uformer [\[8\]](#page-14-7) was proposed by building a hierarchical U-shape architecture with locally-enhanced window Transformer blocks. Besides, by calculating the channel-wise cross-covariance, an efficient Restormer [\[9\]](#page-14-8)

was proposed and achieved state-of-the-art performances in several image restoration tasks.

Nonetheless, these existing Transformers rely on largescale datasets with perfect labels and unconditional optimization, which is commonly redundant. Instead, inspired by the conditional text generation with Transformer [\[63\]](#page-15-13), [\[64\]](#page-15-14), we aim to explore a conditional Transformer for image denoising.

# <span id="page-2-0"></span>**3 METHOD**

In an imaging pipeline with a photosensor, the target imaging scene is formulated as incident lights hitting the camera sensor array and then transformed into digital responses for imaging. In this section, we first introduce the noise formation model in an imaging sensor and generalize the independence of noise and image priors, then describe the proposed LoNPE algorithm/network for noise prior estimation and the Condformer architecture for conditional denoising.

## **3.1 Preliminary on Noise Prior**

#### *3.1.1 Noise Formation Model*

Although the noise in a processed sRGB image is generally complex to explicitly analyze due to the nonlinearity of image signal processing (ISP), the raw noise formation model of a digital sensor in camera is well understood [\[65\]](#page-15-15). In particular, the raw noise in a camera primarily consists of the *shot noise* during photon-to-electron conversion and the *read noise* during electron-to-digital conversion [\[25\]](#page-14-24).

Specifically, due to the quantum nature of light, the collected noisy photoelectrons can be modeled as Poisson random variable, which follows

$$
(\mathbf{L} + \mathbf{N}_s) \sim \mathcal{P}(\mathbf{L})
$$
 (3)

where  $L$  and  $N_s$  indicate the incident clean photoelectron and the shot noise, respectively.  $\mathcal{P}(\cdot)$  denotes the Poisson distribution.

These photoelectrons are subsequently read out as quantizable digital signals, and commonly attached with the read noises  $\mathbf{N}_\text{r}$ , which can be approximately modeled as Gaussian random variables

$$
\mathbf{N}_{\rm r} \sim \mathcal{N}(\mathbf{0}, \sigma_{\rm r}^2) \tag{4}
$$

where  $\mathcal{N}(\cdot)$  denotes the Gaussian distribution.

This Poisson-Gaussian can be further treated as a heteroscedastic Gaussian distribution [\[18\]](#page-14-17), and the final raw digital sensor signals can be formulated as

<span id="page-2-1"></span>
$$
\mathbf{I} \sim \mathcal{N}(\mathbf{L}, \sigma_s^2 \cdot \mathbf{L} + \sigma_r^2) \tag{5}
$$

where  $\sigma_s$  and  $\sigma_r$  indicate the "noise prior", which depends on the imaging environments, including the camera sensor, and photography settings.

In this manner, the noise prior plays a significant role in raw sensor noise modeling, and is commonly proportional to the noise level. Particularly, L indicates the pixel-wise intensity of the target scene illuminance, indicating the "image prior", and thereby has nothing with the noise prior.

<span id="page-3-0"></span>

Fig. 2: Investigation on independence of the image prior and the noise prior. We select three noisy-clean pairs from SIDD training dataset, which are captured with different image priors (related to *scene* and *brightness*) or noise priors (related to *ISO level* and *shutter speed*). By investigating the local variance of noisy residues and the local mean of clean image, the statistical results show that the noise prior depends on only the camera settings, but little on the image prior.

## <span id="page-3-1"></span>*3.1.2 Independence of Noise Prior and Image Prior*

To further illustrate the independence of noise prior and image prior, as shown in Fig. [2,](#page-3-0) we investigate several raw noisy-clean pairs from SIDD-Medium training dataset, where the noisy observations are captured under different scene illuminances (*e.g*., scene and brightness) indicating the image prior and different imaging environments (*e.g*., ISO level and shutter speed) indicating the noise prior. As described above, the noise prior should depend on these imaging environments, and affects the statistical parameter of distribution in pixel-wise variances.

However, it is infeasible to calculate the pixel-wise variances on a single image. We randomly sample  $1000 \times 16 \times 16$ local raw noisy-clean patch pairs, and calculate the local variances  $\sigma^2$  of the noisy residues and the local means  $\mu$  of the clean patches, to further approximate the corresponding pixel-wise statistic of noise. As formulated in Eq.[\(5\)](#page-2-1), the pixelwise variance  $\sigma^2$  of noises should be proportional to the intensity  $\mu$  of illuminances. Consequently, as the statistical results shown in Fig. [2,](#page-3-0) its slope and intercept represent  $\sigma_s^2$ and  $\sigma_{\rm r}^2$ , respectively.

From these observations, on a common sence and environmental brightness, namely with the same image prior, the statistical results of noise show a non-negligible discrepancy for various imaging environments. Specifically, higher ISO level indicates larger sensitivity of the sensor, leading more noises affecting image quality. Faster shutter speed causes lower exposure, and commonly needs to increase the ISO to compensate for the lack of exposure, indirectly increasing the image noise. Nonetheless, under a common imaging environment (*e.g*., ISO level or shutter speed) with the same noise prior, different scenes/brightnesses share a statistically similar result of the noise distribution. Thus, this observation indicates the noise prior is beyond and independent on the image prior.

# <span id="page-3-2"></span>**3.2 Locally Noise Prior Estimation**

Specifically in practical usage, we can only capture a corrupted noisy observation and commonly have little additional information on the environmental illumination, sensor technology, and photography settings. Therefore, the independence of noise prior and image prior is a critical principle that we can use to estimate the noise prior from a single noisy image.

As aforementioned, under a common imaging environment, different scenes should have statistically similar noise priors, yet the image prior of a scene generally indicates the features for visual perception, which are commonly represented as texture or edges. The final image commonly has a specific statistical distribution, and each pixel can be formulated as

$$
\mathbf{I}_i = \Phi(\{\mathbf{I}_j\}_{j \in \mathcal{O}(i)}) \tag{6}
$$

where  $\mathcal{I}(\cdot)$  indicates image prior model implemented as an onefold denoising model,  $\mathcal{O}(i)$  denotes the local neighbors of location i.

