In this work we propose a comprehensive theoretical framework combining percolation theory to nonlinear dynamics in order to study hypergraphs with a time-varying giant component. We consider in particular hypergraphs with higher-order triadic interactions that can upregulate or downregulate the hyperedges. Triadic interactions are a general type of signed regulatory interaction that occurs when a third node regulates the interaction between two other nodes. For example, in brain networks, the glia can facilitate or inhibit synaptic interactions between neurons. However, the regulatory interactions may not only occur between regulator nodes and pairwise interactions but also between regulator nodes and higher-order interactions (hyperedges), leading to higherorder triadic interactions. For instance, in biochemical reaction networks, the enzymes regulate the reactions involving multiple reactants. Here we propose and investigate higher-order triadic percolation on hypergraphs showing that the giant component can have a non-trivial dynamics. Specifically, we demonstrate that, under suitable conditions, the order parameter of this percolation problem, i.e., the fraction of nodes in the giant component, undergoes a route to chaos in the universality class of the logistic map. In hierarchical higher-order triadic percolation we extend this paradigm in order to treat hierarchically nested triadic interactions demonstrating the non-trivial effect of their increased combinatorial complexity on the critical phenomena and the dynamical properties of the process. Finally, we consider other generalizations of the model studying the effect of considering interdependencies and node regulation instead of hyperedge regulation. The comprehensive theoretical framework presented here sheds light on possible scenarios for climate networks, biological networks and brain networks, where the hypergraph connectivity changes over time.

I. INTRODUCTION

Higher-order networks [1-6] capture the many-body interactions among two or more nodes present in a large variety of complex systems, ranging from the brain to chemical reaction networks. Higher-order networks display a very rich interplay between topology and dynamics [1, 2, 7] which is leading to significant progress in network theory. Notably, higher-order interactions affect synchronization [8–12], percolation [13–20], epidemic spreading [21-23], and random walks and diffusion [24, 25].

Triadic interactions are a general type of higher-order interactions in which one or more nodes regulate the activity of a link between two other nodes. This type of interaction is widely observed in nature such as brain networks, ecological networks, and biochemical reaction networks [26–29]. Indeed, in the brain, the glia inhibit or facilitate the synaptic interactions between pairs of neurons; in biochemical reaction networks, the reactions are controlled by increasing or decreasing the activity of enzymes. Recently, there is a growing interest in triadic interactions from theoretical side. Importantly, triadic interactions have been recently shown to give rise to a paradigmatic change in the theory of percolation, according to the recently proposed triadic percolation [13, 30] model. Futhermore, it has been shown that triadic interactions affect learning [31, 32], signal processing and network dynamics [33, 34].

Triadic interactions can be generalized to hypergraphs, where one or more nodes can regulate the presence of a hyperedge or its strength. For instance, in chemical reaction networks, enzymes can regulate chemical reactions which can be represented as hyperedges [29, 35] including the set of their reactants. In this work, we propose higher-order triadic percolation (HOTP) and its variations showing the important effects arising when triadic percolation is formulated on hypergraphs.

Percolation [36–39] is one of the most fundamental critical phenomena defined on networks and has been extensively used to characterize the robustness of networks [40]. Percolation on simple networks is characterized by a second order phase transition at which the emergence of the giant component can be observed, when nodes or links are randomly damaged. In the last decades important progress in network theory has demonstrated that more general percolation problems, including k-core percolation [41], and interdependent percolation on multiplex networks [42–46] can display discontinuous hybrid transitions, higher-order critical points [47] and exotic phase diagrams [48]. In all these problems the size of the giant component is monitored after a (random) damage is inflicted to the nodes or to the links of the network, and after the eventual cascade of failure events triggered by the initial perturbation reaches a steady state.

Triadic percolation [13, 30], however demonstrates that

^{*} hanlin.sun@su.se

[†] ginestra.bianconi@gmail.com

percolation can become a fully-fledged dynamical process in which the giant component never reaches a steady state. If the triadic interactions are defined on top of a random network [13], the giant component becomes in general time-dependent and its size, that defines the order parameter of the model, can undergo a route to chaos in the logistic map universality class [49, 50]. Moreover triadic percolation on spatial networks leads to topological changes in the structure of the giant component generating non-trivial spatio-temporal patterns, as shown in Ref. [30].

In this work we investigate higher-order triadic percolation (HOTP) on hypergraphs. We reveal that on hypergraphs, the HOTP is a fully-fledged dynamical process whose order parameter displays period-doubling and a route to chaos, when both positive and negative regulations are present with non-zero probability. Thus the phase diagram of HOTP reduces in this scenario to an orbit diagram that we hereby prove to be in the universality class of the logistic map.

The critical properties of HOTP are highly non-trivial. Here we characterize them in important limiting cases in which there are exclusively positive or exclusively negative regulatory interactions, characterizing their discontinuous hybrid transitions, period-2 bifurcations, and continuous transitions. When both positive and negative regulations are present, we indicate the conditions for observing unusual orbit diagrams with a reentrant collapsed phase. In this case we observe a phase transition between a collapsed state with a null giant component and an active phase with a non-zero and time-varying giant component while the probability of down-regulating the hyperedges increases.

Triadic interactions can also be hierarchically nested as recognized in the context of ecological networks in Ref. [28]. In order to study the effects of hierarchical regulation, we propose and study hierarchical higher-order triadic percolation (HHOTP). In this scenario, the regulatory interaction between a node and a hyperedge is controlled by other regulatory interactions and so on. We reveal that the dynamics of HHOTP is significantly different from the dynamics of HOTP due to the combinatorial complexity of their HHOTIs. Indeed as long as the hypergraphs contains negative HHOTIs with a nonvanishing probability, HHOTP displays a much richer dynamics than HOTP which can lead to period-doubling and a route to chaos also if no positive HHOTIs are present. Moreover, our theoretical derivation reveals that the route to chaos of HHOTI is no longer in the logistic map universality class.

This work includes an in depth discussion of two other interesting variations of HOTP: the interdependent higher-order triadic percolation (IHOTP), and the higher-order node dynamical percolation model (HONDP). In IHOTP, we adopt the notion of interdependent hypergraph giant component introduced in Ref. [14] which in absence of regulation is already known to display discontinuous hybrid transition. This different nature of the underlying percolation process has dramatic effects on the dynamics of IHOTP. In particular, here we indicate the conditions under which the route-to-chaos in IHOTP is impeded. The study of HONDP allows us to discuss in detail the effect of regulating the nodes instead of the hyperedges revealing important differences with HOTP.

