Abstract

The current perspective about the explosions of blue supergiants is that they resemble SN 1987A. These so-called peculiar Type II supernovae, however, are one of the rarest types of supernovae and may not hence be the fate of all blue supergiants. In this work, we explore other explosion scenarios for blue supergiants. We create synthetic light curves from the explosions of blue supergiant models born from binary mergers, over a range of explosion energies and ^{56}Ni masses. We find that blue supergiant explosions may also lead to intermediate-luminosity red transients. We thus identify two categories of supernovae possible from blue supergiant explosions: those with high ^{56}Ni masses ($\gtrsim 0.01 M_{\odot}$) result in slow-rising, dome-shaped light curves like SN 1987A. Lower ^{56}Ni masses result in low-luminosity, short-plateau light curves resembling some intermediate-luminosity red transients and Type II supernovae like SN 2008bp, which are possible from the explosions of compact blue supergiants and not from the far more extended red supergiants. Our results indicate that blue supergiant explosions are more diverse than SN 1987A-like events and may be hidden among different kinds of transients, explaining the possible discrepancies between the expected fraction of blue supergiants born from binary mergers and the observed fraction of SN 1987A-like supernovae.

Key words: supernovae: general — stars: massive — binaries: close

1 Introduction

Blue supergiants (BSGs), with spectral classes between B0 and B1, are observed in plenty in the local and distant Universe (Menon et al. 2024). Yet, despite their abundance, the nature of their explosive fates has not been thoroughly explored. SN 1987A was the explosion of a BSG, whose progenitor was imaged to be a B1a supergiant (Sonneborn et al. 1987). Indeed, the progenitor properties of SN 1987A can be well explained via stellar-merger scenario (Podsiadlowski et al. 1992; Menon & Heger 2017; Urushibata et al. 2018), including the features of the supernova (SN) light curve as well, along with a few other SNe with similar light-curve shapes (Menon et al. 2019). Collectively these SN 1987A-like SNe are called “peculiar Type II SNe.”

Recently, Menon et al. (2024) demonstrated that the majority of BSGs observed today have been born from binary mergers of post-main sequence Hertzsprung-gap or red supergiants (RSGs) with their main-sequence companions. They further predicted that a substantial fraction of the observed BSGs may also die as BSGs. Stellar mergers are expected to be the outcome of about $\sim 30\%$ of massive binary star systems (de Mink et al. 2014), of which the majority may occur during the post-main sequence expansion of the primary star. SN 1987A-like events, however, are rare, comprising only $\lesssim 5\%$ of the known core-collapse SNe (e.g., Kleiser et al. 2011; Pastorello et al. 2012; Taddia et al. 2016; Sit et al. 2023). This fraction is far fewer than the observed fraction of BSGs among massive star populations, a large number of which are expected to remain as BSGs when they undergo core-collapse and explode, according to the binary-merger models of Menon et al. (2024).

The light curve of SN 1987A has a slow rise lasting for about 80 days (Arnett et al. 1989), while typical Type II SNe have a luminosity plateau lasting for around 100 days (Anderson et al. 2014). The explosions of BSGs have been mostly associated with the characteristic slow-rising, dome-shaped light curves of SN 1987A which are due to the compactness of BSGs ($R_* \lesssim 70 R_\odot$, e.g., Taddia et al. 2016; Sit et al. 2023 but see also Kleiser et al. 2011; Tsuna et al. 2020). Due to the small radii of BSGs, the adiabatic expansion after the explosion is efficient and, therefore, the luminosity declines quickly at first. Then, the SN ejecta are heated by the nuclear decay energy of ^{56}Ni and this ^{56}Ni heating makes the characteristic slow rise of SN 1987A (e.g., Woosley 1988; Shigeyama & Nomoto 1990; Blinnikov et al. 2000; Dessart & Hillier 2019; Pumo et al. 2023). In the case of SN 1987A, the amount of ^{56}Ni synthesized at the explosion is estimated to be around $0.07 M_\odot$ (Arnett et al. 1989).