Due to the intrinsic sophisticated characteristics of image, the statistical variance of a whole image is less effective to infer neither noise prior nor image prior. To effectively separate the noise prior and the image prior, we present a **Lo**cally **N**oise **P**rior **E**stimation (**LoNPE**) algorithm by eliminating the effect of image prior, such as the sophisticated textures, spatially non-local structures and edges, and *etc*.

A primal motivation is to employ the local luminance constancy in a smooth patch, where

$$
\mathbf{I}_i \simeq \mathbb{E}_{j \in \mathcal{O}(i)}(\mathbf{I}_j) \tag{7}
$$

in other words, the image prior is negligible in a local smooth patch, and is represented as the mean value of pixels in local region. Thus, on the local neighbor locations  $\mathcal{O}(i)$ , the statistical distribution of  $\{\mathbf I_i\}_{i\in\mathcal{O}(i)}$  should be approximately

<span id="page-4-0"></span>

Fig. 3: Pipeline of LoNPE algorithm. The dynamic range of the input raw noisy image has been normalized into [0, 1].

same, and could be utilized to estimate the noise prior as its independency on the image prior.

As illustrated in Fig. [3,](#page-4-0) we firstly preprocess the image to restrict its theoretical value range into  $[0, 1]$ , then partition it into a group of local patches, and select the smooth patches to eliminate the interference of image prior. Next, we calculate these patches' statistical values of mean and variance, to finally estimate the noise prior  $(\sigma_s, \sigma_r)$  with a simple least square optimization solver.

## <span id="page-4-2"></span>*3.2.1 LoNPE Algorithm*

Due to the variety of sensor bit depth  $B$  (*e.g.*,  $B = 10$ in iPhone 7 camera,  $B = 14$  in Canon 80D camera), the theoretical value range of raw digital sensor image  $[0,2^B]$ might be different. For generally analyzing, we preprocess the raw image by normalizing its theoretical value range into  $[0, 1]$ , as

$$
\mathbf{I} = \mathbf{I} \cdot 2^{-B} \tag{8}
$$

Subsequently, the image is firstly partitioned into  $n$ patches  $\{\bar{\mathbf{I}}_i\}_{i=1}^n$  at same size of  $\mathcal{O}$ . As shown in Fig. [3,](#page-4-0) on the assumption of local illuminance constancy, we select  $m$  smoother patches  $\{\mathbf I_i\}_{i=1}^m$  as samples for noise prior estimation. In detail, on a smooth patch, the local luminance should be approximated by its statistical mean, as

<span id="page-4-5"></span>
$$
L_i = \mathbb{E}_{j \in \mathcal{O}(i)}(\mathbf{I}_j) \tag{9}
$$

besides, the statistical variance  $\sigma^2$  should contain only noise prior, and is formulated as

<span id="page-4-6"></span>
$$
\sigma_i^2 = L_i \cdot \sigma_s^2 + \sigma_r^2
$$
  
=  $\mathbb{E}_{j \in \mathcal{O}(i)} (\mathbf{I}_j - L_i)^2$  (10)

Particularly, to eliminate the image prior, these smooth patches are sampled from the original patch pools  $\{\mathbf I_i\}_{i=1}^n$  by employing a local smoothness criterion  $\lambda_{\mathcal{S}}$ , which is designed to quantify the local smoothness of an heteroscedastic Gaussian distribution, and is formulated as

$$
\lambda_{\mathcal{S}} = \sigma_i / \sqrt{L_i} \tag{11}
$$

that, the lower  $\lambda_{\mathcal{S}}$ , the higher smoothness in *i*-th local patch.

<span id="page-4-1"></span>

*raw noisy image*

Fig. 4: Framework of LoNPE network. The backbone of network is same as the one in DoTNet [\[66\]](#page-15-16).

Based on the independence of noise prior and image prior, all local patches of an image should share a common noise prior ( $\sigma_{\rm s}$ ,  $\sigma_{\rm r}$ ). Then, we have

<span id="page-4-4"></span>
$$
\begin{bmatrix}\n\sigma_1^2 \\
\sigma_2^2 \\
\vdots \\
\sigma_m^2\n\end{bmatrix} =\n\begin{bmatrix}\nL_1 \\
L_2 \\
\vdots \\
L_m\n\end{bmatrix} \cdot \sigma_s^2 + \sigma_r^2
$$
\n
$$
= \begin{bmatrix}\nL_1 & 1 \\
L_2 & 1 \\
\vdots & \vdots \\
L_m & 1\n\end{bmatrix} [\sigma_s^2 \quad \sigma_r^2]^T
$$
\n(12)

if only  $\mathit{Rank}([\mathbf{L},\;\mathbf{1}])\;\geq\; 2$  where  $\mathbf{L}\;=\;[L_1,L_2,...,L_m]^\text{T}$ , it would be effective to estimate the noise prior  $(\sigma_s, \sigma_r)$  using a simple least square optimization algorithm.

Note that, LoNPE algorithm estimate the noise prior from a single raw noisy observation I (or  $I_{raw}$ ) as

<span id="page-4-3"></span>
$$
[\sigma_{\rm s}, \sigma_{\rm r}] = \Psi_{\rm LoNPE}(\mathbf{I}_{\rm raw}) \tag{13}
$$

which strictly follows the statistical characteristics of raw sensor noise prior, it might be infeasible to directly apply to a sRGB color image due to the sophisticated ISP procedure.

## <span id="page-5-0"></span>*3.2.2 LoNPE Network*

Inspired by the concept of noise representation in [\[66\]](#page-15-16), that the noise level could be represented as an explicit parameter and is easy to learn by an external neural network. We build a learnable CNN model to predict the noise prior  $(\hat{\sigma}_{s}, \hat{\sigma}_{r}) \rightarrow (\sigma_{s}, \sigma_{r})$  from a single sRGB noisy color image  $\mathbf{I}_{rgb}$ , which is formulated as

$$
[\hat{\sigma}_{\rm s}, \hat{\sigma}_{\rm r}] = \Phi_{\rm LoNPE}(\mathbf{I}_{\rm rgb}) \tag{14}
$$

where  $\Phi_{\text{LONPE}}(\cdot)$  denotes the noise prior estimation network, and called "LoNPE network". The framework of LoNPE network is shown in Fig. [4,](#page-4-1) consisting of a backbone as the DoTNet in [\[66\]](#page-15-16) for feature extraction and two fully-connected layers for decision. Due to the physical characteristics of shot noise (photon-to-electron conversion rate) and read noise (quantization range of digital signal), the output range of  $\sigma_s$ and  $\sigma_r$  are limited to [0, 1].