The paper is structured as follows. In Section II, we introduce random hypergraphs with higher-order triadic interactions and with hierarchical triadic interactions; in Sections III and IV we define HOTP and HHOTP and we investigate their critical properties; in Section V, we discuss other generalizations of HOTP, including IHOTP and HONDP; finally, in Section VI we provide the concluding remarks. The paper also includes two Appendices. In the Appendix A we prove that the order parameter of HOTP undergoes a route-to-chaos in the universality class of the logistic map. In Appendix B we discuss HOTP and HONDP in presence of partial regulation, i.e. where hyperedges (for HOTP) or nodes (for HONDP) are regulated with probability $1 - \rho_0 < 1$.

II. RANDOM HYPERGRAPHS WITH HIGHER-ORDER TRIADIC INTERACTIONS

We consider random hypergraphs with higher-order triadic interactions. These higher-order networks can be modeled as a multilayer structure [37] formed by a structural hypergraph and a signed bipartite network encoding the triadic interactions.

A. Structural hypergraphs

We consider a structural hypergraph $\mathcal{H}(V, E_H)$ formed by a set of nodes V and a set of hyperedges E_H . Each hyperedge α of cardinality $m_{\alpha} = m$ is characterized by the set of nodes v it contains, i.e.,

$$\alpha = [v_1, v_2, \cdots, v_m]. \tag{1}$$

The hyperdegree k of a node is defined as the number of its incident hyperedges.

Hypergraphs can always be represented as factor graphs, i.e. bipartite networks G = (V, U, E) formed by a set of nodes V, a set of factor nodes U, and a set of links E_F between nodes and factor nodes. The factor graph G = (V, U, E) corresponding to the hypergraph $H(V, E_H)$ can be constructed by mapping each hyperedge $\alpha \in E_H$ uniquely to factor nodes $u_\alpha \in U$ and connecting node $v \in V$ to the factor node $u_\alpha \in U$ if the node v belongs to hyperedge α in the hypergraph H. Thus, the hyperdegree of a node in the hypergraph is indicated by the degree of its corresponding node in the factor graph and the cardinality of a hyperedge is indicated by the degree of its corresponding factor node (see Fig. 1).

In this work we consider exclusively random hypergraphs with hyperdegree distribution P(k) and hyperedge cardinality distribution Q(m). We denote with $\langle k \rangle = \sum_k kP(k)$ the average hyperdegree of the nodes of the hypergraph and with $\langle m \rangle = \sum_m mQ(m)$ the average cardinality of the hyperedges of the hypergraph. We furthermore assume that their factor graph representation is locally tree-like (see for a detailed discussion of this assumption Ref. [14]). This assumption is generally met by the considered random hypergraphs under very general conditions over the distributions P(k) and Q(m), and applies to the case in which P(k) and Q(m) have finite moments as for Poisson distributions. In the following we make use to the hypergraph generating functions $G_0(x), G_1(x)$ and $G_{1,m}(x)$ defined as

$$G_{1}(x) = \sum_{k} \frac{kP(k)}{\langle k \rangle} x^{k-1},$$

$$G_{0}(x) = \sum_{k} P(k)x^{k},$$

$$G_{1,m}(x) = \sum_{m} \frac{mQ(m)}{\langle m \rangle} x^{m-1}.$$
(2)

The considered random hypergraphs reduce to networks when all the hyperedges have cardinality m = 2, (i.e. are edges). In terms of the cardinality distribution Q(m), this happens when $Q(m) = \delta_{m,2}$ where here and in the following $\delta_{x,y}$ indicates the Kronecker delta. In this work we provide general results for arbitrary hypergraphs but if not otherwise explicitly stated, we will perform the numerical analysis and the Monte Carlo simulations on hypergraphs having hyperedges with constant cardinality m and Poisson hyperdegree distribution P(k) with average hyperdegree c.

B. Higher-order triadic interactions

1. Higher-order triadic interactions

Higher-order triadic interactions (HOTIs) occur when one or more nodes regulate a hyperedge. The HOTIs are signed, i.e. they can be associated with a positive or negative regulatory role. For instance, an enzyme can speed up or inhibit a chemical reaction. Here we consider the simple scenario in which the HOTIs occur between the same type of nodes (i.e. we do not distinguish between "enzyme" and "metabolite" in the previous example), generalizations in this direction will be considered in future works. In this framework, triadic interactions are encoded by a regulatory bipartite network $\mathcal{G}_T(V, E_H, W)$ formed by the set of nodes V and the set of factor nodes E_H where each factor node represents a hyperedge of the structural hypergraph. The signed HOTI are represented by the edges W of the bipartite network \mathcal{G}_T . Specifically, each edge in W indicates the existence of a (triadic) regulatory interaction from a node in V to a hyperedge in E_H (see Fig. 1 (a) and (b)). We call a node a positive (or negative) regulator of a hyperedge if the node

regulates the hyperedge positively (or negatively). Note that the sign of regulation is a property of the regulatory interaction but not of a node.

We observe that HOTIs reduce to the triadic interactions investigated in Ref. [13] when the structural hypergraph reduces to a network, i.e. has all hyperedges of cardinality m = 2 (see Fig. 1 (c) and (d)).

In this work, we consider an ensemble of hypergraphs with random HOTIs. While the structural hypergraph is sampled from the ensemble of random hypergraphs defined in the previous paragraph, the HOTIs are described by a random bipartite regulatory network. Specifically, we assume that the regulatory interactions between nodes and hyperedges are random and each hyperedge is regulated by κ^+ positive regulators and κ^- negative regulators. The regulatory degree distributions are given by $\hat{P}(\kappa^+)$ and $\hat{P}(\kappa^-)$, respectively. We also assume that there are no correlations among the regulatory degree κ_{α}^{\pm} of a hyperedge α , its cardinality m_{α} and the hyperdegree k_i of its regulatory nodes. Finally, we assume that positive and negative regulatory degrees are independent, which is a valid assumption since the regulatory networks we consider are sparse.

As a reference for the future derivations, we observe that we indicate with $G_0^{\pm}(x)$ the generating function of the degree distribution $\hat{P}(\kappa^{\pm})$ of the positive and negative regulatory interactions of a random hyperedge, given by

$$G_0^{\pm}(x) = \sum_{\kappa^{\pm}} \hat{P}(\kappa^{\pm}) x^{\kappa^{\pm}}.$$
(3)

In this work we will discuss the general theory for arbitrary distribution $\hat{P}(\kappa^{\pm})$, however, if not explicitly stated, our numerical and Monte Carlo results will be conducted always for Poisson $\hat{P}(\kappa^{\pm})$ distribution with average degree c^{\pm} .

2. Hierarchical higher-order triadic interactions

Triadic interactions can be nested hierarchically, leading to significant effects as it has been recognized in the context of ecological networks [28].