Since the slow light-curve rise observed in SN 1987A-like SNe is powered by ^{56}Ni decay heating, this characteristic slow light-curve rise would become less significant if the amount of ^{56}Ni synthesized during the explosions of BSGs is small. In such a case, BSG explosions might not be observed as SN 1987A-like events and it is possible that a population of BSG explosions do not become SN 1987A-like events.

Intermediate-luminosity red transients (ILRTs) are a class of “gap transients” which have peak absolute magnitudes between those of classical novae and SNe (Rau et al. 2009; Kasliwal 2012; see Pastorello & Fraser 2019 for a review). They are characterized by a low-luminosity plateau lasting for a couple of months (e.g., Cai et al. 2021). The late-time light-curve decline rate is consistent with those of the ^{56}Co decay rate from $M_{^{56}\text{Ni}} \sim 10^{-3} - 10^{-4} M_\odot$, indicating that they could be related to terminal SN explosions (e.g., Cai et al. 2021). Because of their faint nature as well as the low-mass progenitor observed for SN 2008S (Prieto et al. 2008; Adams et al. 2016), ILRTs have been related to low mass core-collapse SNe such as electron-capture SNe (e.g., Botticella et al. 2009; Cai et al. 2021, but see also Tominaga et al. 2013; Moriya et al. 2014; Kozyreva et al. 2021). In the case of a potential ILRT AT 2019krl, a BSG was identified as a progenitor (Andrews et al. 2021). Thus ILRTs can come from several different progenitors.

In this work, we explore the light-curve properties of BSG explosions over a range of explosion energies ($E = 0.001 - 1 \text{ B}$, where $1 \text{ B} \equiv 10^{51} \text{ erg}$) and ^{56}Ni masses ($M_{^{56}\text{Ni}} = 0.001 - 0.07 M_\odot$). The progenitor models are taken from Menon et al. (2024) which are evolved from detailed stellar-merger models until core carbon-depletion and have masses of $16 - 40 M_\odot$. We identify a dichotomy in SNe from BSG explosions, which depends mainly on the ^{56}Ni mass ($M_{^{56}\text{Ni}}$) ejected: for $M_{^{56}\text{Ni}} \gtrsim 0.01 M_\odot$ we get SN 1987A-like light curves and for $M_{^{56}\text{Ni}} \lesssim 0.01 M_\odot$ we get low-luminosity, short-plateau light curves that are consistent with certain ILRTs and Type II SNe like SN 2008bp.

The rest of this paper is organized as follows. We first introduce the BSG progenitor models and our methods of SN light-curve calculations in Section 2. We present the results of the light-curve calculations in Section 3 and show that BSG explosions can result in low-luminosity, short-plateau Type II SNe when the amount of ^{56}Ni is sufficiently small. We compare the low-luminosity, short-plateau light curves from BSGs with those of ILRTs in Section 4 and show that they are indeed similar. We summarize our discoveries of this paper in Section 5.

2 Methods

2.1 Progenitor models

The BSG models used in this paper are from Menon et al. (2024), which have been evolved through a binary merger of a core hydrogen-depleted giant (on the Hertzsprung gap or as a RSG) with its main-sequence companion. These post-merger models evolved to core He-burning BSGs and matched the spectroscopic properties of the majority of the sample of early B-type supergiants in the Large Magellanic Cloud (LMC). Those models with masses $\approx 16 - 25 M_\odot$ always exploded as BSGs, while those with higher masses (upto $40 M_\odot$) either exploded as BSGs or as cooler stars with $T_{\text{eff}} \leq 10 \text{ kK}$, depending on the dynamics of the merging process.

For this study, we select representative BSG progenitor models that span the upper and lower mass range of B-type supergiants. These models are evolved until core carbon-depletion and summarized in Table 1. After the core carbon depletion, the envelope structure determining light-curve properties is not expected to change much until core collapse. The density structure of the BSG models are presented in Fig. 1. In the same figure, we also show the $15.8 M_\odot$ ($20.0 M_\odot$ at the zero-age main sequence [ZAMS]) RSG SN progenitor model ($1064 R_\odot$) from Sukhbold et al. (2016) for comparison.