To learn an effective LoNPE network, we need to calculate the groundtruth noise prior, by applying the LoNPE algorithm  $\Phi_{\text{LONPE}}(\cdot)$  with numerous training samples of raw noisy observations, *e.g*., SIDD-Medium raw-domain dataset. Subsequently, we train the LoNPE network by optimizing the following objective function,

<span id="page-5-1"></span>
$$
\mathcal{L}_{\text{LONPE}} = \left\| \Phi_{\text{LONPE}}(\mathbf{I}_{\text{rgb}}) - \Psi_{\text{LONPE}}(\mathbf{I}_{\text{raw}}) \right\|_{1} \tag{15}
$$

where  $\left\Vert \cdot\right\Vert _{1}$  represents L1 loss function, minimizing the mean absolute error (MAE) between the estimated noise prior and the corresponding groundtruth.

### **3.3 Conditional Denoising Transformer**

As discussed in Section [1,](#page-0-2) a conditional denoising model is necessary for improving the performance by decomposing the optimization space under the guidance of noise prior. Considering the image prior and noise prior in a noisy image, an excellent conditional denoising model should be good at extracting the implicit image prior to learn how to restore the corrupted pixels, and utilizing the explicit noise prior to precisely control the intensity of restoration.

Due to the strong capability of Transformer-based denoising models (*e.g*., CAT [\[49\]](#page-14-48), Uformer [\[8\]](#page-14-7), Restormer [\[9\]](#page-14-8) and *etc*), we design a **Cond**itional denoising Trans**former** (**Condformer**) by embedding the noise prior into the selfattention module. Particularly, as the independence of noise prior and image prior, guiding the model to learn from image prior and noise prior separately is the primary principle in designing the Condformer.

#### *3.3.1 Embedding noise prior in latent space*

Existing image denoising networks typically use a global residual connection for noise prediction and an U-shape encoder-decoder structure for image prior representation, suggesting that noise is implicitly concealed in the latent space as illustrated in Fig. [5.](#page-6-1) In latent space manipulation [\[67\]](#page-15-17), [\[68\]](#page-15-18), the latent space code from the encoder effectively represents implicit semantic attributes for domain transfer. Inspired by this and considering the residual attribute of noise, the latent space code of a noisy image significantly represents noise statistics.

As mentioned earlier in Section [1,](#page-0-2) an effective conditional denoising model should separately consider the image and noise priors, adhering to the principle of their independence. Specifically as shown in Fig. [5,](#page-6-1) we firstly extract the latent space code  $X$  of the noisy image using a denoiser encoder, and then construct a feature fusion module to embed the noise prior  $(\sigma_{\rm s},\sigma_{\rm r}).$ 

## *3.3.2 Overall pipeline*

Considering the efficiency in practical applications, we employ the Restormer as our denoiser baseline, replacing its self-attention module by a conditional self-attention module that embeds noise prior in the latent space. Following [\[9\]](#page-14-8), given a noisy color observation  $\mathbf{I}_{\text{rgb}} \in \mathbb{R}^{ \mathfrak{Z} \times h \times w }$ , we construct a multi-scale hierarchical denoiser encoder which consists of three channel-wise Transformer blocks to capture crosscovariance across channels, generating the latent space code  $\mathbf{X} \in \mathbb{R}^{8c \times \frac{h}{8} \times \frac{w}{8}}$ , where *c* is the number of channels.

On handling the latent space code, we introduce a conditional self-attention module (CondSA) that embeds the noise prior into the implicit latent code for conditional optimization of denoising model. The rectified latent code is

$$
\hat{\mathbf{X}} = \text{CondSA}(\mathbf{X}, \mathbf{z}) \tag{16}
$$

This is then fed into a feed-forward network (FFN) for feature transformation. In particular, to effectively exploit the noise prior  $(\sigma_s, \sigma_r)$  estimated by LoNPE algorithm or network, CondSA encodes this prior into a latent conditional embedding vector  $\mathbf{z} \in \mathbb{R}^{1 \times \tilde{k}}$  using a shallow module with fully-connected layers. Each CondSA has a specific embedding vector to adapt the intermediate features. The rectified latent space code, equipped with noise prior, guides the denoiser decoder for specific denoising. In particularly, to preserve fine structural and textural details in the restored images, we use a hierarchical skip-connection strategy [\[9\]](#page-14-8) that integrates low-level features from the encoder and highlevel features from the decoder.

Consequently, as depicted in Fig. [5,](#page-6-1) the denoised output  $\hat{\mathbf{L}}_{rgb}$  can be formulated as

$$
\hat{\mathbf{L}}_{\text{rgb}} = \Phi_{\text{Condformer}}(\mathbf{I}_{\text{rgb}}, (\sigma_{\text{s}}, \sigma_{\text{r}}))
$$
\n(17)

where  $\Phi_{\text{Condformer}}(\cdot)$  represents the Condformer model, with inputs consisting of a noisy observation  $I_{rgb}$  and the estimated noise prior  $(\sigma_s, \sigma_r)$  from LoNPE algorithm  $\Phi_{\text{LONPE}}(\mathbf{I}_{\text{raw}})$  or network  $\Psi_{\text{LONPE}}(\mathbf{I}_{\text{rgb}})$ .

Following the convention of supervised denoising methods, we train the Condformer by optimizing the pixel-wise objective function as

$$
\mathcal{L}_{\text{Condformer}} = \left\| \mathbf{L}_{\text{rgb}} - \hat{\mathbf{L}}_{\text{rgb}} \right\|_{1} \tag{18}
$$

where  $L_{rgb}$  denotes the clean target corresponding to the denoised output.

Subsequently, we introduce the preliminary definition of the self-attention module in Restormer, and describe the proposed CondSA for embedding the conditional noise prior.