Hierarchical higher-order triadic interactions (HHOTI) can be described by a multilayer regulatory network formed by L layers, where each layer $\mu \in \{1, 2, \dots L\}$ is a bipartite network $\mathcal{G}_T^{[\mu]}$. The first layer is formed by nodes in V connected to factor nodes in E_H , i.e. $\mathcal{G}_T^{[1]} = (V, E_H, W^{[1]})$. Thus the first layer reduces to the fundamental HOTI defined in the previous paragraph. The second layer indicates the set of regulatory interactions $W^{[2]}$ of the regulatory interactions in $\mathcal{G}_T^{[1]}$, the third layers indicates the regulatory interactions W^3 of the regulatory interactions in layer 2 and so on (see Fig. 1 (e)). Thus we can describe these further layers with $\mu > 1$ as bipartite networks $\mathcal{G}_T^{[\mu]} = (V, W^{[\mu-1]}, W^{[\mu]})$ fully determining the regulatory interactions $W^{[\mu]}$ between the

FIG. 1. Schematic diagrams of hypergraphs with higher-order triadic interactions (HOTI) and hierarchical higher-order triadic interactions(HHOTI). In panel (a), the shaded areas represent hyperedges with cardinality 3 (yellow), 4 (purple) and 2 (green). The green arrow denotes positive regulation and the red arrow denotes negative regulation between nodes and hyperedges. Panel (b) shows the corresponding factor graph representation of the hypergraph in (a). Panel (c) shows an example of a network with triadic interactions. The positive regulatory interaction between a node and a hyperedge (the green arrow) is further regulated by a fourth node (the red arrow).

nodes in V and the factor nodes representing the regulatory interactions $W^{[\mu-1]}$ at the previous layer.

The bipartite networks $\mathcal{G}_T^{[\mu]}$ that will be considered will be random bipartite networks. Specifically, we assume that the regulatory interactions between nodes and factor nodes in $W^{[\mu-1]}$ are random and that each factor node in $W^{[\mu-1]}$ has degree κ^{\pm} indicating the number of positive and negative regulatory interactions, respectively each drawn from the corresponding distribution $\hat{P}_{\mu}(\kappa^{\pm})$.

As a reference for the future derivations, we observe that we indicate with $G_{0,[\mu]}^{\pm}(x)$ the generating function of the degree distribution $\hat{P}_{[\mu]}(\kappa^{\pm})$ of the positive and negative regulatory interactions of the factor nodes in $W^{[\mu]}$

$$G_{0,[\mu]}^{\pm}(x) = \sum_{\kappa^{\pm}} \hat{P}_{[\mu]}(\kappa^{\pm}) x^{\kappa^{\pm}}.$$
 (4)

In this work we will focus mostly on numerical results obtained for distributions $\hat{P}_{[\mu]}(\kappa^{\pm})$ independent of the layer L, i.e. $\hat{P}_{[\mu]}(\kappa^{\pm}) = \hat{P}(\kappa^{\pm})$ with $\hat{P}(\kappa^{\pm})$ being a Poisson distribution with average c^{\pm} .

III. HIGHER-ORDER TRIADIC PERCOLATION ON RANDOM HYPERGRAPHS

A. Higher-order triadic percolation

Here we formulate higher-order triadic percolation (HOTP) that generalizes triadic percolation, proposed for networks in Ref. [13], to hypergraphs. In this framework, nodes are active if they belong to the hypergraph giant component, while hyperedges are upregulated or downregulated according to the activity of their regulator nodes and a stochastic noise. The hypergraph giant component considered here is the largest extensive connected component whose nodes and hyperedges satisfy the following self-consistent and recursive conditions [14].

- A node is in the giant component if it belongs to at least one hyperedge that is in the hypergraph giant component.
- A hyperedge is in the giant component if
 - (i) it is not down-regulated,
 - (ii) it includes at least one node that is in the hypergraph giant component.

Higher-order triadic percolation is a dynamic process determined by a simple 2-step iterative algorithm. At time t = 0, every hyperedge is active with probability p_{H}^{0} . For $t \ge 1$:

- Step 1: Given the set of active hyperedges at time t 1, a node is considered active at time t if it belongs to a least a hyperedge in the hypergraph giant component.
- Step 2: A hyperedge is deactivated if it is regulated by at least one active negative regulator and/or is not regulated by any active positive regulator and it is considered active otherwise. All other hyperedges are deactivated with probability 1 - p.

Given a random hypergraph, at each time t, Step 1 implements hyperedge percolation [14] where the probability that a hyperedge is intact is given by $p_H^{(t-1)}$. This process determines the fraction of nodes in the hypergraph giant component $R^{(t)}$ at time t, given by

$$R^{(t)} = 1 - G_0(1 - \hat{S}^{(t)}).$$
(5)

where $\hat{S}^{(t)}$ is the probability that starting from a random node and choosing one of its hyperedge at random we reach a hyperedge in the hypergraph giant component. The probability $\hat{S}^{(t)}$ together with the probability $S^{(t)}$ that starting from a random hyperedge and choosing one of its nodes at random we reach a nodes in the hypergraph giant component, obey the following self-consistent set of equations

$$\hat{S}^{(t)} = p_H^{(t-1)} \left[1 - G_{1,m} (1 - S^{(t)}) \right], \qquad (6)$$

$$S^{(t)} = 1 - G_1(1 - \hat{S}^{(t)}).$$
(7)

Thus Eqs. 6 and 7 together with Eq. 5 determine $R^{(t)}$ starting from the knowledge of $p_H^{(t)}$ and implements Step 1. Note that this step differs from the Step 1 of standard triadic percolation [13], as here we consider nodes only active if the belong to the hypergraph giant component while in the standard triadic percolation defined on simple networks we define node active if the belong to the standard giant component of their network.

Step 2 requires the formulation of an additional equation determining the probability $p_H^{(t)}$ that the hyperedges are intact given the probability $R^{(t)}$ that the nodes are active, (i.e. they belong to the hypergraph giant component at Step 1). This equations reads

$$p_H^{(t)} = pG_0^- \left(1 - R^{(t)}\right) \left(1 - G_0^+ \left(1 - R^{(t)}\right)\right), \quad (8)$$

where $G_0^{\pm}(x)$ are the generating functions defined in Eq. 3.

Note that Eq. 8 is the same equation used in Ref. [13] to define the Step 2 of standard triadic percolation, however here $p_H^{(t)}$ indicates the probability that a hyperedge is intact while in standard triadic percolation it indicates the probability that an edge is intact.

From this definition of higher-order triadic percolation it is clear that this dynamical process reduces to standard triadic percolation [13] if $P(m) = \delta_{m,2}$, i.e. if the hypergraph reduces to a network.

