The thermodynamics of point defects is crucial for determining the functional properties of various materials. Typically, defect stability is assessed using grand-canonical defect formation energy, which requires deducing the equilibrium chemical potential or Fermi level that governs atom and electron exchange with the environment. This process is complicated by the interplay of chemical potential and Fermi level and their dependence on composition and temperature. Typically, the grand-canonical formation energy is incorporated as an additional term to the bulk Gibbs energy, creating a defect-centric framework where each new defect state necessitates a distinct Gibbs energy formulation. The calculation of phase diagrams (CALPHAD) method offers a more flexible alternative by integrating defect energies into the total Gibbs energy model, allowing for easier extrapolation to more complex compositions. Additionally, CALPHAD unifies the analysis of chemically and electronically driven defects using chemical composition as the primary variable. However, the Compound Energy Formalism (CEF) used in CALPHAD has limitations, including a lack of clear connections between defect formation energies and Gibbs energy parameters and an exponential increase in complexity with added chemical or charge variations. We present the theoretical derivation of the Defect Energy Formalism (DEF), which we have recently proposed. DEF overcomes the limitations of CEF by establishing explicit relationships between the absolute defect energies— independent of chemical potential or Fermi level— and the Gibbs energy parameters of defective compounds. This results in a first-principles model for dilute defects, eliminating the need for model fitting to experimental or simulation data. Additionally, DEF reduces the inherent complexity of CEF by applying the superposition of absolute defect energies, making it feasible for modeling multi-component and chemically complex compounds. This paper presents a formal, general derivation of DEF and offers guidelines for its application, promising more accurate and efficient thermodynamic modeling of defective materials.

I. INTRODUCTION

Thermodynamics of point defects determines the functional properties of many materials in several applications, from semiconductors (thermoelectrics^{1–6}, photovoltaics^{7–15}) to insulators (optical materials^{16–23}, ion-conducting materials^{22,24–28}, non-stoichiometric materials^{28–32}). The thermodynamics of isolated defects in solids is well-established through formation energies, typically defined as the excess grand-potential energy in a grand-canonical ensemble, offering a defect-centric perspective^{33–35}. First principles methods like density functional theory (DFT) have significantly advanced, enabling precise calculations of formation energies for various point defects (vacancies, interstitials, antisites) across different charge states^{36–41}. In this defect-centric approach, the defect formation free energy is considered an additional contribution to the total free energy, expressed as ($G = G(\text{bulk}) + \Delta G_{\text{defect}}$). However, this method is inherently system-specific, requiring the determination of a new ΔG_{defect} term for each new composition or higher-order multi-component system. The CALPHAD approach offers an adaptable alternative by incorporating the influence of defects directly into the comprehensive description of total free energy rather than treating them as isolated excess terms.

In this framework, defects are introduced as distinct entities that interact with other components, such as chemical elements. Their impact on the Gibbs energy is integrated into interaction parameters within the CALPHAD model. CALPHAD’s hierarchical formulation enables straightforward extrapolation to higher-order multi-component systems. For instance, interaction parameters initially determined for a binary compound can be leveraged to predict free energy across other compositions, including ternary compounds.

The CALPHAD method for collecting, reporting, and computing thermodynamic data has been hugely successful both in industry and academia, leading to the rapid development of metal alloys for numerous applications^{42–53}. For ordered ionic compounds and semiconductors, the compound energy formalism (CEF) has often been utilized^{54–59}, which divides the lattice into different sublattices. Each sublattice can host various constituents (e.g., chemical element or vacancy). An “end member” represents a specific combination of these constituents on the sublattices, where each constituent exclusively occupies one sublattice. CEF formulates the Gibbs energy using these end members as the primary first-order parameters, while higher-order parameters characterize interactions among constituents within individual sublattices⁵⁸. Defective compounds (e.g., non-stoichiometric oxides) can be recognized in CEF by defin-

FIG. 1. **Linear Mapping Principle underlying DEF.** Comparing CEF and DEF for thermodynamic modeling of dilute Ni vacancies in $\text{Ni}_{1-\delta}\text{O}$. The schematic Gibbs energy is given by the blue curve, approximated in CALPHAD using interpolation of end-member parameters. Traditional CEF uses the fully defective end-member, which in this case is O, and effectively approximates the blue curve with the red line, which greatly underestimates the G of NiO with dilute Ni vacancies. The DEF method, in contrast, approximates the blue curve with the green line derived from the slope as it approaches the pristine compound (‘dilute limit’). The DEF provides a much more accurate estimate of G in the composition region pertinent to dilute defect concentrations.

ing point defects as constituents on the relevant sublattice. For example, non-stoichiometry of $\text{Ni}_{1-\delta}\text{O}$ can be defined as $(\text{Ni}, \text{Vac})(\text{O})$ (see Figure I).

We have identified two bottlenecks in CEF that limit its application in describing defective compounds. Firstly, there lacks a clear connection between defect formation energies and the CEF parameters of Gibbs energy. While previous studies^{33,58,60–62} have hinted at connections between defect formation energies and Gibbs energies of end members, a systematic relationship remains elusive. Consequently, most studies use a standard “assessment” approach, fitting parameters to available experimental and computational data. This approach limits model development to specific material and thermodynamic ranges (temperatures, compositions) where data is accessible, hindering the creation of first-principles models. Even studies using first-principles DFT to compute defect formation energies typically use these values merely as starting points for fitting assessments to experimental data^{62–66}, rather than as direct inputs into Gibbs energy formulation. Secondly, the number of parameters in the CEF Gibbs energy formulation grows exponentially with added chemical or charge complexity (e.g., doped impurities, alloying components, or charged defects). CEF includes all potential end members as independent parameters, making it excessively intricate for multi-component and chemically complex compounds, as well as for describing charge carriers such as holes and

free electrons. This computational complexity has constrained existing models of defective semiconductors and insulators to a limited set of binary examples where experimental data exists, so the model can ultimately be fit to experimental data (e.g., GaAs⁶⁷, CdTe⁶¹, UO_2 ⁶⁸, PbSe⁶⁴, PbX (X=S,Te)^{65,66}, ZnS⁶⁹, ZnO⁶²).

To address the existing limitations of CEF, we theoretically derive the Defect Energy Formalism (DEF) as a special case of CEF for CALPHAD thermodynamics of dilute defects. For formulating the Gibbs energy of a defective compound, DEF applies two main principles pertinent to dilute defects:

First is the linear mapping of defect formation energies along chemical composition, inspired by an earlier study by Anand *et al*⁷⁰, showing that the projection of a defective compound energy to its constituent species on the convex hull reflects the defect formation energy. Here, we evolve this concept to establish the physics-based relationship between DEF end members and defect formation energies. Additionally, we show that the Boltzmann statistics of dilute charge carriers naturally arise in the DEF formalism, similar to the CEF formalism. Figure I illustrates the concept of defining DEF end-members from the projection of the defect formation energy on the convex hull to its constituent species. This concept underlies the principle of linear mapping, as implemented in DEF and detailed in this work.

Second is applying the superposition principle to the Gibbs energy of DEF end-members containing multiple defects, offering a computationally efficient framework by reducing the number of independent end-members in the sublattice model. In a system with s sublattices, each hosting N_s constituents, the number of CEF end-members equals $\prod_s N_s$, whereas for DEF it equals $\sum_s N_s$. In simpler terms, DEF simplifies the complexity of CEF parameters from a combinatorial factor of single-defect end-members to a summation. This reduction stems naturally from the superposition principles applicable to dilute defects, unlike CEF, which handles arbitrary constituent mixing on each sublattice. A DEF end-member with multiple defects describes a compound hosting non-interacting, isolated defects, unlike CEF, where an end-member with multiple defects corresponds to “fictitious” end members with unrealistically high concentrations of interacting defects (see Figure I).

In a recent study, we introduced DEF and demonstrated its application, confirming its feasibility⁷¹. Here, we present a formal derivation of the DEF applicable to any type of point defects (vacancies, interstitials, and anti-sites), offering guidelines for constructing DEF models for any materials and combinations of dilute point defects. The organization of this paper is as follows: In section II, we derive the DEF formulation for defective compounds with neutral defects, detailing the derivation of DEF end-member Gibbs energy in section II A and the construction of DEF sublattice models in sections II B and II C. In section III, we derive the DEF formulation for defective compounds with charged defects, followed

by constructing a DEF sublattice model in section III A. Section IV presents general guidelines for constructing DEF for any compounds and combinations of defects.

II. DEFECT ENERGY FORMALISM FOR NEUTRAL DEFECTS

The DEF construct is a modified version of the standard CEF, seen as a special case with specific constraints on the mixing behavior of its constituents. A phase in DEF is divided into one, two or more sublattices, labeled s , each containing N_s constituents. For instance, $(A,C)_p(B,D,E)_q$ represents a typical two-sublattice model where A and C mix on the first sublattice and B, D, and E mix on the second, with p and q as stoichiometric coefficients for a formula unit containing $p + q$ atoms. In a typical CEF model, each sublattice can mix multiple primary constituents at arbitrary ranges. In DEF, however, defect concentrations remain in the dilute range, so defects are considered secondary constituents. Here, we focus on DEF models where each sublattice hosts one primary constituent (an atomic species) and multiple defects (e.g., vacancies, anti-sites, or interstitials) as secondary constituents, such as $(A,Vac,B)_p(B,A)_q$ for A-vacancy and B-antisite, and A-antisite. End-members represent phases with only one constituent per sublattice. Within the DEF construct, one end-member corresponds to defect-free ordered compounds with each sublattice hosting primary constituents (e.g., $(A)_p(B)_q$), while others are defective compounds with at least one defect constituent on a sublattice (e.g., $(Vac)_p(B)_q$). Despite appearing as nonphysical due to the notation showing high defect concentrations (e.g., $(Vac)_p(B)_q$), defective end-members in DEF actually correspond to physical compounds with dilute defect concentrations (see Figure I).

The constitution of a DEF phase is described by the site fractions of each constituent J on each sublattice s , denoted by y_J^s . The summation of constituents' site fractions on each sublattice yields 1, or $\sum_J y_J^s = 1$. The content of each component I per formula unit is then related to the site fractions on individual sublattices according to the following equation (see equation 4 in Ref.⁵⁸):

$$X_I = \frac{\sum_s a^s y_I^s}{\sum_s a^s (1 - y_{vac}^s)} \quad (1)$$

where a^s is the stoichiometry coefficient of sublattice s . The composition X_I denotes the composition of a component per formula unit of atoms and not per site. Therefore, it directly relates to the composition space in a typical convex hull or phase diagram. We refer to the composition space as the X -space and the constitution of DEF site fractions as the Y -space.