2.2 Explosion and light-curve modeling

We conduct explosion and subsequent light-curve modeling by using one-dimensional radiation hydrodynamics code STELLA (Blinnikov et al. 1998; Blinnikov et al.

Fig. 1. Density structure of BSG progenitors adopted in this work. The top panel shows the structure in the radius coordinate and the bottom panel shows the structure in mass coordinate. The structure of a RSG progenitor model from Sukhbold et al. (2016) is presented with the dashed line for comparison.

Fig. 2. Effects of ^{56}Ni mass in shaping bolometric light curves of BSG explosions. The top panel shows the 1 B models and the bottom panel shows the 0.3 B models. We fix the progenitor model ($R = 37.4 R_{\odot}$ and $M = 19.7 M_{\odot}$) in this figure. When the ^{56}Ni mass is large enough, we find the luminosity peak powered by the ^{56}Ni heating becomes apparent and the SN 1987A-like SN light curves can be reproduced. When the ^{56}Ni mass becomes too low, we stop finding the light curve peak powered by the ^{56}Ni heating and BSG explosions end up to have low-luminosity, short-plateau light curves. The bolometric light curve of SN 1987A (Hamuy et al. 1988) is presented as a reference.

2000; Blinnikov et al. 2006). The central $1.4 M_{\odot}$ of the progenitor models is removed as a compact remnant and the remaining structure is put as the initial condition for the STELLA calculations. The explosion is triggered by inserting thermal energy at the innermost layers of the progenitors above the mass cut at $1.4 M_{\odot}$. STELLA does not treat explosive nucleosynthesis and the amount of ^{56}Ni is a free parameter. In this work, ^{56}Ni is uniformly mixed within the entire ejecta.

Evolution of spectral energy distributions (SEDs) is numerically followed in each timestep in STELLA. We adopt 100 frequency bins between 1 \AA and $50,000 \text{ \AA}$ in a log scale. We can obtain light curves in any photometric bands by convolving the SEDs with any filter response functions. We present bolometric light curves as well as the V and R -band light curves in the Johnson-Cousins filter system (Bessell 1990) in this paper.

3 Results

Fig. 2 presents how ^{56}Ni mass affects the light curves of BSG explosions based on a progenitor model for SN 1987A. This progenitor has the radius $R = 37.4 R_{\odot}$ and the mass $M = 19.7 M_{\odot}$. This mass does not exclude the compact remnant mass of $1.4 M_{\odot}$ and the ejecta mass in the calculation is $18.3 M_{\odot}$. In Fig. 2a, we assume the explosion energy $E = 1 B$. We can find that the bolometric light curve of the explosion of this progenitor model with $M_{^{56}\text{Ni}} = 0.07 M_{\odot}$ matches well to that of SN 1987A.

As we decrease $M_{^{56}\text{Ni}}$ from this model, we can find that the light-curve peak caused by the ^{56}Ni heating become earlier and fainter. Then, when the ^{56}Ni mass becomes sufficiently low ($M_{^{56}\text{Ni}} \lesssim 0.003 M_{\odot}$ in the example in Fig. 2a), we no longer find the luminosity increase due to the ^{56}Ni heating. The previous study by Pumo et al. (2023) also found that the effects of the ^{56}Ni heating become negligible with a similar ^{56}Ni mass. When the effects of the ^{56}Ni heating become negligible, the luminosity is mainly powered by the thermal energy provided by the initial shock wave triggered the explosion as in the case of Type II SNe from more extended RSGs. Because BSGs are compact, the adiabatic cooling becomes efficient and the plateau luminosity and duration become low. In the example presented in Fig. 2, we can find that the plateau luminosity is around 10^{41} erg with the plateau duration of around 50 days. Such a short, low-luminosity plateau is difficult to be realized by RSG explosions because low explosion energy required to realize a faint plateau luminosity makes a plateau duration even longer (e.g., Kasen & Woosley 2009).