B. Higher-order triadic percolation as a fully-fledged dynamical process

Higher-order triadic percolation defines a fully-fledged dynamical process in which the fraction of node in the giant component $R^{(t)}$ is in general a non-trivial function of time. In order to see this we can encode the dynamical Eqs. 5-7 implementing Step 1 and determining $R^{(t)}$ once $p_H^{(t-1)}$ is known as a function

$$R^{(t)} = f_m\left(p_H^{(t-1)}\right). \tag{9}$$

Note that the function $f_m(p_H^{(t-1)})$ already encodes for the result of the percolation process, thus encodes already for the percolation phase transition of hyperedge percolation. On the other side Step 2 is determined by the Eq. 8 that evidently can be expressed as a function determining $p_H^{(t)}$ once $R^{(t)}$ is known, i.e.

$$p_H^{(t)} = g_p\left(R^{(t)}\right),\tag{10}$$

The iteration of Step 1 and Step 2 occurring at time t is thus enclosed in the one-dimensional map

$$R^{(t)} = h_{m,p}\left(R^{(t-1)}\right) = f_m\left(g_p\left(R^{(t-1)}\right)\right).$$
 (11)

This one-dimensional map, defines the evolution of the percolation order parameter R of HOTP as a function of time, i.e. $R = R^{(t)}$ for an infinite random hypergraph with HOTI. This one dimensional map thus encode the dynamical nature of HOTP, and can be used to predict the dynamical behavior of the order parameter. Indeed, by iterating the map we can build a Cobweb plot that accurately predicts the dynamics of the order parameter on large hypergraphs (see Fig. 2). As we will discuss below and prove in Appendix A, this map undergoes a route to chaos in the universality class of the logistic map. In particular the dynamics of the order parameter can either go to a fixed point $R = R^{\star}$, corresponding to a static asymptotic state of HOTP, or it can display periodic oscillations or even display a chaotic dynamics in the thermodynamic limit (see Fig. 2).

The critical behavior of the dynamics can be studied by analysing its derivative J. A stable stationary solution R^* of Eq. 11 satisfy the fix point equation

$$R^{\star} = h_{m,p}(R^{\star}), \tag{12}$$

together with the stability conditions on the derivative J of the map,

$$|J| = \left| h'_{m,p}(R^{\star}) \right| < 1.$$
(13)

Thus the stationary solution loses its stability for |J| = 1. When J = 1, as long as $R = R^* > 0$, we observe a discontinuous hybrid transition with a square root singularity. When J = -1 we observe instead a bifurcation, resulting in period-2 oscillations. Similarly, the critical point of the onset of period-4 oscillations can be obtained by analysing the derivative J_2 of the second-iterate function $h_{m,p}^2 = h_{m,p} \circ h_{m,p}$. The bifurcation of period-2 oscillations takes place at $J_2 = -1$, resulting in period-4 oscillations.

In the next paragraphs we will discuss how this these theoretical insights shed light into the critical properties of HOTP.

C. Critical properties of higher-order triadic percolation

In order to investigate the critical properties of HOTP we consider the effect induced by the sign of the HOTI.

FIG. 2. Time series (panels (a)-(d)) of the order parameter R of HOTP and their corresponding Cobwebs (panels (e)-(h)) are shown to display a variety of dynamical behavior: a steady state (panels (a) and (e)), period-2 oscillations (panels (b) and (f)), period-4 oscillations (panel (c) and (g)) and chaotic dynamics (panel (d) and (h)). The time series are obtained by Monte Carlo simulations on on hypergraphs of $N = 10^6$ nodes with HOTIs. The structural hypergraph has hyperedges of fixed cardinality m = 10 and Poisson hyperdegree distribution P(k) with average c = 10. The degree distributions $\hat{P}(\kappa^{\pm})$ are Poisson with an average regulatory positive and negative degree $c^+ = 3$ and $c^- = 5.5$ respectively. In the Cobweb, the blue curves denote function $R = f_m(p_H)$ and the orange curves denote function $p_H = g_p(R)$ as defined in Eq. 9 and Eq. 10. The timeseries and the Cobweb plots are obtained for p = 0.27 (panels (a) and (e)), p = 0.35 (panels (b) and (f)), p = 0.68 (panels (c) and (g)) and p = 0.88 (panels (d) and (h)).

FIG. 3. Examples of the map $h_{m,p}(R)$ encoding for the dynamics of HOTP when the HOTIs are exclusively positive (panel (a)); when the HOTIs are exclusively negative (panel (b)) and when the hypergraphs include both positive and negative HOTIs with non vanishing probability (panel (c)). The map is unimodal only the scenario (c), thus we can observe a route to chaos of the order parameter only in presence of both positive and negative HOTIs. For all three panels, the structural networks have constant hyperedge cardinality m = 3 and Poisson hyperdegree distribution with an average c = 4. Moreover the data ar obtained for $\hat{P}^{\pm}(\kappa)$ with average degree c^{\pm} given by $c^{+} = 2$, $c^{-} = 0$ (panel (a)); $c^{+} = 0$, $c^{-} = 2$ (panel (b)).; $c^{+} = 2$, $c^{-} = 1.5$ (panel (c)).

Thus we will discuss the scenarios in which only positive HOTIs are present, the case in which only negative HO-TIs are present, and the case in which both positive and negative HOTIs are present with non vanishing probability.

1. Higher-order triadic percolation in absence of negative HOTIs

If only positive HOTIs are present, the Eq. 8 determining the regulatory step (Step 2) reduces to

$$p_H^{(t)} = g_p\left(R^{(t)}\right) = p\left(1 - G_0^+\left(1 - R^{(t)}\right)\right).$$
(14)

In this case we cannot have a route to chaos because the map $h_{m,p}(R) = f_m(g_p(R))$ is monotonically increasing with R [50] (see Fig. 3 for an example). Indeed we have

$$h'_{m,p_c}(R) = f'_m(g_p(R))g'_p(R) > 0,$$
(15)

as it can be easily checked that

$$\frac{\partial f_m}{\partial p_H^{(t)}} \ge 0, \quad \frac{\partial g_p}{\partial R^{(t)}} > 0. \tag{16}$$

Specifically, we have that the dynamics reaches a stationary state $R=R^{\star}$ such that

$$R^{\star} = h_{m,p}(R^{\star}) = f_m\left(g_p\left(R^{\star}\right)\right). \tag{17}$$

This stationary state, R^* displays a discontinuous hybrid phase transition between a zero value $R^* = 0$ to a non zero value $R = R^* > 0$ at the critical point $p = p_c$.