The Gibbs energy per formula unit of the DEF phase, G_{uf} , is defined by the surface of reference energy $G_{uf}^{s.r.}$ along with the ideal mixing entropy, following the CEF (see equations 1 and 2 in Ref.⁵⁸). Here, $G_{uf}^{s.r.}$ is a linear

interpolation of end-member Gibbs energies, ${}^0G_{end}$, as follows:

$$G_{fu} = G_{fu}^{s.r.} + kT \sum_s \sum_J a^s y_J^s \ln(y_J^s) \quad (2)$$

$$G_{fu}^{s.r.} = \sum_{\text{end-members}} {}^0G_{end} \prod_s y_J^s$$

where k and T denote the Boltzmann constant and temperature, respectively. In the $G_{uf}^{s.r.}$ formula, the summation runs over all end members, and the product runs over all sublattices in the DEF model. For each end-member, J consists only of the constituents corresponding to that end-member. In DEF, we do not include the excess Gibbs energy term, commonly denoted as ${}^E G$ in a typical CEF model. This is because at dilute defect concentrations, the primary constituent and secondary defects mix like an ideal solution, where each added defect reduces the number of solvent atoms, making chemical activity proportional to chemical composition (i.e., Raoult's law for dilute solutions). Therefore, the only parameters of the Gibbs energy are the end-members, ${}^0G_{end}$.

The grand canonical formation energy for a neutral defect is defined as

$$\Delta H_d = E_{def} - E_{pristine} - \sum_i \Delta N_i \mu_i \quad (3)$$

where E_{def} and $E_{pristine}$ denote the energies of the defective and pristine structures, respectively, ΔN_i is the number of atoms of species i added to or removed from the defective structure (e.g., +1 for interstitials, -1 for vacancies) and μ_i is the chemical potential of the species i . The defect formation energy depends on the chemical equilibrium condition through the last term, which measures the chemical work associated with the exchange of an atomic species between the host compound and the chemical reservoir. The chemical potential of species i is equal in both the host compound and the chemical reservoir, as dictated by the condition of chemical equilibrium.

We relate the grand-canonical formation energy from equation 3 to the DEF end-member Gibbs energy, ${}^0G_{end}$, from equation 2, inspired by Anand *et al.*'s graphical representation of defect formation energy on the convex hull⁷⁰. They showed that projecting the defective compound formation energy relative to the (extended) convex hull onto its constituent species gives the defect formation energy of equation 3. Their derivation applies to any chemical equilibrium condition, such as the coexistence of defective $A_p B_q$ with A-vacancy and pure A. In the CALPHAD framework, equilibrium is determined by common tangents on the convex hull. Therefore, the chemical potential of A-vacancy formation in a binary $A_p B_q$ compound (without other defects) is derived from the B-rich condition, indicated by the common tangent at the defective compound's composition. In section II A, we show that when the *absolute defect energy* is projected onto the convex hull's relevant endpoint and adjusted to

a unified reference energy, it becomes independent of the chemical potential. This energy, independent of chemical potential, directly relates to the DEF end-member Gibbs energy. In sections II B and II C, we demonstrate the construction of DEF for various defective compounds with neutral point defects.

A. From defect formation energies on the convex hull to DEF end-member

In this section, we convert the defect formation energy, projected onto the convex hull endpoint, to the DEF Gibbs energy of defective end members. Anand *et al.* illustrated how to obtain the grand-canonical defect formation energy, ΔH_d from equation 3, by projecting the defective structure's formation energy distance relative to the (extended) convex hull onto the relevant endpoint⁷⁰(see Figure 2(a) and (b)). Here, instead of a general chemical equilibrium condition, we impose the chemical equilibrium condition from the convex hull's common tangent so that no extended convex hull is considered. Also, we project the absolute defect energy instead of the convex hull distance and unify all energies, including formation energies of defective and pristine compounds and the absolute defect energy using a common reference energy. This unification is crucial for mapping defect formation energies onto DEF end members, showing that the DEF defective end-member Gibbs energy is directly related to a chemical-potential-independent absolute defect energy.

Considering A_pB_q with $p + q$ atoms in its primitive cell, the formation energies of the pristine and defective compounds (ΔH_f^p and ΔH_f^d) are defined with reference to their pure states. We reformulate the defect formation energy of equation 3 in terms of ΔH_f^p and ΔH_f^d . If the total energies of the defective (E_{def}) and pristine (E_{pristine}) structures are calculated for a supercell with l times more atoms than the primitive cell, the formation energies (per atom) of the defective and pristine structures are defined as

$$\begin{aligned}\Delta H_f^d &= \frac{E_{\text{def}} - lp\mu_A^0 - lq\mu_B^0 - \sum \Delta N_i \mu_i^0}{l(p+q) + \sum \Delta N_i} \\ \Delta H_f^p &= \frac{E_{\text{pristine}} - lp\mu_A^0 - lq\mu_B^0}{l(p+q)}\end{aligned}\quad (4)$$

where μ_A^0 and μ_B^0 are the chemical potential (reference energy) of elements A and B in their standard state. μ_i^0 is the reference chemical potential of species i added or removed to form the defect, for example, A for an A interstitial in A_pB_q . Rewriting the defect formation energy of equation 3 in terms of the formation energies of the defective and pristine structures yields the following

equation:

$$\begin{aligned}\Delta H_d &= \left(E_{\text{def}} - \sum_i \Delta N_i \mu_i \right) - E_{\text{pristine}} \\ &= \left(l(p+q) + \sum \Delta N_i \right) [\Delta H_f^d - \Delta H_f^p] \\ &\quad + \sum \Delta N_i \Delta H_f^p - \sum \Delta N_i \Delta \mu_i\end{aligned}\quad (5)$$

Anand *et al.* used a different formulation of equation 5 (Eq. 10 in Ref.⁷⁰) to show that the projection of the convex hull distance of a defective compound, E_{CH} in Figure 2, to the corresponding end on the convex hull (i end) is equal to the defect formation energy ΔH_d . This ΔH_d is chemical potential dependent. The equilibrium chemical potential is determined by the common tangent at the defective phase composition. As shown in Figure 2 (a) and (b) changes in the convex hull and the resulting common tangent affect both ΔH_d and $\Delta \mu_i$. However, DEF end-member Gibbs energies ${}^0G_{\text{end}}$ must be chemical-potential-independent and well-defined regardless of Gibbs energy changes in competing phases. Therefore, instead of projecting E_{CH} , which varies with the environment's chemical potential, we project the chemical-potential independent value $\Delta H_f^d - \Delta H_f^p$, we call the absolute defect energy (see Figure 2 (a,b)). Note that $\Delta H_f^d - \Delta H_f^p$ measures the absolute defect energy of the defective compound relative to the pristine compound, setting the defect-free A_pB_q as the reference state, unlike E_{CH} , which measures the distance between the defective compound and the chemical potential energy line (convex hull common tangent). By rearranging equation 5, we project $\Delta H_f^d - \Delta H_f^p$ onto its corresponding endpoint as follows

$$\begin{aligned}\Delta H_d + \sum \Delta N_i \Delta \mu_i - \sum \Delta N_i \Delta H_f^p \\ = \overbrace{\left(l(p+q) + \sum \Delta N_i \right)}^{f_i^d} [\Delta H_f^d - \Delta H_f^p]\end{aligned}\quad (6)$$

As shown in Ref.⁷⁰, f_i^d is the projection factor that projects E_{CH} , and similarly $\Delta H_f^d - \Delta H_f^p$, to the i -end on the convex hull. Figure 2 illustrates this projection for a defective A_pB_q with an A-vacancy. According to equation 6, the projection on the A-end is $-(\Delta H_{A\text{-vac}} - \Delta \mu_A + \Delta H_f^p)$ with $\Delta N_A = -1$. The negative sign in front of the parenthesis arises from the A-vacancy projection factor, $f_i^{A\text{-vac}}$, which inverts the absolute defect energy direction when projected onto the opposite side relative to the A_pB_q composition (see Figure 2). As we elaborate later in section II B, the A-vacancy defective compound corresponds to Vac:B DEF end-member and must be projected to the B-end. Accordingly, the B-end projection is $\frac{p}{q}(\Delta H_{A\text{-vac}} - \Delta \mu_A + \Delta H_f^p) = \frac{p}{q}(\Delta H_{A\text{-vac}}) + \Delta \mu_B - \Delta H_f^p$ (see Figure 2(a,b)). Note that $\Delta \mu_A$ and $\Delta \mu_B$ are related according to $\frac{p}{p+q}\Delta \mu_A + \frac{q}{p+q}\Delta \mu_B = \Delta H_f^p$. Although ΔH_d and $\sum \Delta N_i \Delta \mu_i$ (left hand side of equation 6) vary with chemical potential, their sum does

FIG. 2. Formation energy per atom convex hull. a,b) Graphical representation of an A-vacancy formation energy and chemical potential change for model (a) A - A_pB_q - B and (b) A - A_pB_q - AB_3 - B convex hulls. The equilibrium chemical condition is determined by the common tangent line at the defective compound composition, A_pB_q+B coexistence line for (a) and $A_pB_q+AB_3$ coexistence line for (b). The formation energy of the defect-free A_pB_q and defective A_pB_q are shown by the black square and blue circle, respectively. E_{CH} denotes the convex-hull distance, defined as the distance of the defective structure above the convex hull (see Ref.⁷⁰). The common tangent lines determining the chemical potential condition are shown by bold red lines. Defect lines connecting the defective and pristine formation energies are shown by blue lines. The projection of E_{CH} and common tangent line onto the A-end give the grand-canonical defect formation energy and chemical potential of A, respectively. The absolute defect energy, $\Delta H_f^d - \Delta H_f^p$, and its projections on the A-end and B-end are shown by yellow arrows. c,d) Graphical representation of adjusting the projected absolute defect energies to the common SER reference line for (c) A - A_pB_q - B and (d) A - A_pB_q - AB_3 - B convex hulls. The projected absolute defect energies and the adjustment energies are all independent of the convex hull shape and, therefore, the equilibrium chemical conditions determined by it.

not. Replacing ΔH_d from equation 3 into equation 6 results in $\Delta H_d + \sum \Delta N_i \Delta \mu_i = E_{def} - E_{pristine} - \sum \Delta N_i \mu_i^0 = \Delta E_{def} - \sum \Delta N_i \mu_i^0$, a value that is independent of the chemical potential of the coexistence condition. ΔE_{def} is the difference between the total energy of the defective and pristine structures, commonly ob-

tained through DFT total energy calculations. ΔE_{def} is chemical-potential-independent and needs to be calculated only once for a defective structure, regardless of its equilibrium conditions or coexistence with competing phases.