Because $M_{^{56}\text{Ni}}$ is required to be small not to have a luminosity peak powered by the ^{56}Ni heating, it would be natural to investigate BSG explosions with a small explosion energy. In Fig. 2b, we present the bolometric light curves of BSG explosions with $E = 0.3 B$ with various ^{56}Ni masses. With the lower explosion energy, we still find that the effect of the ^{56}Ni heating disappears with $M_{^{56}\text{Ni}} \lesssim 0.003 M_{\odot}$. The plateau luminosity decreases and the plateau duration increases with the lower explosion energy in a similar way as in Type II SNe from RSGs.

Fig. 3 explores the effects of the ^{56}Ni mass on the light curves of the explosions of BSGs with various radii. The adiabatic cooling depends on the progenitor radii, and they are expected to affect the properties of BSG explosions with low $M_{^{56}\text{Ni}}$. All the BSG explosion models present the ^{56}Ni -powered slow rise in their light curves when $M_{^{56}\text{Ni}} = 0.03 M_{\odot}$. When $M_{^{56}\text{Ni}} = 0.01 M_{\odot}$, the slow rise from the ^{56}Ni heating starts to be insignificant in the models with $R = 37.4 R_{\odot}$, $51.0 R_{\odot}$, and $76.0 R_{\odot}$, and they only show the plateau phase when

Fig. 3. Bolometric light curves from the explosions of BSGs with various radii ($10.8 - 76.0 R_{\odot}$) with $M_{56\text{Ni}} = 0.03, 0.01, 0.003$ and $0.001 M_{\odot}$ and $E = 0.3 B$. A light curve of a RSG explosion ($R = 414 R_{\odot}$, $M = 8.7 M_{\odot}$ with the ZAMS mass of $9.0 M_{\odot}$ in Sukhbold et al. 2016) with $M_{56\text{Ni}} = 0.001 M_{\odot}$ is presented for comparison (dashed line). In one case, the numerical computation was terminated before reaching 120 days because of numerical issues.

$M_{56\text{Ni}} = 0.003 M_{\odot}$. The $R = 17.7 R_{\odot}$ BSG explosion shows the low-luminosity, short plateau with insignificant luminosity increase with $M_{56\text{Ni}} = 0.001 M_{\odot}$. Our most compact BSG model ($R = 10.8 R_{\odot}$) may still have a small effect of the ^{56}Ni heating with $M_{56\text{Ni}} \simeq 0.001 M_{\odot}$. We can also find that low-luminosity, short-plateau light curves are difficult to be realized by RSG explosions. Overall, BSG explosions need to have $M_{56\text{Ni}} \lesssim 0.01 M_{\odot}$ in order not to have a luminosity peak so that they can be observed as low-luminosity, short-plateau Type II SNe. This critical mass is smaller than the average ^{56}Ni mass estimated in Type II SNe ($\simeq 0.04 M_{\odot}$, Anderson 2019).

Because the plateau phase is caused by the recombination within the hydrogen-rich envelope as in the case of RSG explosions, the photospheric temperature during the plateau phase is found to be around 5000 K. The photospheric velocities can be small when the explosion energy is small as presented in Fig. 4.

4 Comparison with observations

Among Type II plateau SNe, low-luminosity ($\sim 10^{41} \text{ erg s}^{-1}$), short-duration plateaus of ~ 50 days are

quite rare. Still, in the Type II SN light-curve sample compiled by Anderson et al. (2014), one Type II SN, SN 2008bp, is found to have such a property and its light curve indeed match well to our BSG explosion model with a small amount of ^{56}Ni having no slow rise powered by the ^{56}Ni heating (the top panel of Fig. 5).

The more common variety of low-luminosity, short-plateau light curves are found among the sample of ILRTs. In the middle panel of Fig. 5, we compare our low-luminosity, short-plateau BSG explosion models with some representative ILRTs. The low-luminosity plateau phase of ILRTs lasting for a couple of months is consistent with the predicted properties of low-energy, small ^{56}Ni mass explosions of BSGs discussed in the previous section. Indeed, their overall light-curve features are found to be similar to ILRTs. Some differences such as the early luminosity bump in, e.g., SNhunt120, may be caused by circumstellar interaction, for example. The low photospheric velocities observed in ILRTs (e.g., Cai et al. 2021) are also consistent with our BSG models (Fig. 4). Therefore, we propose that a fraction ILRTs may originate from faint BSG explosions with a small amount of ^{56}Ni .