The phase transition takes place at $p = p_c$ when the stationary solution $R = R^{\star} = 0$ loses its stability, i.e. when

$$|J| = \left| h'_{m,p_c}(R^*) \right|_{R^* = 0} = 1.$$
(18)

In order to show that the transition is discontinuous an hybrid, consider expand the stationary point equation around the critical point $p = p_c$. Let us indicate with δp the distance from the critical point, i.e. $0 < \delta p = p - p_c \ll 1$ and with δR the corresponding change in the order parameter $0 < \delta R = R^*(p) - R^*(p_c) \ll 1$. Assuming that $h_{m,p}(R)$ is differentiable up to the second order at $R_c = R^*(p_c)$, we can expand Eq. 17 obtaining

$$\delta R = h'_{m,p_c} \left(R_c \right) \delta R + \frac{1}{2} h''_{m,p_c} \left(R_c \right) \left(\delta R \right)^2 + \frac{\partial h_{m,p_c} \left(R_c \right)}{\partial p} \delta p$$

Since $h'_{m,p_c}(R_c) = 1$ at $p = p_c$, we obtain

$$\frac{1}{2}h_{p_c}^{\prime\prime}(R_c)\left(\delta R\right)^2 + \frac{\partial h_{p_c}(R_c)}{\partial p}\delta p = 0.$$
 (19)

Thus since $h_{p_c}''(R_c)$ and $\partial h_{p_c}(R_c)/\partial p$ are finite and have opposite signs, the order parameter R has a square-root singularity for $p \to p_c^+$, i.e.

$$\delta R = R^{\star}(p) - R^{\star}(p_c) \propto (p - p_c)^{1/2}$$
(20)

indicating that the transition is hybrid. Our theoretical predictions perfectly match our simulation results (see Fig. 4). In particular we have considered a random hypergraph with fixed hyperedge cardinality m (i.e. with $Q(m') = \delta_{m',m}$ and Poisson distribution P(k) and $\hat{P}(\kappa)$. The hypergraph with larger hyperedge cardinality m is more robust and displays simultaneously a lower critical threshold p_c , and a smaller discontinuity $R^*(p_c)$ (see Fig. 4(b)). This result is in line with the result on simple hyperedge percolation [14], where hypergraphs with larger hyperedge cardinality m are more robust, albeit in that case the percolation transition is continuous.

2. Higher-order triadic percolation in absence of positive HOTIs

In this paragraph, we consider the other limiting case in which HOTP includes only negative HOTIs. In this

FIG. 4. Phase diagram of random hyperedge percolation in absence of negative HOTIs. Panel (a) shows the size of the giant component R as a function of p_H . Solid lines indicate theoretical predictions (Eq. 6 - Eq. 8) symbols indicate the results of Monte Carlo simulations. Panel (b) shows the numerical calculation of critical threshold p_c and the non-trivial fixed point $R^*(p_c)$ at $p = p_c$ as a function of the hyperedge cardinality m. The Monte Carlo simulations are performed on hypergraphs with HOTI having $N = 10^5$ nodes. The structural hypergraph has hyperedges of fixed cardinality m and has Poisson hyperdegree distribution P(k) with an average hyperdegree c = 4. The degree distribution $\hat{P}^+(\kappa)$ of is Poisson with an average positive regulatory degree $c^+ = 2$.

case a hyperedge is down-regulated if at least one of is negative regulator nodes is active. This scenario can be interpreted as HOTP in the limit in which the positive regulatory interactions a very large. Thus in Step 2 of HOTP we substitute Eq. 8 with

$$p_H^{(t)} = pG_0^- \left(1 - R^{(t)}\right).$$
(21)

Indeed, according to our interpretation, this equation can be obtained from Eq. 8 by putting $G_0^+(1-R^{(t)})$ identically equal to zero.

Also in this case, similarly to the precedent limiting case, the map $h_{m,p}(R)$ is monotonic, thus we do not observe a route to chaos (see Figure 3). However, it can be easily show that, differently from the precedent limit-

ing case, in absence of any positive interactions the map $h_{m,p}(R)$ is monotonically decreasing. In fact if we have

$$J = h'_{m,p}(R) = \frac{\partial f_m}{\partial p_H^{(t)}} \frac{\partial g_p}{\partial R^{(t)}} \le 0$$
 (22)

since it can be shown easily that

$$\frac{\partial f_m}{\partial p_H^{(t)}} \ge 0, \quad \frac{\partial g_p}{\partial R^{(t)}} < 0.$$
(23)

It follows that the only critical points of the dynamic equations can be a period-2 bifurcation for J = -1. This can occur at $R^{\star} = 0$ or at $R^{\star} > 0$. Note however that we can additionally also observe continuous phase transitions from a stationary solution $R^{\star} = 0$ to a stationary solution $R^{\star} > 0$. This transition will not occur at a specific value of J, and can occur as long as |J| < 1, condition that ensures the stability of the stationary solution. Indeed the continuous transition occurs whereas the hyperedge percolation equation displays a phase transition, as the change of solutions between $R^{\star} = 0$ and $R^{\star} > 0$ is already encoded in the function $f_m(p_H)$. This happens when the maximum of $p_H = g_p(R)$ which is reached at R = 0 equals to the critical threshold of hyperedge percolation p_H^c provided that |J| < 1 (see Fig. 5.(a)). Interestingly, in this scenario, the threshold for the continuous transitions is independent of the regulatory network and only depends on the structural hypergraph.

The period-2 oscillation emerges when the non-trivial fixed point R^* loses its stability. This happens when $p > p_H^c$ and J = -1 (see Fig. 5(b)). Thus, the tricritical point separating the period-2 oscillation and the continuous transition is reached when

$$J = -1 \quad \text{and} \quad p = p_H^c. \tag{24}$$

Assuming the random structural hypergraph has a Poisson hyperdegree distribution with an average c and a fixed hyperedge cardinality m, the critical threshold of hyperedge percolation is given by [14]

$$p = p_H^c = 1/c(m-1).$$
(25)

Furthermore considering a Poisson regulatory degree distribution $\hat{P}^{-}(\kappa)$ with an average c^{-} we can calculate Jat R = 0, $p_{H} = p_{H}^{c}$ obtaining

$$J = \left. \frac{\partial f_m}{\partial p_H^{(t)}} \right|_{p_H = p_H^c} \left. \frac{\partial g_p}{\partial R^{(t)}} \right|_{R=0} = -2cpc^-.$$
(26)

Thus imposing J = -1 we find that the tricritical point occurs for

$$c^{-} = \frac{m-1}{2}, \quad p = \frac{1}{c(m-1)}.$$
 (27)

For a generalization of this approach to the more complex scenario in which hyperedges are not regulated with probability $\rho_0 > 0$ we refer the reader to Appendix *B*.