Aside from projecting to the relevant end-point, we

FIG. 3. Formation energy per atom convex hull. Graphical representation of the absolute defect energy for a) B-interstitial and b) B-antisite in an A-A_pB_q-B convex hull.

need to unify the reference energy between ΔH_f^p , ΔH_f^d , and the projection of equation 6. The reference state for ΔH_f^p and ΔH_f^d is the stable element reference (SER), as shown in Figure 2(c,d) and equation 4. Accordingly, the projection of $\Delta H_f^d - \Delta H_f^p$ (equation 6), referenced to the pristine compound, must be adjusted to the SER. Additionally, we must convert the projection on the convex hull from per atom values to per formula unit values to describe the DEF end-member Gibbs energy (see equation 2). These adjustments will convert the B-end projection of A_pB_q with an A-vacancy to the DEF Vac:B end-member as

$$\begin{aligned}
 {}^0G_{\text{Vac:B}} &= q \left[\underbrace{\frac{p}{q} (\Delta H_{\text{A-vac}} - \Delta \mu_{\text{A}} + \Delta H_f^p)}_{\Delta E_{\text{A-vac}} + \mu_{\text{A}}^0} \right. && \left. \underbrace{\Delta H_f^p + \mu_{\text{B}}^0}_{\text{Adjustment to SER}} \right] \\
 &= p \Delta E_{\text{A-vac}} + \overbrace{p \mu_{\text{A}}^0 + q \mu_{\text{B}}^0 + (p+q) \Delta H_f^p}^{{}^0G_{\text{A:B}}} && (7)
 \end{aligned}$$

The conversion approach between the absolute defect energy and DEF end-member Gibbs energy, detailed in this section, applies to any type of point defect. For example, for a B-interstitial defect in A_pB_q (i.e., $\Delta N_B = +1$), in a three-sublattice model (A)_p(B)_q(Vac, B)_m, the DEF end-member corresponds to the B-end projection of the absolute defect energy $\Delta H_f^d - \Delta H_f^p$, which according to equation 6 is $\Delta H_{B^i} + \Delta \mu_B - \Delta H_f^p = \Delta E_{B^i} - \mu_B^0 - \Delta H_f^p$ (see Figure 3(a)). Adjusting to SER and per formula unit results in $m(\Delta E_{B^i} - \mu_B^0 - \Delta H_f^p + \Delta H_f^p + \mu_B^0) = m \Delta E_{B^i}$.

We construct all defective DEF end-members with respect to the defect-free compound A_pB_q, ensuring that the mapping between the convex hull composition and

DEF constitution space is physical in the dilute defect range. As detailed in sections II B and II C, the pristine compound forms the origin of the DEF constitution space. In other words, the projected absolute defect

FIG. 4. **Superposition principle underlying DEF.** Superposition of the projected absolute defect energies to obtain DEF end-member Gibbs energies, illustrated for (A,Vac)(B,Vac)(Vacⁱ,Aⁱ). As detailed in section II C, the axes of the constitutional cube are formed by the A-vacancy, B-vacancy, and A-interstitial defect lines, shown by the blue, brown, and orange lines, respectively. The Gibbs energy of the DEF end-members on the constitutional cube is obtained from the superposition of the projected absolute defect energies, illustrated by defect basis vectors, onto the pristine end-member Gibbs energy, illustrated by the black square point.

energies measure the energy of defective end-members with respect to the pristine compound. Accordingly, the Gibbs energy of the pristine end-member must be added to all defective end-members. Therefore, for B-interstitial defects in A_pB_q , ${}^0G_{A:B:B^i} = {}^0G_{A:B:Vac} + m\Delta E_{B^i}$. The case of vacancies is slightly different. For example, for a defective A_pB_q with A-vacancy defects, the defective end-member can be described as ${}^0G_{Vac:B} = {}^0G_{A:B} - {}^0G_{A:Vac} = {}^0G_{A:B} - {}^0G_{A:B} + {}^0G_{Vac:B}$. Note that the second equation gives the projection on the B-end; thus, the first two terms cancel out. The first equation gives the flipped projection on A-end for A-vacancy detailed in Ref.⁷⁰ (see Figure 2).

For a B-antisite defect, the defective end-member energy can be described as

$$\begin{aligned}
 {}^0G_{B:B} &= {}^0G_{A:B} - {}^0G_{A:Vac} + {}^0G_{B:Vac} \\
 &= \underbrace{{}^0G_{A:B}}_{\text{DEF origin}} + \underbrace{(-{}^0G_{A:B} + {}^0G_{Vac:B})}_{\text{B-end projection of A-vac}} \\
 &\quad + \underbrace{{}^0G_{B:Vac}}_{\text{B-end projection of B-interstitial}} \\
 &= {}^0G_{A:B} + p\Delta E_{Vac_A} + p\Delta E_{B^i}
 \end{aligned} \tag{8}$$

Note that ${}^0G_{Vac:B}$ indicates the end-member containing A-vacancy, while ${}^0G_{B:Vac}$ shows the end-member containing B-interstitial. Therefore, a B-antisite defect can be considered a combination of these two individual defects (see Figure 3(b)).

For DEF end-members containing multiple defects, the superposition principle can be directly applied to the projected absolute defect energies. For example, for the Vac:Vac end-member, the absolute defect energy projections on the B-end and A-end are simply added so that:

$$\begin{aligned}
 {}^0G_{Vac:Vac} &= \underbrace{{}^0G_{A:B}}_{\text{DEF origin}} + \underbrace{(-{}^0G_{A:B} + {}^0G_{Vac:B})}_{\text{B-end projection of A-vac}} \\
 &\quad + \underbrace{(-{}^0G_{A:B} + {}^0G_{A:Vac})}_{\text{A-end projection of B-vac}} \\
 &= {}^0G_{A:B} + p\Delta E_{A-vac} + q\Delta E_{B-vac}
 \end{aligned} \tag{9}$$

Similarly, the $Vac:Vac:A^i$ in the three-sublattice model can be described as (see Figure 4)

$$\begin{aligned}
 {}^0G_{Vac:Vac:A^i} &= \underbrace{{}^0G_{A:B}}_{\text{DEF origin}} + \underbrace{(-{}^0G_{A:B} + {}^0G_{Vac:B})}_{\text{B-end projection of A-vac}} \\
 &\quad + \underbrace{(-{}^0G_{A:B} + {}^0G_{A:Vac})}_{\text{A-end projection of B-vac}} + \underbrace{{}^0G_{Vac:Vac:A^i}}_{\text{A-end projection of B-interstitial}} \\
 &= {}^0G_{A:B} + p\Delta E_{A-vac} + q\Delta E_{B-vac} + m\Delta E_{B^i}
 \end{aligned} \tag{10}$$

The general derivation of the DEF end-member Gibbs energy aligns with our earlier derivation of DEF in Ref.⁷¹ as shown in Appendix A for an example vacancy defect.

FIG. 5. Mapping of the constitutional square for the (A,Vac)(B,Vac) DEF model, formed by $(1 - y_{vac}^1) - (1 - y_{vac}^2)$ axes, into the mole fraction composition X_B . $X_B = 1$ and $X_B = 0$ lines are shown by thick green and orange lines, respectively.

B. AB compound with dilute A-vacancy and B-vacancy

In this section, we first derive the mapping between the composition space in a standard convex hull, X , and the constitutional space defined by the site fractions of constituents in the DEF sublattice model, Y , for the AB binary compound with dilute neutral vacancies, described by a two-sublattice model as (A,Vac)(B,Vac). The constitutional square consists of two axes, y_{vac}^1 and y_{vac}^2 , denoting the site fractions of vacancies in the first and second sublattices, respectively. Within each sublattice, the total site fractions of distinct constituents equal one. Hence the site fractions of A and B, y_A^1 and y_B^1 , follow $1 - y_{vac}^1 = y_A^1$ and $1 - y_{vac}^2 = y_B^1$. Therefore, the constitutional space of the two-sublattice model has two degrees of freedom. On the other hand, the composition of mole fractions of components in the X space for a binary system has one degree of freedom. The X -composition of each component A or B per formula unit (or per mole of formula unit) can be related to the DEF site fractions using the following equations (see equation 1),

$$\begin{aligned}
 X_A &= \frac{y_A^1}{y_A^1 + y_B^1} = \frac{1 - y_{vac}^1}{(1 - y_{vac}^1) + (1 - y_{vac}^2)} \\
 X_B &= \frac{y_B^1}{y_A^1 + y_B^1} = \frac{1 - y_{vac}^2}{(1 - y_{vac}^1) + (1 - y_{vac}^2)}
 \end{aligned} \tag{11}$$

which provides the functional mapping between X and Y . As shown in Figure 6(a), the mapping expands the 1-dimensional X -space, associated with two defects lines, A-vacancy, and B-vacancy, into the 2-dimensional constitutional square Y . In other words, the non-parallel A-vacancy and B-vacancy lines form the orthogonal ba-

FIG. 6. Mapping the composition and formation energy from a model convex hull (A-AB-B) to the constitutional square of a two-sublattice DEF model for A-vacancy and B-vacancy, (A, Vac)(B, Vac). Formation energies of defect-free AB (ΔH_{AB}), defective AB with A-vacancy, and defective AB with B-vacancy are represented by the black square, blue circle, and brown diamond, respectively. The defect lines for A-vacancy and B-vacancy are indicated by the blue and brown lines, respectively. (a) Graphic representation of the mapping between X_B on the convex hull and the constitutional square of the two-sublattice model. Physically relevant X_B values for A-vacancy lie on the AB-B side (B-rich), colored green, and for B-vacancy lie on the A-AB side (A-rich), colored pink. The corresponding areas on the constitutional square for A-vacancy and B-vacancy are colored green and pink, respectively. (b) Graphic representation of the mapping between absolute defect energies, ΔE_{VacA} and ΔE_{VacB} , and DEF end-members' Gibbs energies. These defect energies measure the Gibbs energy of defective end-members relative to the pristine end-member A:B, as detailed in Section II A.

sis vectors for the Y-space.