#### *3.3.3 Conditional Self-Attention Mechanism*

Aiming to alleviate the high complexity of the conventional self-attention module when calculating the key-query cross-covariance across spatial dimensions, the self-attention

<span id="page-6-1"></span>

Fig. 5: Architecture of Condformer. The information flow is successively transmitted into the denoiser encoder, the latent module, and the denoiser decoder, where the latent module stacks groups of CondSA blocks. Particularly, the noise prior is generated via LoNPE network, and is then embedded as a conditional vector  $z$  into the query tensor  $Q$  and key tensor  $K$  in each CondSA block.

in Restormer attempts to calculate the key-query crosscovariance across channels, and is formulated as

$$
\mathbf{Y} = W^Y \text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) + \mathbf{X}
$$
 (19)

that,

$$
Attention(Q, K, V) = Softmax(QKT/\alpha)V
$$
 (20)

where **X** and **Y** are the input and output features.  $Q \in$  $\mathbb{R}^{c \times hw}$ ,  $\mathbf{K} \in \mathbb{R}^{c \times hw}$  and  $\mathbf{V} \in \mathbb{R}^{c \times hw}$  indicate the *query*, key and *value* matrix obtained by encoding the input feature  $\mathbf{X} \in \mathbb{R}^{c \times h \times w}$  with linear layers  $W^Q$ ,  $\breve{W^K}$  and  $\tilde{W}^V$  respectively, each of which stacks a  $1 \times 1$  convolution and a  $3 \times 3$ depth-wise convolution layer. Besides,  $\alpha$  is a learnable scaling parameter to control the magnitude of the cross-covariance of  $Q$  and  $K$  before applying a softmax layer.

By extracting and exploring the local and non-local features, the whole network indeed aims to employ the image priors of the noisy observation, which exactly meets the unconditional optimization paradigm in Fig. [1a.](#page-0-0) According to the optimization of conditional denoising model in Eq.[\(2\)](#page-1-1) and Fig. [1b,](#page-0-1) the noise prior should be embedded into a conditional self-attention module as

$$
\mathbf{Y} = W^Y \text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}, \mathbf{z}) + \mathbf{X}
$$
 (21)

where  $\mathbf{z} \in \mathbb{R}^{1 \times 2k}$  represents the conditional embedding vector from the noise prior  $(\sigma_s, \sigma_r)$  by repeating k times in channel dimension.

The conditional attention should effectively represent the correlation between-in the intermediate image features, and the latent correlation between the intermediate image features and noise prior. Therefore, a fusion module is necessary for correlation representation of noise and image priors. Intuitively, the query tensor  $Q$  and the key tensor  $K$ indicates the information for feature retrieval [\[42\]](#page-14-41); instead, the value tensor  $V$  represent the property of the input feature. Therefore, it is reasonable to embed noise prior into the query/key tensors and generate the conditional counterparts  $\mathbf{\dot{Q}}'$  and  $\mathbf{K}'$ , so we have

$$
Attention(Q, K, V, z) = Softmax(Q'K'^{T}/\alpha)V
$$
 (22)

and

$$
\mathbf{Q}' = \Phi_{LFM}(\mathbf{Q}, \mathbf{z}), \quad \mathbf{K}' = \Phi_{LFM}(\mathbf{K}, \mathbf{z}) \tag{23}
$$

where  $\Phi_{LFM}$  represents a linear fusion module (LFM) layer for feature fusion. In detail, in order to fuse the query/key tensor and the conditional embedding vector in channel and spatial dimension, we can simply concatenate them in channel-wise and feed them into a a  $1 \times 1$  convolution and a  $3 \times 3$  depth-wise convolution layer as the convention. In this way, the noise prior would be embedded into each channel and a local receptive field of the tensors.

# <span id="page-6-0"></span>**4 EXPERIMENTS**

We first describe the experimental setup and then evaluate the performances of our LoNPE and Condformer on noise statistics and blind image denoising. Finally, we perform ablation studies to demonstrate the effectiveness of our methods.

## **4.1 Experimental Setup**

## *4.1.1 Datasets and Metrics*

To demonstrate the effectiveness of our LoNPE and Condformer, we conduct experiments on both synthetic and real datasets. Below are the details of the synthetic and real datasets, and evaluation metrics.

*Synthetic Datasets*. Following [\[53\]](#page-15-3), we adopt several sRGB image datasets for training the LoNPE and Condformer networks, including the DIV2K and Flicker2K dataset [\[69\]](#page-15-19) with 3650 high-quality 2K images, the Berkeley segmentation dataset (BSD) [\[70\]](#page-15-20) with 400 images, Waterloo Exploration Database (WED) dataset [\[71\]](#page-15-21) with 4744 images. Considering both signal-dependent and signal-independent noises, we randomly add noises on the clean sRGB image with Poisson-Gaussian noise model. The noise level are set to  $\sigma_s \sim [0, 0.3]$ and  $\sigma_{\rm r} \sim [0, 50/255]$ , both of which indicate the groundtruth noise prior to demonstrate the effectiveness of our LoNPE algorithm. Especially, the Poisson-Gaussian noise will be degraded to additive Gaussian white noise (AWGN) when  $\sigma_s = 0$ . To evaluate the performance, we apply our methods

<span id="page-7-1"></span>

Fig. 6: Noise prior estimation on synthetic noises with Poisson-Gaussian distribution. By applying our LoNPE algorithm, we can effectively calculate a relative accurate noise prior from a single noisy observation.

on several benchmarks, including CBSD68 [\[70\]](#page-15-20), Kodak24 [\[72\]](#page-15-22) and Urban100 [\[73\]](#page-15-23).

*Real Datasets*. Consistent with previous real image denoising work [\[9\]](#page-14-8), we adopt the SIDD-Medium dataset [\[10\]](#page-14-9) for real noise statistics and real image denoising tasks, which contains 320 noisy-clean image pairs in both raw and sRGB domains. Particularly, we first apply our LoNPE algorithm on 320 noisy raw images to estimate their corresponding noise priors, and then utilize them to help training the LoNPE and Condformer networks on the 320 sRGB noisy-clean image pairs. For validation, 1024 pairs of noisy-clean sRGB image patches from SIDD validation dataset [\[10\]](#page-14-9) are adopted. Besides, evaluation is also conducted on 1280 noisy  $256 \times 256$ patches from the SIDD benchmark dataset [\[10\]](#page-14-9) and 50 noisy  $512 \times 512$  images from the DND benchmark dataset [\[12\]](#page-14-11).