FIG. 5. The function $g_p(R)$ and $f_m(p_H)$ of HOTP and their corresponding Cobweb are shown on hypergraphs including only negative HOTIs. The function $g_p(R)$ with p that is below, at, and above the critical threshold p_c of continuous transition (a) and period-2 bifurcation (b) are shown. The structural hypergraphs have Poisson hyperdegree distribution with an average c = 3 and fixed hyperedge cardinality m = 2. The regulatory network is formed exclusively by negative regulations with a Poisson degree distribution $\hat{P}^-(\kappa)$ with an average $c^- = 0.4$ (panel (a)) and $c^- = 0.78$ (panel (b)).

By studying the the iteration of the map $h_{m,p} \circ h_{m,p}(R)$ it can be shown that period-4 bifurcations are not possible. Thus the characterization of the critical properties of HOTP in absence of positive regulation reveals that in this case only period-2 bifurcations and continuous transitions can be observed.

In Fig 6 we compare our theoretical predictions with Monte Carlo simulations performed on hypergraphs with fixed cardinality m and Poisson hyperdegree distribution P(k). From this figure we can observe the presence of two period-2 bifurcations of small value of m which at the tricritical point disappear giving rise to a continuous phase transition, as predicted by our theory (see Fig. 6 (d)). Moreover, also in this case, as in the scenario where only positive regulation are present, we observe that for hypergraph with hyperedges of fixed cardinality m, hypergraphs with larger value of m are more robust. In fact, for larger values of m, the onset of period-2 oscillation occurs at smaller values of p, and collapse of the network (onset of period-2 oscillations or continuous phase transition at R = 0) also occurs at a values of pthat decreases with m.

FIG. 6. The theoretical phase diagrams/orbit diagrams of HOTP with exclusive negative HOTIs are compared to Monte Carlo simulations (panels (a), (b), and (c)). Panel (d) shows the critical points for period-2 bifurcation (dashed line) and continuous transition (solid line) as a function of m. The dashed lines join the solid line at the tricritical point. The structural hypergraph has $N = 5 \times 10^5$ nodes, Poisson hyperdegree distribution P(k) with an average hyperdegree c = 10 and hyperedges with fixed cardinality m = 4 (panel (a)), m = 5 (panel (b)) and m = 6 (panel (c)). The Poisson distribution $\hat{P}^-(\kappa)$ has average degree $c^- = 2.5$.

3. Route to chaos in higher-order triadic percolation

When both positive and negative HOTIs are present, the order parameter of HOTP undergoes a route to chaos in the universality class of the logistic map and HOTP becomes a fully-fledged dynamical process (see Fig. 7). This can be demonstrated by considering the map $R^{(t)} = h_{m,p}(R^{(t-1)})$ and, using the results of Feigenbaumm [49, 50], showing that the map is continuous, unimodal and displays a quadratic maximum conditions that define the logistic map universality class of the route to chaos (see Fig. 3 for an example and Appendix A For a detailed discussion). This phenomenology is in line to what happens for standard triadic percolation [13].

Interestingly, the increase of random deactivation of hyperedges (i.e. the decrease of p) does not result in a monotonic suppression of the giant component. Instead, the order parameter R in some cases displays a non-monotonous behavior as a function of p and reentrant phase transitions (see Fig. 8). This consist on a collapsed state with $R^{(t)} = 0$ for all values of t, observed in a ranges of values of $p \in [p_-, p_+]$, while for $p < p_-$ and for $p > p_+$ the giant component is non zero. The reentrant nature of the phase implies the naïvely not intuitive result that for a higher level of random damage (smaller values of p) the giant component can be restored. Reentrant phase transitions are also observed in correlated multilayer networks [48] and in multilayer networks with extended-range percolation [51], however in all these example the fraction of nodes in the giant component is unique in the thermodynamics limit, while this is an example of a reentrant orbit diagram of percolation. Finally we note that such phenomenon can be also observed on networks, (i.e. for $Q(m) = \delta_{m,2}$), under suitable conditions.

This interesting result can be physically interpreted as follows. The random deactivation of hyperedges has two opposite consequences. The decrease in network connectivity will reduce the number of nodes in the giant component. Meanwhile, the number of active negative regulators is also reduced, resulting in an increasing number of active hyperedges. The dynamics is driven by the competition between these two effects. Therefore, on hypergraphs with a larger number of negative regulators, smaller value of p might result in the activation of more hyperedges and hence might lead to a transition between an inactive state without giant component to an active state with non-zero giant component and a non-trivial dynamics.

Let us provide the theoretical understanding for the occurrence of the reentrant collapsed phase. Specifically, let us investigate the conditions for observing a non-trivial dynamics of the order parameter. In order to illustrate the argument, let us consider a continuous unimodal map $h_{m,p}(R)$ (see Fig. 9) with maximum \tilde{R} having compact support on a proper subinterval of [0, 1]. Furthermore, let us assume that the map has two fixed points of $R = h_{m,p}(R)$ denoted $\underline{R^*}$ and $\overline{R^*}$ with $\underline{R^*} < \overline{R^*}$

FIG. 7. In presence of both positive and negative HOTIs, the phase diagram of HOTP reduces to an orbit diagram displaying a route to chaos in the universality class of the logistic map. Panel (a) displays the theoretical prediction of this orbit diagram and panel (b) displays the results of Monte Carlo simulations. The structural hypergraph has $N = 10^6$ nodes, hyperedges of fixed cardinality m = 10 and Poisson hyperdegree distribution P(k) with an average hyperdegree c = 10. The Poisson degree distribution $\hat{P}^{\pm}(\kappa)$ with an average $c^+ = 3$ and $c^- = 5.5$.

where $\underline{R^{\star}}$ is an unstable fixed point. Let us denote with \overline{R} the value of R with $R > \underline{R^{\star}}$ satisfying $h_{m,p}(\overline{R}) = \underline{R^{\star}}$. This scenario is consistent for example (see Fig. 9) with the properties of the map $h_{m,p}(R)$ for a random hypegraph with Poisson hyperdegree distribution P(k) with average hyperdegree c and constant hyperedge cardinality m where the regulatory degree distribution $\hat{P}(\kappa^{\pm})$ are Poisson distributions with averages c and c^{\pm} respectively. In this case the function $h_{m,p}(R)$ has a unique maximum at $R = \tilde{R}$ at

$$\tilde{R} = -\frac{1}{c^+} \log \frac{c^-}{c^+ + c^-}.$$
(28)

Moreover $\partial h/\partial R|_{R=\underline{R^{\star}}} > 1$, thus $\underline{R^{\star}}$ is an unstable fixed point, while $\partial h/\partial R|_{R=\overline{R^{\star}}} < 1$, thus $\overline{R^{\star}}$ is a stable fixed point.