As shown in Figure 5, each line on the $(1 - y_{vac}^1)(1 - y_{vac}^2)$ constitutional square maps into one point on X_B . The line at $y_{vac}^1 = 1$ corresponds to $X_B = 1$ and the line at $y_{vac}^2 = 1$ corresponds to $X_B = 0$. The diagonal line at $y_{vac}^1 = y_{vac}^2$ corresponds to $X_B = \frac{1}{2}$. On these three lines exist 4 special points, constituting the end-members at $y_{vac}^1 = 1, y_{vac}^2 = 0$, corresponding to the Vac:B end-member, $y_{vac}^1 = 0, y_{vac}^2 = 1$, corresponding to the A:Vac end-member, $y_{vac}^1 = 0, y_{vac}^2 = 0$, corresponding to the A:B end-member, and $y_{vac}^1 = 1, y_{vac}^2 = 1$, corresponding to the Vac:Vac end-member (see Figure 6 and 5). Note that at $y_{vac}^1 = 1, y_{vac}^2 = 1$, X_B is ill-defined and this point sits at the intersection of all constant X_B contour lines (see Figure 5).

As illustrated in Figure 6(a), the AB-B segment of X_B , which includes the A-vacancy defect line extending from pristine AB to B (AB \rightarrow B) corresponds to the top-right triangular region within the Y-square. This region includes any combination of y_{vac}^1 and y_{vac}^2 as long as $y_{vac}^1 \geq y_{vac}^2$. However, only the top edge of the Y-square (or line $y_{vac}^2 = 0$) corresponds to the A-vacancy defect

line on the convex hull as it physically connects to an A-vacancy, forming $A_{1-\delta}B$ in dilute ranges, without B-vacancy defects. Therefore, we map the A-vacancy line on the AB \rightarrow B segment of X_B to the $y_{vac}^2 = 0$ line in the constitutional square, as shown by the blue line in Figure 6(a). Similarly, the A-AB segment of X_B , which includes the B-vacancy defect line extending from pristine AB to A, corresponds to the bottom-left triangular region within the Y-square. The only line on this triangle with a one-on-one mapping to B-vacancy without an A-vacancy is $y_{vac}^1 = 0$, forming the second basis vector of the Y constitutional square (orange line in Figure 6(a)). The vertices of the constitutional square, Y, constitute the DEF end-members, for which there is a one-on-one correspondence to X according to equation 11; A:B defined at $y_{vac}^1 = 1, y_{vac}^2 = 0$ (the origin of the Y-space) maps to $X_B = \frac{1}{2}$ or AB compound composition, Vac:B defined at $y_{vac}^1 = 1, y_{vac}^2 = 0$ maps to $X_B = 1$ or B-end of the convex hull, and A:Vac defined at $y_{vac}^1 = 0, y_{vac}^2 = 1$ maps to $X_B = 0$ or A-end of the convex hull. X_B for Vac:Vac ($y_{vac}^1 = 1, y_{vac}^2 = 1$) is ill-defined. However, the Vac:Vac point in Y sits at the intersections of all X-constant con-

tours (or level lines) (see Figure 5) and, therefore, can be arbitrarily defined as the summation of any X point. We define Vac:Vac as the sum of A:B, A:Vac and Vac:B which aligns with the superposition principle in the context of dilute defects (see equation 9).

As the mapping between X_B and DEF end-members is established, we can relate DEF end-member Gibbs energies (per formula unit for AB) to defect absolute energies according to the procedure detailed in Section II A, and shown in Figure 6(b)

$$\begin{aligned} {}^0G_{A:B} &= \mu_A^0 + \mu_B^0 + 2\Delta H_f^{AB} \\ {}^0G_{A:Vac} &= {}^0G_{A:B} + \Delta E_{B\text{-vacancy}} \\ {}^0G_{Vac:B} &= {}^0G_{A:B} + \Delta E_{A\text{-vacancy}} \\ {}^0G_{Vac:Vac} &= {}^0G_{A:B} + \Delta E_{B\text{-vacancy}} + \Delta E_{A\text{-vacancy}} \end{aligned} \quad (12)$$

The DEF end-members Gibbs energies for a general binary compound A_pB_q is related to the absolute defect energies by

$$\begin{aligned} {}^0G_{A:B} &= p\mu_A^0 + q\mu_B^0 + (p+q)\Delta H_f^{AB} \\ {}^0G_{A:Vac} &= {}^0G_{A:B} + q\Delta E_{B\text{-vacancy}} \\ {}^0G_{Vac:B} &= {}^0G_{A:B} + p\Delta E_{A\text{-vacancy}} \\ {}^0G_{Vac:Vac} &= {}^0G_{A:B} + p\Delta E_{A\text{-vacancy}} + q\Delta E_{B\text{-vacancy}} \end{aligned} \quad (13)$$

The above equations follow the superposition principle underlying the thermodynamic conditions for individual isolated defects at dilute ranges, aligned with the DEF construct for dilute defects. For example, the Gibbs energy of Vac:Vac end-member (an end-member containing multiple defects) is the sum of the formation energies of both A-vacancy and B-vacancy (see equation 9). This represents a defective compound containing both A-vacancy and B-vacancy defects at dilute concentrations. The DEF end-member Gibbs energies from equation 13 can be substituted into equation 2 to obtain the Gibbs energy per formula unit of the defective compound.

C. AB compound with dilute A-vacancy, B-vacancy, and A-interstitial

Here, we describe the DEF for the binary AB compound with dilute ranges of neutral vacancies and a self-interstitial defect, described by a three-sublattice model as (A,Vac)(B,Vac)(Vacⁱ,Aⁱ). The first and second sublattices contain the A and B substitutional sites, hosting A, B, or vacancy defects, while the third sublattice contains interstitial sites, primarily occupied by vacancies and host secondary A-interstitial defects. The constitutional space (or Y -space) with 3 sublattices forms a cube with eight end-members (or eight vertices). As shown in Figure 7(a), the constitutional cube is formed by three axes (or three degrees of freedom), y_{vac}^1 , y_{vac}^2 , and $y_{A^i}^3$, denoting the site fractions of A- and B- vacancies and

A-interstitial in the first, second, and third sublattices, respectively. Each of the non-parallel defect lines (A-vacancy, B-vacancy, or A-interstitial), all intersecting at the AB point on the convex hull, form one axis of the constitutional cube in the Y -space (see Figure 7(a)). The point of intersection, or the A:B:Vacⁱ serves as the origin for the Y -constitutional cube.

The X -composition of each component A or B per formula unit is related to the DEF site fractions using the following equations (see equation 1).

$$\begin{aligned} X_A &= \frac{y_A^1 + y_{A^i}^3}{y_A^1 + y_B^1 + y_{A^i}^3} = \frac{(1 - y_{vac}^1) + y_{A^i}^3}{(1 - y_{vac}^1) + (1 - y_{vac}^2) + y_{A^i}^3} \\ X_B &= \frac{y_B^1}{y_A^1 + y_B^1 + y_{A^i}^3} = \frac{1 - y_{vac}^2}{(1 - y_{vac}^1) + (1 - y_{vac}^2) + y_{A^i}^3} \end{aligned} \quad (14)$$

which provide the mapping between the X - and Y -spaces. The mapping expands the 1-dimensional X -space associated with three defects lines, A-vacancy, B-vacancy, and A-interstitial, into a 3-dimensional constitutional cube, as shown in Figure 7(a). Figure 8 illustrates the X_B -constant contours (or level planes) on the Y -space (or constitutional cube of the DEF model). As shown in Figure 8, each plane on the $(1 - y_{vac}^1) - (1 - y_{vac}^2) - y_{A^i}^3$ constitutional cube maps into one point on X_B . The face plane at $y_{vac}^2 = 1$ corresponds to $X_B = 0$, and the body diagonal plane, formed by $y_{vac}^1 = y_{vac}^2$ and $1 - y_{vac}^2 = y_{A^i}^3$ lines, corresponds to $X_B = \frac{1}{2}$. The plane corresponding to $X_B = 1$ collapses into the line at $y_{vac}^1 = 1$ and $y_{A^i}^3 = 0$. Note that the plane at $y_{A^i}^3 = 0$ replicates the composition square for the (A,Vac)(B,Vac) model detailed in section II B.

To map the defect formation energy from the convex hull to the corresponding end-member Gibbs energy, ${}^0G_{end}$, on the constitutional cube, we first identify the physically relevant lines on the Y -cube to the X_B values for each defect line. As shown in Figure 7(a), both the B-vacancy and A-interstitial defect lines lie on the A-AB side of X_B on the convex hull and, as expected by the X - Y mapping of equation 14, their physically relevant Y -lines span over the $X_B < X_A$ region on the Y -cube (colored red in Figure 7(a)). On the other hand, the A-vacancy defect line lies on the AB-B side of X_B , and thus its physically relevant Y -line maps into the $X_B > X_A$ region on the Y -cube (colored green in Figure 7(a)). As shown in Figure 7(a), the lines at $y_{vac}^2 = 0$ and $y_{A^i}^3 = 0$, $y_{vac}^1 = 0$ and $y_{A^i}^3 = 0$, and $y_{vac}^2 = 0$ and $y_{vac}^1 = 0$, corresponds to the physically relevant Y -value for A-vacancy, B-vacancy, and A-interstitial defect lines, respectively. As shown in Figure 7(a), these are the basis vectors (axes) on the Y -constitutional cube, and each axis represents a single defect type at different concentrations in the dilute ranges of isolated defects. As shown in Figure 7(a), the origin for the Y -constitutional cube, or the A:B:Vacⁱ end-member, corresponds to the defect-free AB compound with the formation energy of ΔH_f^{AB} . Other end-members are obtained by extending the origin along

FIG. 7. Mapping the composition and formation energy from a model convex hull (A-AB-B) to the constitutional cube of a three-sublattice DEF model for A-vacancy, B-vacancy, and A-interstitial. Formation energies of defect-free AB (ΔH_{AB}), defective AB with A-vacancy, defective AB with B-vacancy, and defective AB with A-interstitial are shown by the black square, blue circle, brown diamond, and orange hexagon, respectively. The defect lines for A-vacancy, B-vacancy, and A-interstitial are shown by the blue, brown, and orange lines, respectively. (a) Graphic representation of the mapping between X_B on the convex hull and the constitutional cube of the three-sublattice model (or Y-space cube). The X_B composition on the AB-B and A-AB sides maps into the green and pink regions of the Y-space cube, respectively. Lines on the constitutional cube that are physically relevant to the individual defect lines on the convex hull are shown by the respective colors of the defect lines, i.e., blue, brown, and orange for A-vacancy, B-vacancy, and A-interstitial. Projections of the constitutional cube into planes defined by (b) $y_{Ai}^3 = 0$, (c) $y_{vac}^1 = 1$ and (d) $y_{Ai}^3 = 1$.