*Evaluation Metrics*. Two commonly-used image quality assessment criteria are adopted to evaluate the performances: Peak Signal-to-Noise Ratio (PSNR) and Structural SIMilarity (SSIM) [\[74\]](#page-15-24), and are calculated in the sRGB domain. Note that, since the clean groundtruthes of SIDD and DND benchmark datasets are unavailable, we calculate these metrics on only SIDD validation dataset and obtain the metrics of them from the online servers<sup>[1](#page-7-0)</sup>.

## *4.1.2 Implementation Details*

*Settings on LoNPE Algorithm*. As described in Section [3.2.1,](#page-4-2) to accurately calculate the noise prior of a noisy observation in raw domain, our LoNPE algorithm  $\Psi_{\text{LONPE}}$  is applied on top  $\frac{m}{n} = 10\%$  of the sampled local patches, which are at size of  $\mathcal{O} = 16 \times 16$  for each raw image. Given a  $h \times w$  raw noisy image, we first sample  $n = \left\lfloor \frac{h}{16} \right\rfloor \times \left\lfloor \frac{w}{16} \right\rfloor$  local patches, and select the top m smooth patches with lower  $\lambda_{\mathcal{S}}$ , then calculate its noise prior using Eq.[\(13\)](#page-4-3).

*Settings on LoNPE Network*. As described in Section [3.2.2,](#page-5-0) for practical applications on estimating the noise prior of a sRGB noisy image, we need to train an effective LoNPE network  $\Phi_{\text{LONPE}}$  as illustrated in Fig. [4.](#page-4-1) Similar to [\[66\]](#page-15-16), for a single noisy image, we randomly sample 8 local patches of size  $32 \times 32$  and average the output  $(\hat{\sigma}_{s}, \hat{\sigma}_{r})$  as the final

DND: <https://noise.visinf.tu-darmstadt.de>

predicted noise prior. In the training phase, AdamW optimizer [\[75\]](#page-15-25) is employed with cosine annealing [\[76\]](#page-15-26) learning rate from  $10^{-3}$  to  $10^{-6}$  during 50K mini-batch iterations, on minimizing the objective function in Eq.[\(15\)](#page-5-1), and the batch size is set to 64.

*Settings on Condformer*. Following the settings of Restormer in [\[9\]](#page-14-8), we build our Condformer with groups of Transformer block in the encoder or decoder modules. Yet in the latent module, we stack 8 CondSA blocks with the predicted noise prior to recify the latent space. In the training phase, we adopt the AdamW optimizer with  $(\beta_1, \beta_2) = (0.9, 0.999)$  and set weight decay to 10<sup>-4</sup>. Using progressive training strategy proposed by [\[9\]](#page-14-8), we set the batch size and patch size pairs to  $[(64, 128^2), (16, 256^2), (8, 384^2), (4, 512^2)]$  at training iterations [0k, 150k, 200k, 250k]. We train our Condformer models for total 300k iterations and the initial learning rate is set to  $4 \times 10^{-4}$  and gradually reduced to  $10^{-6}$  through the cosine annealing. Data augmentation is performed on the training data through horizontal flip and random rotation of 90, 180, and 270.

Both of the LoNPE and Condformer networks are implemented on PyTorch framework using NVIDIA A800 GPUs.

#### **4.2 Experiments on Noise Statistics**

In this section, we conduct several statistical experiments by analyzing the statistics of synthetic or real noises, to further demonstrate the effectiveness of our LoNPE algorithm on noise prior representation.

#### *4.2.1 On synthetic noises*

As illustrated in Section [3.1.2,](#page-3-1) the noise prior is beyond and independent of the image prior. From Eq. [\(5\)](#page-2-1), the noise prior  $(\sigma_s, \sigma_r)$  affects raw noisy observations but is implicit in the sRGB color observations due to unknown ISP operations. To address this, we randomly add noises on the clean sRGB images with Poisson-Gaussian sampling and employ our LoNPE algorithm on the synthesized noisy images to estimate the corresponding noise prior.

As shown in Fig. [6,](#page-7-1) we set three degree of noise priors  $(\sigma_s, \sigma_r)$  as  $(0.05, 0.02)$ ,  $(0.10, 0.04)$  and  $(0.15, 0.08)$ , representing mild, moderate and severe corruptions, respectively.

<span id="page-7-0"></span><sup>1.</sup> SIDD: [https://abdokamel.github.io/sidd/;](https://abdokamel.github.io/sidd/)

<span id="page-8-0"></span>

Fig. 7: Statistical experiments on noise prior of raw sensor images from various scenes in SIDD-Medium training datasets. We can find that different imaging environments cause various noise priors, *e.g*., higher ISO level causes more shot noises and higher shutter speed causes more read noises. Instead, different target scenes show similar noise priors, indicating the independence of image prior and noise prior.

We sample Poisson-Gaussian noises and add them to 100 images from the Urban100 dataset. By applying LoNPE algorithm, we obtain the estimated noise prior values of each image with different noise level, and find that the mean estimation results are close to the groundtruthes with less discrepancy, particularly for the signal-dependent noise prior  $\sigma$ <sub>s</sub>. However, there exists a nonnegligible discrepancy in the signal-independent noise prior  $\sigma_r$  estimation, and the discrepancy increases as the noise level is enlarged. A reason is that, the image context reflects the signal intensity of the target scene illuminance, and could interfere the estimation of the signal-independent  $\sigma_{\rm r}$ . This issue is particularly pronounced at the high-frequency regions, *e.g*., edges and textures. That is why we need to employ the local smoothness criterion  $\lambda_{\mathcal{S}}$  to eliminate the interference of image prior.

#### *4.2.2 On real noises*

As described in Section [3.2,](#page-3-2) the goal of LoNPE is to calculate the noise prior from a single raw noisy observation based on the independence of noise prior and image prior. Thus, the most critical thing for demonstration is the statistical experiment on the correlations of the estimated noise prior  $(\sigma_s, \sigma_r)$  and the imaging environments.