FIG. 8. We provide two examples of orbit diagrams showing the reentrant phase transition on HOTP, which the hypergraph can be re-activated by decreasing the value of p, i.e. increasing the probability of random deactivation of the hyperedges. Panels (a) and (b) show two examples of theoretical orbit diagrams of HOTP displaying the reentrant phase transition. Panels (c) and (d) show the orbit diagrams obtained by implementing the corresponding Monte Carlo simulations. Panels (e) and (f) reveals that Eq. 30, i.e. the intersection between the curve $y = h_{m,p}(h_{m,p}(\tilde{R})) - R^*$ and the orange dash line indicates y = 0, provides the correct prediction of the value of p at which the either the hypergraph collapse of the reentrant phase transition are observed. In both examples, the structural hypergraph has $N = 5 \times 10^5$ nodes, Poisson hyperdegree distribution P(k) with average c = 30 and hyperedges with fixed cardinality given by m = 2 (in panels (a),(c),(e) and m = 3 (in panels (b),(d),(f)). The Poisson degree distributions $\hat{P}^{\pm}(\kappa)$ have average positive and negative regulatory degree given by $c^+ = 1, c^- = 2.9$ (in panels (a),(c),(e)); and $c^+ = 1, c^- = 4$ (in panels (b),(d),(f)).

Under the stated conditions of the map $h_{m,p}$, if $R > \overline{R}$ or $R < \underline{R^{\star}}$, the dynamics will converge to the trivial collapsed state. In order to observe a non-trivial dynamics the interval $(\underline{R^{\star}}, \overline{R})$ must be mapped onto this itself under the action of the map $h_{m,p}$. Therefore, the condition for having non-trivial dynamics is given by

$$h_{m,p}(\dot{R}) < \overline{R},\tag{29}$$

or using $h_{m,p}(\overline{R}) = \underline{R^{\star}},$

$$h_{m,p}(h_{m,p}(\tilde{R})) > \underline{R^{\star}}.$$
(30)

A graphic illustration can be found in Fig. 9.

In Fig. 8 (c) and (d) we show two examples in which the reentrant collapsed state is observed. In panels (e) and (f) we examine the condition of having a non-trivial

FIG. 9. A graphic illustration of the critical condition for having a non-trivial giant component in HOTP. The blue curve indicates function $h_{m,p}(R)$ and the orange line indicates f(R) = R. The red line shows the dynamic of iterating from initial condition $R = \tilde{R}$.

dynamics for corresponding cases. We reveal that the collapsed state emerge exactly when the mentioned condition is fulfilled.

IV. HIERARCHICAL HIGHER-ORDER TRIADIC PERCOLATION

Higher-order triadic interactions can be hierarchically nested, as discussed in Sec. II B 2. This leads to hierarchical higher-order triadic percolation (HHOTP) where the regulatory interactions of the hyperedges can be further regulated by a hierarchy triadic interactions (see Fig. 1). These hierarchical triadic interactions (HHOTIs) are for instance observed in ecological networks [28].

Assuming that the nested HHOTIs regulate the interactions simultaneously, we define the HHOTP by a two steps iterative dynamics, which differs from the dynamics of HOTP only by a modification of Step 2. Indeed Step 2 becomes

Step 2': A hyperedge is down-regulated if

- (a) it is regulated by at least one active negative regulator and/or is not regulated by any active positive regulator via active regulatory interactions in $W^{[1]}$, and it is considered active otherwise. All other hyperedges are deactivated with probability 1 - p.
- (b) An active regulatory interaction in $W^{[\mu]}$ requires that it is not down-regulated by regulatory interactions in $W^{[\mu+1]}$.

According to this rule, the probability of retaining a

FIG. 10. The dependence of the order parameter R of HHOTI versus p is shown for hypegraphs having exclusively positive HHOTIs. S Panel (a) shows the dependence of the phase diagram with the number of hierarchical layers L, panel (b) shows the dependence with the value m of the hyperedge cardinality. Solid lines indicate theoretical predictions symbols indicate the results of Monte Carlo simulations on hypergraphs of $N = 5 \times 10^4$ nodes. The structural hypergraphs have a Poisson hyperdegree distribution P(k) with an average c = 2 and hyperedges of fixed cardinality m (m = 8 in panel (a)). The regulatory network is formed exclusively by positive regulations and has a Poisson regulatory degree with an average $c^+ = 2.5$ (panel (a)) and $c^+ = 5$ (panel (b)).

hyperedge is given by

$$p_{H}^{(t)} = pG_{0}^{-} \left(1 - p_{H,[2]}^{(t)}R^{(t)}\right) \times \left(1 - G_{0}^{+} \left(1 - p_{H,[2]}^{(t)}R^{(t)}\right)\right),$$

$$p_{H,[\mu]}^{(t)} = G_{0,[\mu]}^{-} \left(1 - p_{H,[\mu+1]}^{(t)}R^{(t)}\right) \times \left(1 - G_{0,[\mu]}^{+} \left(1 - p_{H,[\mu+1]}^{(t)}R^{(t)}\right)\right) \quad (31)$$

for $\mu \in \{2, \ldots, L\}$ with $p_{H,[L+1]} = 1$. Note that here the generating function $G_{0,\ell}^{\pm}(x)$ is given by Eq. 4. These equations that implement Step 2' can be encoded into a map

$$p_H^{(t)} = g_p\left(R^{(t)}\right),\tag{32}$$

FIG. 11. Illustrative examples of the map $h_{m,p}(R)$ representing the HHOTP dynamics for specific values of p are plotted in the first and third row together with the identity line (dashed) whose intersection with the map indicates the fix point $R^* = h_{m,p}(R^*)$. The corresponding theoretical phase diagrams/orbit diagrams of HHOTI are plotted in the second and fourth row. Panel (a) shows the HHOTP with exclusive positive regulations. Panels (b), (c), (g) and (h) show the HHOTP with exclusive negative regulations, and panel (i) shows an example of the general case with both positive and negative regulations. The different panels correspond to different phase transitions: a discontinuous transition (d, f), a continuous transition (e), a period-2 bifurcations (j) and a route to chaos (k,l). The random hypergraphs have a Poisson hyperdegree distribution with an average c and a Poisson regulatory degree distribution with an average c^+ and c^- for all layers. The hyperedges have a fixed cardinality m. The hierarchical regulations have L layers. The parameters used in the figure are: c = 3, $c^+ = 5$, m = 5, L = 10(panel (a)), c = 5, $c^- = 3$, m = 10, L = 2 (panel (b)), c = 3, $c^- = 10$, m = 2, L = 50 (panel (c)), c = 3, $c^- = 2$, m = 2, L = 4(panel (j)), c = 3, $c^- = 5$, m = 3, L = 100 (panel (k)), c = 30, $c^+ = 20$, $c^- = 30$, m = 10, L = 10 (panel (l)).