the three axes of Y-cube, corresponding to $A:B:A^i$ for A-interstitial axis, $Vac:B:Vac^i$ for A-vacancy axis, and $A:Vac:Vac^i$ for B-vacancy axis. The DEF end-member Gibbs energies for the AB binary compound with A-vacancy, B-vacancy, and A-interstitial defects are

$$\begin{aligned}
 {}^0G_{A:B:Vac^i} &= \mu_A^0 + \mu_B^0 + 2\Delta H_f^{AB} \\
 {}^0G_{A:Vac:Vac^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{B-vacancy} \\
 {}^0G_{Vac:B:Vac^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{A-vacancy} \\
 {}^0G_{Vac:Vac:Vac^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{B-vacancy} + \Delta E_{A-vacancy}
 \end{aligned}$$

$$\begin{aligned}
 {}^0G_{A:B:A^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{A^i} \\
 {}^0G_{A:Vac:A^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{B-vacancy} + \Delta E_{A^i} \\
 {}^0G_{Vac:B:A^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{A-vacancy} + \Delta E_{A^i} \\
 {}^0G_{Vac:Vac:A^i} &= {}^0G_{A:B:Vac^i} + \Delta E_{B-vacancy} \\
 &\quad + \Delta E_{A-vacancy} + \Delta E_{A^i}
 \end{aligned} \tag{15}$$

For a general binary compound A_pB_q with a DEF sublattice model of $(A,Vac)_p(B,Vac)_q(Vac^i,A^i)_m$, the end-member Gibbs energies are

$${}^0G_{A:B:Vac^i} = p\mu_A^0 + q\mu_B^0 + (p+q)\Delta H_f^{AB}$$

FIG. 8. Mapping of the constitutional cube for the (A,Vac)(B,Vac)(Vacⁱ,Aⁱ) DEF model, formed by $(1 - y_{\text{vac}}^1) - (1 - y_{\text{vac}}^2) - y_{A^i}^3$, into the mole fraction composition X_B . The contour level planes in the constitutional cube are labeled with corresponding X_B values. Level planes for $X_B < 0.5$ and $X_B \geq 0.5$ are colored red and green, respectively.

$$\begin{aligned}
{}^0G_{A:\text{Vac}:\text{Vac}^i} &= {}^0G_{A:B:\text{Vac}^i} + q\Delta E_{B\text{-vacancy}} \\
{}^0G_{\text{Vac}:B:\text{Vac}^i} &= {}^0G_{A:B:\text{Vac}^i} + p\Delta E_{A\text{-vacancy}} \\
{}^0G_{\text{Vac}:\text{Vac}:\text{Vac}^i} &= {}^0G_{A:B:\text{Vac}^i} + q\Delta E_{B\text{-vacancy}} + p\Delta E_{A\text{-vacancy}} \\
{}^0G_{A:B:A^i} &= {}^0G_{A:B:\text{Vac}^i} + m\Delta E_{A^i} \\
{}^0G_{A:\text{Vac}:A^i} &= {}^0G_{A:B:\text{Vac}^i} + q\Delta E_{B\text{-vacancy}} + m\Delta E_{A^i} \\
{}^0G_{\text{Vac}:B:A^i} &= {}^0G_{A:B:\text{Vac}^i} + p\Delta E_{A\text{-vacancy}} + m\Delta E_{A^i} \\
{}^0G_{\text{Vac}:\text{Vac}:A^i} &= {}^0G_{A:B:\text{Vac}^i} + q\Delta E_{B\text{-vacancy}} \\
&\quad + p\Delta E_{A\text{-vacancy}} + m\Delta E_{A^i}
\end{aligned} \tag{16}$$

A similar DEF model for the B-interstitial defect, (A,Vac)(B,Vac)(Vacⁱ,Bⁱ) is illustrated in Appendix Figure A1. The general recipe for constructing a typical DEF model for neutral defects is provided in section IV.

III. DEFECT ENERGY FORMALISM FOR CHARGED DEFECTS

For a compound with charged defects, the concentration of defects is controlled by the Fermi level through the charge neutrality condition

$$0 = n - p - \sum_{d,q} q_d c_d \tag{17}$$

where n , p and c_d are the concentration of free electrons, holes, and defect d with a net charge of q_d (e.g., +2 for a doubly ionized donor with 2 electrons removed or -2 for an acceptor with 2 electrons added), respectively. k and

T are the Boltzmann constant and temperature. n and p are a function of the Fermi level, while c_d is a function of both the Fermi level and chemical potential. The concentration of electrons and holes for non-degenerate semiconductors, with the Fermi level several kT below the conduction band, follows the Boltzmann distribution⁷²

$$\begin{aligned}
n &= N_c \exp\left(-\frac{E_c - E_f}{kT}\right) \\
p &= N_v \exp\left(-\frac{E_f - E_v}{kT}\right)
\end{aligned} \tag{18}$$

where N_v (N_c) is the effective density of states in the valence (conduction) band, and E_f , E_c , and E_v denote the Fermi level, the conduction band minimum, and the valence band maximum energies, respectively. The effective density of states (per volume) in the valence and conduction band are given by $N_v = 2 \left(\frac{2\pi m_h^* kT}{h^2}\right)^{3/2}$ and

$N_c = 2 \left(\frac{2\pi m_e^* kT}{h^2}\right)^{3/2}$, where h is the Planck's constant, m_h^* and m_e^* are the effective masses of holes and electrons at the valence band and conduction band edges, respectively. Multiplying N_v and N_c in the volume per formula unit of the compound, V_0 , counts the effective densities per formula unit (e.g., see Ref.^{61,64}), which we consider in this work. Note that according to equation 18, the product of n and p is constant and independent of E_f , given by $np = N_c N_v \exp\left(-\frac{E_g}{kT}\right)$, where $E_g = E_c - E_v$ is the band gap of the defect-free compound.

The concentration of defect d in the dilute range, c_d , is given by the Arrhenius relation³⁶

$$c_d^q = c_0 \exp\left(-\frac{\Delta H_d^q}{kT}\right) \tag{19}$$

where c_0 denotes the concentration of possible defect sites in the host compound and ΔH_d^q denotes the grand-canonical formation energy for the defect d with a net charge of q , which in addition to chemical potential depends on E_f according to the following equation.

$$\Delta H_d^q = E_{\text{def}}^q - E_{\text{pristine}} - \sum \Delta N_i \mu_i + qE_f \tag{20}$$

Here, E_{def}^q and E_{pristine} denote the energies of the defective and pristine structures, respectively, where the defective structure has a net charge of q . ΔN_i is the number of atoms of species i added to or removed from the defective structure (e.g., +1 for interstitials, -1 for vacancies) and μ_i is the chemical potential of the species i .

The equilibrium Fermi level, E_f^* , is uniquely determined by solving the charge neutrality condition of equation 17 for E_f . As shown in Figure 9(a), the equilibrium Fermi level can be associated to a plane on the formation energy convex hull in the composition-Fermi level space ($X - E_f$). The formation energy of defect d varies with E_f with a slope of q according to equation 20. Therefore,

FIG. 9. Formation energy convex hull in the composition-Fermi level space ($X - E_f$). a) Graphical illustration of a typical A-AB-B convex hull along the Fermi level and chemical composition. The A-AB-A convex hull, including the A+AB and AB+B common tangent lines, is independent of the Fermi level because it consists of charge neutral compounds, resulting in a flat extrusion of the A-AB-B hull along E_f . In contrast, the energy of a defected compound with a net charge q depends on E_f and varies with a slope of q along E_f , as shown by shaded triangles. The absolute defect energy of defected AB (ΔE_d) are shown for A-vacancy with $q = -1$ and B-vacancy with $q = +1$. b) Graphical representation of unifying the electronic energy reference for charge carriers and ionic defects. The convex hull at the equilibrium Fermi level (E_f^*) is shifted to the intrinsic Fermi level (E_f^i). The chemical-potential-independent absolute defect energy is shifted by $-q\mu_e$ (see equation 25).

the charge state of defect d is implicitly determined by E_f^* , where different charge states of a given defect d enter the charge neutrality condition of equation 17. The equilibrium Fermi level E_f^* is a measure of the chemical potential of electrons at equilibrium, μ_e (i.e., $\mu_e = E_f^*$)⁷³, defined as the Gibbs energy required to add or remove an electron from the compound.

We define the standard chemical potential for electrons and holes, μ_e^0 and μ_h^0 , respectively, for the Fermi level of the intrinsic case or a defect-free compound. Therefore, μ_e^0 and μ_h^0 represent the Gibbs energy change for creation of an electron and hole through the electron-hole pair reaction ($e^- + h^+ \leftrightarrow 0$) in the absence of any ionic defect. The electron-hole pair reaction implies that $\mu_e^0 + \mu_h^0 = 0$ at equilibrium. The intrinsic Fermi level is simply determined through $n = p$ (see equation 17), resulting in $E_f^i = \frac{E_v + E_c}{2} - \frac{kT}{2} \ln\left(\frac{N_c}{N_v}\right)$. We consider the intrinsic Fermi level as the reference electronic energy in the DEF framework because it corresponds to a defect-free compound with a net charge of zero. This choice for the reference electronic state is consistent with the choice for the reference chemical state corresponding to the defect-free compound (see section II A). Setting $E_f^i = 0$ results in $E_c = \frac{E_g}{2} + \frac{kT}{2} \ln\left(\frac{N_c}{N_v}\right)$ and $E_v = -\frac{E_g}{2} + \frac{kT}{2} \ln\left(\frac{N_c}{N_v}\right)$. The standard chemical potential of an electron is the

Gibbs energy change due to adding an electron to the conduction band minimum, with the energy term equal to $\frac{E_g}{2} + \frac{kT}{2} \ln\left(\frac{N_c}{N_v}\right)$ and the entropy contribution term equal to $-kT \ln N_c$, corresponding to the selection of an electron site among N_c available sites. Therefore, $\mu_e^0 = \frac{E_g}{2} + \frac{kT}{2} \ln\left(\frac{N_c}{N_v}\right) - kT \ln N_c$. Similarly, the standard chemical potential for a hole is equal to the energy for removing an electron from the valence band with an entropy term corresponding to selection of a candidate hole site among N_v available sites, resulting in $\mu_h^0 = \frac{E_g}{2} - \frac{kT}{2} \ln\left(\frac{N_c}{N_v}\right) - kT \ln N_v$.