Based on the independence of image prior and noise prior investigated in Fig. [2,](#page-3-0) the noise prior is quantifiable using our LoNPE algorithm. To demonstrate the effectiveness of our LoNPE algorithm, we conduct a statistical study on the estimated noise priors of SIDD noisy observations with various target scenes and imaging environments. Specifically, according to the camera information of the SIDD-Medium raw-domain training dataset, we mainly analyze the estimated noise prior under various brightness (including "highlight", "normal-light" and "low-light"), scenes (including scene "001", "002", "007" and "008"), ISO levels (ranging from 100 to 3200), and shutter speed (ranging from 1/1600 to 1/60). Subsequently, the statistical results in Fig. [7](#page-8-0) can be summarized into several points:

*1) Higher ISO level leads to more shot noise.* Under same brightness, the shot noise prior  $\sigma_s$  is proportional to the ISO levels. Since the ISO settings represent the photo-sensibility of camera sensor, a higher ISO level amplifies the electrical signal generated by the photons hitting the sensor. As shot noise follows Poisson distribution, its relative strength becomes more pronounced as you increase the ISO. The higher the amplification, the more noticeable the noise will be in the final image. This is crucial in low-light conditions to brighten the image. Thus, the slope of variance  $(\sigma_s^2)$  in Eq. [\(5\)](#page-2-1) would be larger as the ISO increased.

*2) Higher shutter speed leads to more read noises.* Under same brightness, the read noise prior  $\sigma_{\rm r}$  is proportional to the shutter speed. In camera sensor, especially those designed for high-speed photography, the demand to read out quickly can introduce more noises. Fast readout processes might require higher readout clock speeds and increased electronic noise, contributing to the overall read noise.

*3) Independence of noise and image priors.* Empirically, the environmental brightness is proportional to the intensity of photons and should influence only shot noise; instead, the ISO and shutter speed indicate the magnification of electrons from photons and would affect the shot noise and read noise, respectively. Besides, the captured signal in a digital image is a sum of both the scene-derived signal and various sensor noises. However, these sensor noises overlay the signal in a way that their behavior and characteristics do not alter based on the attributes of the target scene itself. This phenomenon is well demonstrated by statistical analysis in Fig. [7.](#page-8-0) We can find that different scenes (with various image priors) have similar noise prior under the same imaging environment, which is strong evidence of demonstrating the independence of noise prior and image prior.

Understanding the independence of noise prior and image prior allows photographers and engineers to develop better noise removal algorithms and improve sensor designs. By treating the scene and sensor noise as separate entities, it becomes easier to process images to enhance the desired signal intensity while minimizing the impact of sensor noise on the final image.

<span id="page-9-0"></span>TABLE 1: Quantitative comparisons of different synthetic image denoising methods on several validation datasets with a fixed  $\sigma_s$  and various  $\sigma_r \in [15, 25, 50]/255$ . PSNR↑ criterion is adopted to evaluate the performances.

† : Model is re-trained on Poisson-Gaussian noise model with the same settings as our Condformer.

<span id="page-9-1"></span>

Fig. 8: Visual results of restoring the Poisson-Gaussian noisy images. We can find that our Condformer can preserve the details and remain less distortions as compared with other methods, showing higher generalization on various corruptions with different noise levels.

## **4.3 Experiments on Image Denoising**

## *4.3.1 On synthetic images*

In this section, we conduct Poisson-Gaussian image denoising experiments on synthetic validation datasets. Note that, recent blind denoisers were commonly trained on noise models as Gaussian (G), spatially-variant Gaussian (SV-G) and Poisson-Gaussian (P-G) distributions. We formulate the corresponding noises as follows,

$$
N_G \sim \mathcal{N}(0, \sigma_r^2)
$$
  
\n
$$
N_{SVG} \sim M \odot \mathcal{N}(0, 1)
$$
  
\n
$$
N_{P-G} \sim \mathcal{N}(0, \sigma_s^2 \cdot L + \sigma_r^2)
$$
\n(24)

obviously, Gaussian noise model is a specific case of P-G noise model when  $\sigma_s = 0$ , and SV-G noise model is more fine-grain as applying a spatial map M to represent the variance of Gaussian, thus P-G noise model can be regarded as a specific case of SV-G by setting the map relative to image context L.

In comparison of synthetic image denoising, several current state-of-the-art blind denoisers are selected, including: 1) Gaussian noise model drived: DnCNN [\[15\]](#page-14-14) and Restormer [\[9\]](#page-14-8); 2) SV-G noise model drived: VDN [\[16\]](#page-14-15), DRANet [\[77\]](#page-15-27) and VIRNet [\[28\]](#page-14-27); 3) P-G noise model drived: FBI-D [\[78\]](#page-15-28), VBDNet [\[79\]](#page-15-29), CLIPDenoising [\[80\]](#page-15-30) and our Condformer. Moreover, we re-train the Restormer [\[9\]](#page-14-8) and

<span id="page-10-0"></span>TABLE 2: Quantitative comparisons of different real image denoising methods on several benchmarks. Particularly, the criteria of SIDD and DND benchmarks are obtained from the corresponding online server.

<span id="page-10-1"></span>

Fig. 9: Qualitative comparisons on SIDD validation datasets. Our Condformer can preserve more details as accurately guide the model to remove the noises adaptively, instead other unconditional denoisers prone to handle the high-frequency details as undesired noises since the unknownability of noise level in training and testing phases.

MambaIR [\[47\]](#page-14-46) denoisers on P-G noise model with same settings as our Condformer for fair comparisons.

As reported in TABLE [1,](#page-9-0) quantitative comparisons on three public validation datasets with various noise levels show that, our Condformer achieves superior performances against other methods. On denoising accuracy, our Condformer obtains higher PSNR values especially when  $\sigma_s > 0$  and shows slight disadvantages compared with the Restormer trained on Gaussian noise model when  $\sigma_s = 0$ . On model generalization, under same experimental settings, our Condformer achieves excellent performances on all noise levels, instead Restormer† and MambaIR† show lower

generalization on various noise levels. That is, our Condformer possesses a complete and conditional optimization space for divide-and-conquer, which is naturally stronger than any unconditional models. Furthermore, the qualitative comparisons shown in Fig. [8](#page-9-1) demonstrate our Condformer can handle any degree of noisy corruption, being capable of detail preservation and noise removal well.