The event rate of ILRTs is estimated to be 1 – 10%

Fig. 4. Photospheric velocity evolution of the BSG explosion models with $M_{56\text{Ni}} = 0.001 M_{\odot}$ and $E = 0.3 B$. Photosphere is set where the Rosseland-mean optical depth becomes $2/3$.

of core-collapse SNe (Cai et al. 2021; Karambelkar et al. 2023). If a fraction of ILRTs as well as SN 1987A-like SNe originate from BSGs, up to around 10% of core-collapse SNe may originate from BSG explosions. We note again that some ILRTs are known to originate from low-mass progenitors (e.g., SN 2008S) and not all of ILRTs originate from BSGs.

The second group of light curves consist of various SN 1987A-like SNe, that result from high $M_{56\text{Ni}}$ explosions of the BSG models (Fig. 5, bottom panel). These peculiar Type-II SNe are similar in their light-curve shapes to the prototype SN 1987A, and can be well-explained by high-energy explosions ($E \approx 1 B$) with $M_{56\text{Ni}} \geq 0.07 M_{\odot}$. A more precise reproduction of the observed light curves (such as in Menon et al. 2019), can be done by exploring the explosions of other BSG progenitor models.

5 Summary

We explored explosion properties of BSGs especially when the amount of ^{56}Ni produced during the explosions is small. When $M_{56\text{Ni}} \lesssim 0.01 M_{\odot}$, the characteristic slow rise in light curves observed in SN 1987A-like SN light curves may disappear, and BSG explosions are observed as low-luminosity (around $10^{40} - 10^{41} \text{ erg s}^{-1}$), short-plateau (50 – 90 days) SNe. This is because of the compactness of the BSG progenitors that allows the adiabatic cooling efficient. The exact threshold ^{56}Ni mass for BSG explosions to be observed as such Type II SNe depends on the radii of the BSG progenitors. Low-energy, low- ^{56}Ni mass explosions of BSGs can result in transients similar to those of some ILRTs. Therefore, we conclude that a fraction of ILRTs may originate from BSG explosions. The upcoming Legacy Survey of Space and Time (LSST) by the Vera C. Rubin Observatory would allow us to explore the nature

Fig. 5. *Top:* V-band light curves of the BSG explosion models presented in Fig. 2a. We can find that the low-luminosity, short-plateau Type II SN 2008bp reported in Anderson et al. (2014) can be explained by the BSG explosion with $M_{56\text{Ni}} = 0.003 M_{\odot}$. *Middle:* The R-band light curves of some BSG explosions with $M_{56\text{Ni}} = 0.001 M_{\odot}$ are compared to those of ILRTs. Their overall light-curve features are similar in many cases. In one case, the numerical computation was terminated before reaching 120 days because of numerical issues. The light curves of AT 2013lb (Cai et al. 2021), AT 2018aes (Cai et al. 2021), M85 OT2006-1 (Kulkarni et al. 2007; Pastorello et al. 2007), NGC 300-2008OT1 (Berger et al. 2009; Bond et al. 2009; Prieto et al. 2009; Kashi et al. 2010; Humphreys et al. 2011), and SNhunt120 (Stritzinger et al. 2020) are presented. *Bottom:* The bolometric light curves of BSG explosions with $E = 1 B$ and $M_{56\text{Ni}} = 0.07 M_{\odot}$ compared with those of SN 1987A (Hamuy et al. 1988) and other SN 1987A-like SNe: SN 1998A (Pastorello et al. 2005), SN 2000cb (Kleiser et al. 2011; Utrobin & Chugai 2011), SN 2009E (Pastorello et al. 2012), and SN 2009mw (Takáts et al. 2016).

of these faint transients and they may be able to probe diverse deaths of BSGs.