For the general case of a defected compound (non-intrinsic, non-degenerate), the shift in the equilibrium Fermi level E_f^* with respect to the intrinsic Fermi level E_f^i , ΔE_f , measures the chemical potential of electrons ($\Delta E_f = \mu_e$) according to the following equation (rearrangement of equation 18)

$$\begin{aligned} n &= N_c \exp\left(-\frac{E_c - (E_f^i + \Delta E_f)}{kT}\right) \\ &= N_c \exp\left(-\frac{(E_c - E_f^i)}{kT}\right) \exp\left(-\frac{\mu_e}{kT}\right) \end{aligned}$$

$$\begin{aligned} \rightarrow \mu_e &= \left[\frac{E_g}{2} + \frac{kT}{2} \ln \left(\frac{N_c}{N_v} \right) - kT \ln(Nc) \right] + kT \ln n \\ \rightarrow \mu_e &= \mu_e^0 + kT \ln n \end{aligned} \quad (21)$$

Similarly, the chemical potential of holes is given by ($\Delta E_f = -\mu_h$)

$$\begin{aligned} p &= N_v \exp \left(-\frac{(E_f^i + \Delta E_f) - E_v}{kT} \right) \\ &= N_v \exp \left(-\frac{(E_f^i - E_v)}{kT} \right) \exp \left(\frac{\mu_h}{kT} \right) \\ \rightarrow \mu_h &= \left[\frac{E_g}{2} - \frac{kT}{2} \ln \left(\frac{N_c}{N_v} \right) - kT \ln(Nv) \right] + kT \ln p \\ \rightarrow \mu_h &= \mu_h^0 + kT \ln p \end{aligned} \quad (22)$$

Note that according to the above equation, $\mu_e + \mu_h = 0$ is always satisfied, considering that $np = N_c N_v \exp \left(-\frac{E_g}{kT} \right)$.

The DEF construction for defected phases with charged defects includes an auxiliary sublattice to host electronic constituents, including free electrons and holes. Including the auxiliary sublattice besides the regular atomic (or ionic) sublattices is essential for determining the concentration of charge carriers, as is usually desired in the thermodynamic description of semiconductors. Existing studies in the literature have used the CEF both with or without including the charge carrier sublattice. The charge carrier sublattice represents the electron reservoir and thus facilitates the exchange of electrons to or from the regular atomic sublattices in a grand-canonical description. The number of available sites (per formula unit of the compound) on the free electron or hole sublattice are N_c and N_v , respectively. Therefore, one may consider a DEF model with separate sublattices for free electrons and holes such as $(A, \text{Vac}^{-1})(B, A^{+1})(\text{Vac}, e^{-})_{N_c}(\text{Vac}, h^{+})_{N_v}$. However, this representation makes the modeling complex as N_c and N_v can vary with compositions or by adding new chemical components to the system. Therefore, as recommended by other CEF studies^{58,61,67}, we set the number of sites in the free electron and hole sublattices equal. Chen and Hillert⁶⁷ compensate for the incorrect number of sites in the charge carrier sublattices by subtracting the terms $RT \ln N_c$ and $RT \ln N_v$ from the Gibbs formation energy of electrons and holes, respectively (see section 4 in Ref.⁶⁷ for details). As shown in equation 21, these correction terms have emerged in the derivation of μ_e^0 and μ_h^0 , and are inherently embedded in the DEF formalism as detailed below. Therefore, the DEF model can be simplified to host free electrons and holes on a common sublattice as $(A, \text{Vac}^{-1})(B, A^{+1})(\text{Vac}, e^{-}, h^{+})$.

The Gibbs energy per formula unit of the compound with charged defects is defined similar to a compound with neutral defects consisting of the surface of reference energy, $G^{\text{s.r.}}$, and the ideal mixing term for each sublattice. The additional Gibbs energy terms due to the

charge carrier sublattice can be formulated as the following (after section 4 in Ref.⁶⁷)

$$\begin{aligned} G_{\text{fu}} &= G_{\text{fu}}^{\text{at}} + G_{\text{fu}}^{\text{ax}} \\ &= G_{\text{fu}}^{\text{at}} + \sum \sum \overbrace{y_i y_j}^{=1} [({}^0G_{i;j:e^{-}} - {}^0G_{i;j:\text{vac}}) y_e^3 \\ &\quad + ({}^0G_{i;j:h^{+}} - {}^0G_{i;j:\text{vac}}) y_{h^{+}}^3] \\ &\quad + kT (y_e^3 \ln(y_e^3) + y_{h^{+}}^3 \ln(y_{h^{+}}^3) + y_{\text{vac}}^3 \ln(y_{\text{vac}}^3)) \\ &= G_{\text{fu}}^{\text{at}} + y_e^3 \underbrace{[({}^0G_{i;j:e^{-}} - {}^0G_{i;j:\text{vac}}) + kT \ln(y_e^3)]}_{\mu_e} \\ &\quad + y_{h^{+}}^3 \underbrace{[({}^0G_{i;j:h^{+}} - {}^0G_{i;j:\text{vac}}) + kT \ln(y_{h^{+}}^3)]}_{\mu_h} \\ &\quad + kT y_{\text{vac}}^3 \ln(y_{\text{vac}}^3) \end{aligned} \quad (23)$$

where $G_{\text{fu}}^{\text{at}}$ is the Gibbs energy for a DEF model that only consists of the atomic sublattices (see equation 2) and $G_{\text{fu}}^{\text{ax}}$ is the additional Gibbs energy due to the charge carrier (or auxiliary) sublattice. i and j run over end-members that are formed by the atomic sublattices only and thus $\sum \sum y_i y_j = 1$. Additionally, in deriving equation 23, terms such as ${}^0G_{i;j:\text{vac}} \times y_i y_j y_{\text{vac}}^3$ are rearranged as ${}^0G_{i;j:\text{vac}} \times [y_i y_j (1 - y_e^3 - y_{h^{+}}^3)] = {}^0G_{i;j} \times y_i y_j (1 - {}^0G_{i;j:\text{vac}} \times y_i y_j (y_e^3 + y_{h^{+}}^3))$, where the first term is incorporated into $G_{\text{fu}}^{\text{at}}$ and the second term is embedded into $G_{\text{fu}}^{\text{ax}}$. $G_{\text{fu}}^{\text{at}}$ is the Gibbs energy for a DEF without considering the auxiliary charge carrier sublattice, and is given by $G_{\text{fu}}^{\text{at}} = \sum \sum {}^0G_{i;j} y_i y_j + kT \sum_s \sum_k y_k \ln(y_k)$. i and j run over end-members that are formed by the atomic sublattices only, s only runs over atomic sublattices, and k runs over constituents of sublattice s . In the DEF formalism, Gibbs energy of defective end-members describing ionic defects with a non-zero net charge are parameterized as the sum of neutral defect formation energy and the ionization energy (as detailed below).

Within $G_{\text{fu}}^{\text{ax}}$ formulation, the chemical potential of free electrons (μ_e) and holes (μ_h) naturally arise, directly linking the DEF end-members with charge carriers to the chemical potentials of electrons and holes. For example, the term $({}^0G_{i;j:h^{+}} - {}^0G_{i;j:\text{vac}}) + kT \ln(y_{h^{+}}^3)$ in the DEF Gibbs energy corresponds to $\mu_h^0 + kT \ln p$ in equation 21. In deriving this equality, we use the following equation

$$\begin{aligned} \frac{p}{N_v} &= \left(\frac{p}{N_v} N_v \right) \frac{1}{N_v} = \left(\frac{y_{h^{+}}^3}{y_{h^{+}}^3 + y_e^3 + y_{\text{vac}}^3} \right) \frac{1}{N_v} \\ kT \ln \left(\frac{p}{N_v} \right) &= kT \ln y_{h^{+}}^3 - kT \ln N_v \rightarrow kT \ln p = kT \ln y_{h^{+}}^3 \end{aligned} \quad (24)$$

The direct connection between the chemical potential of electrons and holes and the DEF Gibbs energy formulation implies that the end-member Gibbs energy value,

(${}^0G_{i;j:h^+} - {}^0G_{i;j:vac}$), associated with formation of a hole, is μ_h^0 . The mixing entropy term associated with the vacant sites on the auxiliary sublattice (last term in equation 23) approaches zero for low concentration of charge carriers, when $y_{vac}^3 \rightarrow 1$ ($\lim_{X \rightarrow 0} (1-X) \ln(1-X) = -X$), and thus can be neglected.

Considering separate sublattices for free electrons and holes results in the same DEF Gibbs energy formulation as using a common sublattice for both. For separate sublattices, additional terms of the form (${}^0G_{i;j:e^-:h^+} - {}^0G_{i;j:vac:vac}$) appear in the DEF Gibbs energy of equation 23. This term represents the Gibbs energy for an electron-hole pair formation ($e^- + h^+ \leftrightarrow 0$), which is equal to zero at thermal equilibrium, making the Gibbs energy formulation the same as a single sublattice hosting electrons and holes. Additionally, terms of the form $y_i y_j y_{vac}^3 y_{vac}^4 {}^0G_{i;j:vac:vac}$ appear that can be rearranged as $y_i y_j (1 - y_e^3)(1 - y_{h^+}^4) {}^0G_{i;j:vac:vac} = y_i y_j {}^0G_{i;j} - y_i y_j y_e^3 {}^0G_{i;j:vac:vac} - y_i y_j y_{h^+}^4 {}^0G_{i;j:vac:vac} + y_i y_j (y_e^3 y_{h^+}^3) {}^0G_{i;j:vac:vac}$, to give the same formulation as for the common auxiliary sublattice in equation 23. Note that the last term can be neglected because both y_e^3 and $y_{h^+}^3$ are small in the dilute range.