## *4.3.2 On real images*

In this section, we demonstrate the effectiveness of the proposed Condformer for real image denoising. We compare our Condformer with several state-of-the-art real image denoising methods on SIDD validation, SIDD benchmark,

<span id="page-11-0"></span>

Fig. 10: Qualitative comparisons on SIDD benchmark datasets. Especially under low-light imaging environments, noises with severe corruption prone to overwhelm the image contexts. In this case, only our Condformer could preserve more details, *e.g*., textures, edges and natural structures.

<span id="page-11-1"></span>

Fig. 11: Qualitative comparisons on DND benchmark under normal-light imaging environment. Our Condformer preserves the edges and natural structures more distinctly than other denoisers.

and DND benchmark datasets. We select several representative CNN-based denoisers and current state-of-the-art Transformer-based and Mamba-based denoisers, including: 1) CNN-based denoiser: RIDNet [\[3\]](#page-14-2), VDN [\[16\]](#page-14-15),MIRNet [\[81\]](#page-15-31), MPRNet [\[5\]](#page-14-4), NAFNet [\[82\]](#page-15-32), MSANet [\[83\]](#page-15-33), MIRNetv2 [\[4\]](#page-14-3) and VIRNet [\[28\]](#page-14-27); 2) Transformer-based denoiser: Uformer [\[8\]](#page-14-7), Restormer [\[9\]](#page-14-8), CAT [\[49\]](#page-14-48), ShuffleFormer [\[50\]](#page-15-0), GRL [\[52\]](#page-15-2) and ART [\[51\]](#page-15-1); 3) Mamba-based denoiser: MambaIR [\[47\]](#page-14-46). As reported in TABLE [2,](#page-10-0) our Condformer achieves the highest PSNR and SSIM criteria over all the compared denoising methods. Note that, since the clean groundtruth images of SIDD and DND benchmarks are inaccessible, we upload the denoised results of all the considered methods on their online servers for testing.

Particularly, compared with other Transformer-based denoisers, our Condformer needs relatively lower complexity. For example, on SIDD validation dataset, our Condformer achieves 0.32dB gain of PSNR over Uformer with about half of its parameters. Even though Restormer is considered as the baseline of our Condformer without embedded noise prior in the self-attention module, our Condformer gets about 0.2dB gain of PSNR over it with similar computational complexities. In spite of training on a single SIDD-Medium dataset, our Condformer performs excellently on the out-of-distribution DND benchmark.

Qualitatively on the in-distribution SIDD validation and benchmark datasets, as shown in Fig. [9](#page-10-1) and Fig. [10,](#page-11-0) our Condformer can not only successfully remove the noises but also keep the details well, including textures, edges and natural structures. After conditional optimization with noise prior, our Condformer could handle each noisy image in a sensorspecific way, where the denoising intensity is proportional

<span id="page-12-0"></span>

Fig. 12: Qualitative comparisons on DND benchmark under low-light imaging environment. Although noise interferes the image context restoration overwhelmingly under low-light environment, our Condformer remains fewer noises and can restore cleaner flatten regions than other denoisers.

<span id="page-12-1"></span>TABLE 3: Quantitative comparisons of different Transformerbased denoising methods on computational complexity. The FLOPs, Memory and Time are calculated when processing a single  $512 \times 512 \times 3$  sRGB image on a NVIDIA A800 GPU.

to the corruption degree of the noisy observation. Especially under low-light imaging environments, noises prone to overwhelm the image contexts as introducing higher ISO level and indirectly enlarging the shot noises. Furthermore, Fig. [11](#page-11-1) and Fig. [12](#page-12-0) shows that our Condformer has excellent generalization ability as handling the out-of-distribution DND noisy images well, on both detail preservation and undesired noise removal. Note that, since the images have low visibility under low-light imaging environment, we employ image normalization on each denoised result for better visualization.

## *4.3.3 On computational complexity*

In this section, we mainly conduct a comparison of our Condformer and other Transformer-based denoising methods on several computational complexity criteria. In detail, the number of parameters represents the model size for transmission and storage necessaries, FLOPs and Time indicate the time complexity of model, and Memory is the memory usage when running model on a GPU device. The last three criteria are calculated when processing a single  $512 \times 512 \times 3$  sRGB image on a NVIDIA A800 GPU. To avoid randomness, the running time is averaged on handling 100 images with torch.cuda.Event timer. As reported in

<span id="page-12-2"></span>TABLE 4: Ablation study of Condformer with different priors on SIDD Validation dataset.

39.90

TABLE [3,](#page-12-1) our Condformer shows relatively trade-off on the complexities, which is a resource-friendly method.

#### **4.4 Model Analysis**

In this section, we mainly investigate the effects of our Condformer and LoNPE modules with experimental analysis.

#### *4.4.1 Investigation on Condformer*

Aiming at guiding the model to learn from image prior and noise prior separately, the core of our Condformer is embedding the noise prior effectively in the latent space for conditional optimization. Thus, we conduct an ablation study of Condformer in TABLE [4,](#page-12-2) note that all the models in this section are trained during 100K iterations, where the image size is  $3 \times 128 \times 128$  and batch size is set to 8 for training on a single NVIDIA A800 GPU.

Since the key of our Condformer is constructing CondSA blocks in the latent module in Restormer, we first train a baseline model which is same sa Restormer and achieves PSNR of 39.68dB on SIDD validation dataset. Subsequently, to avoid deviation on the performance as introducing an auxiliary vector, we firstly build a void CondSA module by embedding zero vector, and find it gain nothing. However, after embedding the estimated noise prior  $(\hat{\sigma}_{\mathrm{s}}, \hat{\sigma}_{\mathrm{r}})$  from LoNPE network by a naive concatenation with the input tensor of CondSA, the corresponding model achieves about 0.1 PSNR gain, demonstrating the positive role of noise prior. Furthermore, to learn an effective representation of

<span id="page-13-1"></span>TABLE 5: Investigation on LoNPE algorithm with different patch-sampling hyperparameters. Particularly,  $\mathcal{O}$ ,  $m/n$  and  $\lambda_{\mathcal{S}}$  denote the sampling size, ratio and index, respectively.

the correlation between-in the intermediate image features and noise prior, a LFM module is designed for correlation representation of noise prior and image features. The result shows that an effective fusion module can significantly boost the contribution of the noise prior. As reported in TABLE [4,](#page-12-2) the fourth model achieves higher performances than the afore three models, especially gains more than 0.2dB of PSNR against the baseline.