Within the DEF Gibbs energy formulation of equation 23, energy contributions associated with ionized atomic defects must be relative to the reference electronic energy state, same as charge carriers, which we defined as the intrinsic Fermi level, E_f^i . Similar to unifying the chemical energy reference line for neutral defects (see section II A), the formation energy of equation 20 must be shifted by $-q(E_f^* - E_f^i)$ to unify the electronic energy reference line (see Figure 9(b)). Accordingly, the absolute defect energy of a defect d with a net charge of q with a unified chemical and electronic reference state is defined as

$$\begin{aligned} \underbrace{\Delta H_d^q + \sum N_i \mu_i}_{\Delta E_d^q} - q \underbrace{(E_f^* - E_f^i)}_{\mu_e} &= E_{def}^q - E_{pristine} + q(E_f^i) \\ &= \underbrace{E_{def}^q - E_{def}^0}_{\text{ionization energy}} + \underbrace{E_{def}^0 - E_{pristine}}_{\text{neutral defect energy}} \\ &\quad + q \left(E_v + \frac{E_g}{2} - \frac{kT}{2} \ln \left(\frac{N_c}{N_v} \right) \right) \end{aligned} \quad (25)$$

where E_{def}^0 denotes the energy of the charge-neutral defective compound. Typical DFT total energy calculations directly compute the sum of neutral defect and ionization energies. The intrinsic Fermi level is formulated in terms of E_v and E_g , typically obtained from DFT calculations. The defect energy on the right hand side of equation 25 is independent of the equilibrium Fermi level and chemical potential.

The chemical-potential and Fermi-level-independent defect energy of equation 25 is directly connected to the DEF end-member Gibbs energy. For example, consider the $(A, Vac^{-1})(B, A^{+1})(Vac, e^-, h^+)$ model, with a cationic

A-vacancy on the first atomic sublattice and an anionic A-antisite on the second. The end-member $A:A^{+1}:Vac$ associates with a defective compound with dilute anionic A-antisite defects and its Gibbs energy equals ${}^0G_{A:A^{+1}:Vac} = {}^0G_{A:B:Vac} + (E_{A\text{-antisite}}^+ - E_{pristine}) + (E_v + \frac{E_g}{2} - \frac{kT}{2} \ln(\frac{N_c}{N_v}))$. The superposition principle is applied to derive the Gibbs energy of end-members that include both charged ionic defects in the atomic sublattices and charge carriers in the auxiliary sublattice. For example, ${}^0G_{A:A^{+1}:e^-} = {}^0G_{A:B:Vac} + (E_{A\text{-antisite}}^+ - E_{pristine}) + (E_v + \frac{E_g}{2} - \frac{kT}{2} \ln(\frac{N_c}{N_v})) + \mu_e^0 = {}^0G_{A:B:Vac} + \Delta E_{A\text{-antisite}}^+ + (E_v + E_g)$.

A. AB compound with dilute charged A-vacancy and B-vacancy

In the following section, we elaborate on mapping the composition and defect formation energies onto the constitutional space and Gibbs energy of the DEF model for a compound with charged defects. To better understand the importance of the auxiliary charge carrier sublattice in the DEF model, we first consider a DEF model without the auxiliary sublattice for the AB binary compound with dilute charged vacancies, described by two ionic (or atomic) sublattices $(A, Vac^{-2})(B, Vac^{+2})$. The first and second sublattices contain A and B substitutional sites, respectively, hosting A, B, or charged vacancy defects. As shown in Figure 10(a), the constitutional space (or Y -space) forms a square with four end-members, described by two axes, y_{vac}^1 and y_{vac}^2 , representing the site fractions of A and B vacancies in the first and second sublattices, respectively. Similar to neutral defects, each of the non-parallel defect lines (A-vacancy and B-vacancy) intersecting at the AB point on the convex hull forms one axis of the Y constitutional square. Unlike neutral defects, the charge neutrality condition imposes an additional constraint on the mapping between the composition space (X) and the constitutional space of DEF (Y).

The X -composition of A or B relates to the DEF site fractions as per equation 11 similar to neutral defects. However, enforcing charge neutrality constrains the Y -space square into the neutrality line, where $y_{vac}^1 = y_{vac}^2$, as shown in Figure 10(a). Note that $A:B$ and $Vac^{-2}:Vac^{+2}$ end-members are charge-neutral, while $Vac^{-2}:B$ and $A:Vac^{+2}$ have a net charge. The neutrality line restricts the mapping between X and Y to a single point, $X_B = \frac{1}{2}$, extending along the two charge-neutral end members. No other point on the constitutional square, including $Vac^{-2}:B$ and $A:Vac^{+2}$, corresponds to a physically relevant X_B value for A-vacancy and B-vacancy defect lines. As suggested by Rogal *et al*³³, one can use the $(A, Vac^{-2})(B, Vac^{+2})$ model in a standard CEF framework to describe the Gibbs energy of defected compounds (see section 3.2 in Ref.³³). However, there is no direct connection between the formation energies of charged defects projected on the convex hull ends and the end-members of the $(A, Vac^{-2})(B, Vac^{+2})$

FIG. 10. The DEF constitutional space with and without the auxiliary charge carrier sublattice. (a) The constitutional square for the $(A, \text{Vac}^{-2})(B, \text{Vac}^{+2})$ DEF model, mapped to the binary system composition, X_B . The $X_B = 1$ and $X_B = 0$ lines are shown in thick green and orange, respectively. Charge neutrality is only satisfied along the hatched black line. (b) The constitutional cube for the $(A, \text{Vac}^{-2})(B, \text{Vac}^{+2})(\text{Vac}, e^-, h^+)$ DEF model, with basis axes $(1 - y_{\text{vac}}^1)$, $(1 - y_{\text{vac}}^2)$, $(y_e^3 - y_{h^+}^3)$. Charge neutrality is satisfied across the orange plane. Contour lines for constant X_B values are projected on the $(y_e^3 - y_{h^+}^3) = 0$ plane. The top $((y_e^3 - y_{h^+}^3) = 1)$ and bottom $((y_e^3 - y_{h^+}^3) = -1)$ planes contain end-members with free electrons and holes, respectively. The four corners of the charge neutrality plane, marked in red, are physically connected to the absolute defect energy projections on the convex hull at equilibrium Fermi energy.

model, as we aim to develop in DEF. The relevant convex hull for defect formation energy projections is at the equilibrium Fermi level, E_f^* , where charge carriers exist at concentrations different from an intrinsic compound ($\Delta\mu_e \neq 0$, see Figure 9(a)). Rogal *et al.*³³ propose determining the Gibbs energy of charged end-members by considering their charge-neutral combinations (Kröger-Vink approach). However, this requires data for neutral combinations, which is computationally demanding and becomes intractable with several competing combinations.

Instead of the Kröger-Vink approach, we define an auxiliary sublattice to host charge carriers, including free electrons and holes. This method, used in the literature^{61,64-69}, represents the electron reservoir in the grand canonical description. In section III, we establish a direct connection between the DEF end-members, the absolute defect energy of isolated charged defects, and the chemical potentials of charge carriers. The DEF model with the auxiliary sublattice is described as $(A, \text{Vac}^{-2})(B, \text{Vac}^{+2})(\text{Vac}, e^-, h^+)$, where the third sublattice can host vacancies, free electrons, or holes. The auxiliary sublattice adds a new degree of freedom, $y_e^3 - y_{h^+}^3$, representing the excess electrons as the difference between the site fractions of electrons and holes. Note that the concentrations of electrons and holes are interdependent through $np = N_c N_v \exp\left(-\frac{E_g}{kT}\right)$ (see equation 18). The resulting constitutional space is a cube, as shown in Figure 10(b). The charge neutrality condition constrains the Y-space cube to the neutrality plane, given by $y_e^3 - y_{h^+}^3 + 2 \times y_{\text{vac}}^1 - 2 \times y_{\text{vac}}^2 = 0$ (see equation 17). The projection of the charge neutrality plane onto the

$(y_e^3 - y_{h^+}^3) = 0$ plane includes any combination of y_{vac}^1 and y_{vac}^2 . Thus, adding the charge carrier (auxiliary) sublattice allows exploring any y_{vac}^1 and y_{vac}^2 combination, subject to the constraint that their net charge is balanced by free electrons and holes, as defined by the charge neutrality plane. This enables direct mapping of the complete range of X_B values on the convex hull to the DEF Y-space, as shown in Figure 11.

As shown in Figure 11(a), The constitutional cube has 12 end-members at the corners of the three planes defined by $(y_e^3 - y_{h^+}^3) = -1, 0, 1$. The top plane corresponds to $y_e^3 = 1$ and $y_{h^+}^3 = 0$, and the bottom plane to $y_e^3 = 0$ and $y_{h^+}^3 = 1$, each allowing any combination of y_{vac}^1 and y_{vac}^2 . The auxiliary sublattice on the top plane is occupied by free electrons ($y_e^3 = 1$), and on the bottom plane by holes ($y_{h^+}^3 = 1$). Free electron occupation implies $y_e^3 = 1$ or $n = 1$, resulting in $kT \ln n = 0$ or $\mu_e = \mu_e^0$ (see equation 22), making the Gibbs energy of top plane end-members include μ_e^0 for free electron formation. The same applies to the bottom plane for holes. The middle plane has end-members with no charge carriers. Four of the 12 end-members correspond to physically relevant dilute defects: $A:B:\text{Vac}$ and $\text{Vac}^{-2}:\text{Vac}^{+2}:\text{Vac}$ on the middle plane, $A:\text{Vac}^{+2}:e^-$ on the top plane, and $\text{Vac}^{-2}:B:h^+$ on the bottom plane. For example, the $A:\text{Vac}^{+2}:e^-$ end-member describes the creation of a positively charged ionic defect by exchanging free electrons with the reservoir in the grand-canonical description. As shown in Figure 11(b), the chemical-potential Fermi-level-independent defect energies of equation 25 are directly mapped to these four end-members. The Gibbs energy of other end-members

is obtained by decomposing the Gibbs energy of multi-defected, physically connected end-members using the superposition principle. For example, the multi-defected $A:\text{Vac}^{+2};e^-$ end-member can be decomposed into two independent defective end-members: $A:\text{Vac}^{+2};\text{Vac}$, which includes the charged ionic defect, and $A:B:e^-$, which

includes the free electron.

The end-member Gibbs energy for a general DEF model $(A,\text{Vac}^{-q})_\alpha(B,\text{Vac}^{+q})_\beta(\text{Vac},e^-)(\text{Vac},h^+)$, assuming $m_e^* \approx m_h^* \rightarrow N_c \approx N_v$, is formulated based on the absolute defect energies of the defective and pristine compounds (per atom) as follows

$$\begin{aligned}
{}^0G_{A:B:\text{Vac}} &= \alpha\mu_A^0 + \beta\mu_B^0 + (\alpha + \beta)\Delta H_f^{\text{AB}} \\
{}^0G_{A:B:e^-} &= {}^0G_{A:B:\text{Vac}} + (E_v + E_g) \\
{}^0G_{A:B:h^+} &= {}^0G_{A:B:\text{Vac}} + (E_v + E_g) \\
{}^0G_{\text{Vac}^{-q};B:\text{Vac}} &= {}^0G_{A:B:\text{Vac}} + \alpha \left(\Delta E_{\text{Vac}_A^{-q}} - q(E_v + \frac{E_g}{2}) \right) \\
{}^0G_{\text{Vac}^{-q};B:e^-} &= {}^0G_{A:B:\text{Vac}} + \alpha \left(\Delta E_{\text{Vac}_A^{-q}} - q(E_v + \frac{E_g}{2}) \right) + (E_v + E_g) \\
{}^0G_{\text{Vac}^{-q};B:h^+} &= {}^0G_{A:B:\text{Vac}} + \alpha \left(\Delta E_{\text{Vac}_A^{-q}} - q(E_v + \frac{E_g}{2}) \right) + (E_v + E_g) \\
{}^0G_{A:\text{Vac}^{+q};\text{Vac}} &= {}^0G_{A:B:\text{Vac}} + \beta \left(\Delta E_{\text{Vac}_B^{+q}} + q(E_v + \frac{E_g}{2}) \right) \\
{}^0G_{A:\text{Vac}^{+q};e^-} &= {}^0G_{A:B:\text{Vac}} + \beta \left(\Delta E_{\text{Vac}_B^{+q}} + q(E_v + \frac{E_g}{2}) \right) + (E_v + E_g) \\
{}^0G_{A:\text{Vac}^{+q};h^+} &= {}^0G_{A:B:\text{Vac}} + \beta \left(\Delta E_{\text{Vac}_B^{+q}} + q(E_v + \frac{E_g}{2}) \right) + (E_v + E_g) \\
{}^0G_{\text{Vac}^{-q};\text{Vac}^{+q};\text{Vac}} &= {}^0G_{A:B:\text{Vac}} + \alpha \left(\Delta E_{\text{Vac}_A^{-q}} - q(E_v + \frac{E_g}{2}) \right) + \beta \left(\Delta E_{\text{Vac}_B^{+q}} + q(E_v + \frac{E_g}{2}) \right) \\
{}^0G_{\text{Vac}^{-q};\text{Vac}^{+q};e^-} &= {}^0G_{A:B:\text{Vac}} + \alpha \left(\Delta E_{\text{Vac}_A^{-q}} - q(E_v + \frac{E_g}{2}) \right) + \beta \left(\Delta E_{\text{Vac}_B^{+q}} + q(E_v + \frac{E_g}{2}) \right) + (E_v + E_g) \\
{}^0G_{\text{Vac}^{-q};\text{Vac}^{+q};h^+} &= {}^0G_{A:B:\text{Vac}} + \alpha \left(\Delta E_{\text{Vac}_A^{-q}} - q(E_v + \frac{E_g}{2}) \right) + \beta \left(\Delta E_{\text{Vac}_B^{+q}} + q(E_v + \frac{E_g}{2}) \right) + (E_v + E_g)
\end{aligned} \tag{26}$$

The DEF end-member Gibbs energies from equation 26 can be plugged into equation 23 to obtain the Gibbs energy per formula unit of the defective compound.

IV. THE GENERAL RECIPE FOR CONSTRUCTING DEFECT ENERGY FORMALISM

The general procedure for constructing a typical DEF model for neutral defects is as follows:

- *Defect lines and defect formation energy projections on the convex hull:* Plot the desired defective compounds on the formation energy convex hull. Each defective compound corresponds to a point on the convex hull diagram. The line connecting this point to the defect-free compound point is the defect line (see Ref.⁷⁰). Draw the N_d non-parallel defect lines for N_d different defects.

- *DEF constitutional Y-space:* Construct the constitutional space for the DEF model using the N_d defect lines as the orthogonal basis. The origin represents the defect-free compound, and each basis vector corresponds to a defect line. Each axis indicates the site fraction of the corresponding defect on its host sublattice. The end-members are points with site fraction values of 0 or 1 along each axis. Note that the N_d degrees of freedom, associated with fractions of defects (or secondary constituents), can be hosted on N_d sublattices or fewer. For example, two defects (e.g., A-vacancy and B-antisite) can be defined on the first sublattice.
- *DEF end-members' Gibbs energy:* The Gibbs energy of the origin point in the Y-space equals the formation energy of the defect-free compound, which also serves as the reference state for chemical energy. The Gibbs energy of other end-members, formed by translating the origin using defect line vectors, is the sum of the defect-free compound

FIG. 11. Mapping the composition and formation energy from a model convex hull (A-AB-B) to the constitutional space of a three-sublattice DEF model (A,Vac⁻²)(B,Vac⁺²)(Vac,e⁻,h⁺). Formation energies of the defect-free AB, defective AB with A-vacancy, and defective AB B-vacancy are represented by the black square, blue circle, and brown diamond, respectively. The defect lines for A-vacancy and B-vacancy are shown by the blue and brown lines, respectively. The defective compound contains charged defects, determined by the equilibrium Fermi level. (a) Graphic representation of the mapping between X_B composition on the convex hull and the constitutional space (Y -space). The X_B on the AB-B and A-AB sides maps into the green and pink regions of the Y -space, respectively. The charge neutrality plane is illustrated in orange. Lines in the Y -space that are physically relevant to the defect lines on the convex hull are shown in blue and brown. DEF end-members are depicted by black circles on the constitutional cube. Red marks indicate end-members directly connected to the formation energies on the convex hull. (b) Graphic representation of mapping the chemical potential and Fermi-level-independent defect energies onto DEF end-members' Gibbs energies at the corners of the charge neutrality plane.

Gibbs energy and the absolute defect energy of the corresponding defects. Note that the number of independent DEF parameters equals N_d .

The general procedure for constructing a typical DEF model for charged defects is as follows:

- *Identify the intrinsic Fermi level:* The intrinsic Fermi level E_f^i is typically identified from DFT calculations of the valence band maximum and band gap energies using the formula $E_f^i = E_v + E_g/2 - kT/2 \ln(\frac{N_c}{N_v})$.
- *Ionic defect lines projections on the convex hull:* The ionic defect lines with charge q are constructed on the convex hull associated with E_f^i . The chemical-potential-independent defect energies projected on the convex hull are adjusted by adding

qE_f^i to yield the chemical-potential-Fermi-level-independent defect energies (see equations 6 and 25).

- *DEF construction of atomic and auxiliary sublattices:* The DEF model is decomposed into atomic and charge carrier sublattices. The origin of the constitutional space represents the defect-free compound, with each basis vector corresponding to a defect line. An additional basis axis describes the net concentration of free electrons and holes on the auxiliary sublattice. This model consists of $N_d + 1$ degrees of freedom: N_d for the number of ionic defects and one for the charge carriers.
- *DEF end-members Gibbs energy:* The Gibbs energy of end-members formed by the atomic sublattices is connected to their corresponding ionic defect ener-

gies on the convex hull using the same procedure as for neutral defects. The defect-free compound (i.e., the origin) serves as the reference state for chemical and electronic energies. Note that defect formation energies include the additional electronic work term, $q_d E_f^i$. The Gibbs energy of end-members on the auxiliary sublattice is connected to the intrinsic chemical potential of electrons and holes in a non-degenerate, defect-free compound. The reference chemical potentials of electrons and holes, μ_e^0 and μ_h^0 , are added to the Gibbs energy of end-members containing free electrons and holes.

providing critical insights pivotal to the successful derivation of this work. This research is based upon work supported by the National Science Foundation (NSF) under Award Number DMR-1954621.

Appendix A: Notes on DEF End-member Gibbs energy

In a recent study, we derived the DEF end-member Gibbs energy directly from DFT supercell energy calculations⁷¹. In Ref.⁷¹, end-members containing defects were defined by scaling the difference between the pristine supercell and the defective supercell to arrive at a stoichiometry containing the same composition as the end-member (see Eq. 12 in Ref.⁷¹). In this section, we show that the general derivation presented in this paper can be reformatted to arrive at the same formulation as Ref.⁷¹.

For a B-vacancy defect in A_pB_q , represented by the $(A)_p(Va)_q$ end-member, the general derivation presented in this paper gives the Gibbs energy as (see equation 13)

$${}^0G_{A:Vac} = {}^0G_{A:B} + q\Delta E_{B-vac} = p\mu_A^0 + q\mu_B^0 + (p+q)\Delta H_f^p + qE_{def} - qE_{pristine}$$

Reformatting the supercell total energy by the formation energy defined in equation 4 results in $\frac{E_{pristine}}{l} = (p+q)\Delta H_f^p + p\mu_A^0 + q\mu_B^0$. Substituting this equality gives the end-member Gibbs energy as

$${}^0G_{A:Vac} = {}^0G_{A:B} + \Delta E_{B-vac} = \frac{E_{pristine}}{l} + qE_{def} - qE_{pristine} = qE_{def} - \frac{ql-1}{l}E_{pristine}$$

Eq. 12 in Ref.⁷¹ presents the above equation for $q=1$ and $l=32$.

Similarly, for an A-interstitial defect represented by the $(A)_p(B)_q(A^i)_m$ end-member, we can reformat the end-member Gibbs energy of equation 16 in terms of total supercell energies of defective and pristine compounds as the following

$${}^0G_{A:B:A} = {}^0G_{A:B:Vac} + m\Delta E_{A-interstitial} = \frac{E_{pristine}}{l} + mE_{def} - mE_{pristine} = mE_{def} - \frac{ml-1}{l}E_{pristine}$$

Appendix B: (A,Vac)(B,Vac)(Vacⁱ,Bⁱ) Model

FIG. A1. (a) Graphic representation of the mapping between X_B composition on the convex hull and the constitutional cube of the three-sublattice model (Y -space cube). The X_B composition on the AB-B and A-AB sides maps into the green and pink regions of the Y -space cube, respectively. Lines on the constitutional cube relevant to the defect lines on the convex hull are shown in the respective colors: blue for A-vacancy, brown for B-vacancy, and orange for B-interstitial. (b) Mapping of the constitutional cube for the (A,Vac)(B,Vac)(Vacⁱ,Bⁱ) DEF model, $(1 - y_{vac}^1) - (1 - y_{vac}^2) - y_{Bi}^3$, into the composition X_B . Contour planes in the constitutional cube are labeled with corresponding X_B values. Contour planes for $X_B < 0.5$ and $X_B \geq 0.5$ are colored red and green, respectively.