Moreover, although the precision of noise prior estimation might affects the denoising results, the Condformer with estimated noise prior  $(\hat{\sigma}_{s}, \hat{\sigma}_{r})$  is slightly inferior to the upper bound (the one with groudtruth  $(\sigma_{\rm s},\sigma_{\rm r})$  obtained via LoNPE algorithm), but costs fewer time complexities. That is because the noise prior is a low-dimensional vector as easier to learn via a simple network, instead the LoNPE algorithm needs to calculate the numerical solutions iteratively which is timeconsuming.

#### *4.4.2 Investigation on LoNPE*

As described in Section [3.2,](#page-3-2) our LoNPE algorithm is based on the statistical analysis of the sampled local smooth patches from a single noisy raw image. From Eq.[\(12\)](#page-4-4), the noise prior is estimated on  $m$  local patches with statistical mean  $\{L_i\}_{i=1}^m$ and variance  $\{\sigma_i^2\}_{i=1}^m$ . Particularly, from Eqs.[\(9\)](#page-4-5)-[\(10\)](#page-4-6), the precision of statistical values  $L_i$  and  $\sigma_i^2$  are highly relied on the spatial size of samples  $O$ , and the precision of parameter estimation is highly relied on the number of samples  $m$  to ensure a large *Rank*([L, 1]).

We conduct an investigation on the effects of sampling size O and ratio  $m/n$  in TABLE [5.](#page-13-1) Since there is no groundtruth for noise prior in SIDD-Medium raw-domain training dataset, we synthesize noisy samples by randomly sampling the noises from a Poisson-Gaussian distribution with  $(\sigma_{\rm s},\sigma_{\rm r})=(0.2,0.01)$  and adding it on a clean raw noisy image. The average error (*i.e*., mean absolute percentage error  $\Delta(\cdot)$  [\[84\]](#page-15-34)) and running time are reported in TABLE [5,](#page-13-1) with the increase of patch size  $O$  and sampling ratio  $m/n$ , it might introduce a negative effect of image prior. In a word, a larger patch has more precise statistical values but might contains more image priors interfering the noise prior estimation, such as edges and textures. Empirically, we choose  $\mathcal{O} = 16 \times 16$ and  $m/n = 10\%$  which provides more precise estimation of noise prior.

Besides, to further eliminate the image prior in each patch, we introduce a local smoothness criterion  $\lambda_{\mathcal{S}}$  to filter the smooth patches from the original patch pools  $\{I_i\}_{i=1}^n$ , which

<span id="page-13-2"></span>

Fig. 13: Visualization of local patch sampling with  $\lambda_{\mathcal{S}}$ . The local smoothness criterion  $\lambda_{\mathcal{S}}$  can effectively filter the smooth patches to eliminate the interference of image prior to noise prior estimation, instead random sampling might introduce high-frequency patches and cause inaccuracy of local luminance calculation.

can effectively boost the accuracy of noise prior estimation as reported in TABLE [5.](#page-13-1) To further demonstrate the effectiveness of local smoothness criterion, we record the sampled local patches in Fig. [13.](#page-13-2) It is obvious that random sampling local patches from the raw image inevitably captures the numerous high-frequency details, which would interfere the estimation of noise prior because of the nonnegligible deviation on calculating the local luminance in Eq.[\(9\)](#page-4-5). Instead, by employing the local smoothness criterion  $\lambda_{\mathcal{S}}$ , it is easy to filter the smooth patches from the original patch pools, which plays significant role on eliminating the image prior and help estimating noise prior.

# <span id="page-13-0"></span>**5 CONCLUSION AND DISCUSSIONS**

In this paper, by rethinking the real image denoising task and revisiting the formation model of raw sensor noises, we have generalized a principle of the independence of image prior and noise prior, which guides an alternative conditional optimization to tackle the limitations of existing learning-based unconditional denoising methods. At the algorithmic level, we have presented a novel Condformer architecture, which effectively embeds the noise prior into the self-attention module. The noise prior is explicitly estimated using our LoNPE algorithm or network. Extensive experiments confirm the advantages of conditional optimization with noise prior, demonstrating that the proposed LoNPE and Condformer achieve superior performance on both synthetic and real noise statistics and image denoising tasks, respectively.

Nonetheless, due to the defective sensor and circuits technology, the formation model of raw sensor noise is actually more sophisticated than the Poisson-Gaussian noise model. For instance, read noise might follows a heavy-tailed Cauchy distribution [\[25\]](#page-14-24) in extremely low-light environments, dark shading [\[26\]](#page-14-25) can result from sensor non-uniformity, and more sophisticated noise models are emerging [\[85\]](#page-15-35). Therefore, future work should explore the estimation of noise prior in these more complex scenarios, aiming to further enhance noise estimation and denoising performance.

**Yuanfei Huang** (Member, IEEE) received the Ph.D. degree from the School of Electronic Engineering, Xidian University, Xi'an, China, in 2021. He is currently a Lecturer with the School of Artificial Intelligence, Beijing Normal University, Beijing, China. His research interests include image and video processing, computer vision, and machine learning. In these areas, he has published technical articles in referred journals and proceedings including IEEE TPAMI / TIP, *etc*.

**Hua Huang** (Senior Member, IEEE) received his B.S. and Ph.D. degrees from Xi'an Jiaotong University, Xian, China, in 1996 and 2006, respectively. He is currently a Professor with School of Artificial Intelligence, Beijing Normal University, Beijing, China. His current research interests include image and video processing, computational photography, and computer graphics. He received the Best Paper Award of ICML2020 / EURASIP2020 / PRCV2019 / ChinaMM2017.