while the equations that implement Step 1 remain the same as for HOTP and obey Eq. 9, i.e. they are given by $R^{(t)} = f_m \left(p_H^{(t-1)} \right)$. Thus we obtain that the dynamics

of HHOTP can be encoded in a one-dimensional map

$$R^{(t)} = h_{m,p}(R^{(t-1)} = f_m(g_p(R^{(t-1)})).$$
(33)

This map, in presence of negative regulations is no longer unimodal, thus HHOTP displays a phenomenology that is significantly different from HOTP and displays a route to chaos that is not any longer in the universality class of the logistic map. Here we discuss the rich phenomenology of this complex dynamical process by considering first the simple case in which only positive regulations are present, then the case in which only negative regulations are present and finally the general case in which both positive and negative regulations are present with nonzero probability.

When only positive regulations are present, similarly to what happens for HOTP under the same conditions, HHOTP displays a discontinuous hybrid transition. In order to illustrate this phenomenology in a simple case we consider a random hypergraph with fixed hyperedge cardinality m, a Poisson hyperdegree distribution P(k), and Poisson regulatory degree distribution $\hat{P}_{[\mu]}(\kappa^{\pm})$ of a same average degree across all layers. In this scenario we observe that the hypergraphs with a larger hyperedge cardinality m and a smaller number of regulatory layers L are more robust, as indicated by their lower critical percolation threshold p_c , and their smaller discontinuity $R^*(p_c)$ (see Fig. 10).

When only negative regulations are present, HHOTP displays a rich phenomenology and the nature of the dynamics changes drastically with respect to HOTP. We recall that when only negative regulations are present, HOTP displays either continuous transitions or period-2 oscillations. On contrast, HHOTP can display continuous transitions, discontinuous hybrid transitions, periodic oscillations, and chaos (see Fig. 11). Specifically, as long as there negative regulatory interactions and more than one layers, i.e. L > 1, the map $h_{m,p}(R)$ can have multiple local maxima and minima in general, and the order parameter of HHOTP undergoes a route to chaos no longer in the universality class of the logistic map (see Fig. 11).

V. GENERALIZATIONS

A. Interdependent higher-order triadic percolation (IHOTP)

The connectivity of hypergraphs can be probed not only with hypergraph percolation resulting from the random deactivation of hyperedges, but also with several other higher-order percolation processes [14], in which the activation of a hyperedge requires, in addition to the regulatory rules, also cooperation among all nodes that belong to it.

In interdependent hyperedge percolation the interdependent hypergraph giant component is the extensive connected component whose nodes and hyperedges satisfy the following recursive self-consistent conditions.

• A node is in the giant component if it belongs to at least one hyperedge that is in the interdependent hypergraph giant component.

- A hyperedge is in the giant component if
 - (i) it is not deactivated,
 - (ii) *all its nodes* belong to the interdependent hypergraph giant component.

Note that the difference with the hypergraph giant component is in the requirement (ii) for the hyperedge to be active, which imposes that *all* but not *at least one* of the nodes belonging to the hyperedge are in the interdependent hypergraph giant component.

Here we define interdependent higher-order triadic percolation (IHOTP) which generalizes HOTP. As HOTP, IHOTP is defined in terms of a two step iterative process, the first step implementing percolation of the structural hypergraph and the second step implementing regulation of the hyperedges. The difference among HOTP and IHOTP is that in Step 1 of IHOTP we consider interdependent hyperedge percolation instead of simple hyperedge percolation. Specifically, in IHOTP Step 1 of the iterative algorithm is modified as:

• Step 1': Given the set of active hyperedges at time t - 1, a node is considered active if it is in the interdependent hypergraph giant component.

Step 2 of IHOTP is instead the same as for HOTP. It follows that at time t the dynamical equations implementing Step 1 in IHOTP are given by the equations [14] determining the size of the interdependent hypergraph giant component $R^{(t)}$ when hyperedges are intact with probability $p_H^{(t-1)}$, i.e.

$$\hat{S}^{(t)} = p_H^{(t-1)} G_{1,m}(S^{(t)}),
S^{(t)} = 1 - G_1(1 - \hat{S}^{(t)}),
R^{(t)} = 1 - G_0(1 - \hat{S}^{(t)}).$$
(34)

The equation determining the regulation process occurring at Step 2 is unchanged with respect to HOTP and is given by Eq. 8 that we rewrite here for convenience,

$$p_H^{(t)} = pG_0^- \left(1 - R^{(t)}\right) \left(1 - G_0^+ \left(1 - R^{(t)}\right)\right).$$
(35)

We observe that interdependent hyperedge percolation is significantly different from hyperedge percolation, and can undergo a discontinuous phase transition [14]. Interestingly, the discontinuous nature of the percolation transition in interdependent hyperedge percolation dramatically changes the nature of the dynamics in IHOTP. In particular, for certain parameter values, the IHOTP cannot admit a complete route to chaos and can only display steady states or period-2 oscillation.

In order to provide concrete evidence of the effect due to the discontinuous hybrid transition of interdependent hyperedge percolation on the dynamical properties of IHOTP, let us again write Eq. 34 and Eq. 35 in the form of one-dimensional maps

$$R^{(t)} = f_m\left(p_H^{(t-1)}\right), \quad p_H^{(t)} = g_p\left(R^{(t)}\right), \quad (36)$$

FIG. 12. The effect due to the discontinuous hybrid transition of interdependent hyperedge percolation on the dynamical properties of IHOTP. The figure displays the maps $g_p(R)$, $f_m(p_H)$ determining Step 1 and Step 2 of the IHOTP dynamics (panels (a)-(c)), the one-dimensional map $h_{m,p}(R) = f_m(g_p(R))$ encoding for the combined Step 1 and Step 2 dynamics (panels (d)-(f)) and their corresponding phase diagrams/orbit diagrams (panels (g)-(i)). The paneld correspond to parameter values in which the interdependent hyperedge percolation (function $R = g_p(p_H)$) displays either a continuous (panels (a)-(d)-(g)) or a discontinuous phase transition (panels (b),(c),(e),(f),(h),(i)). In panels (a)-(f) the dashed line indicate either the discontinuous jump of intedependent percolation (panels (a)-(c)) or the values of R that cannot be reached by the IHOTP dynamics (panels (d)-(f)). The horizontal line in panels (a)-(c) shows the value $R = \tilde{R}$ at which the function $p_H = g_p(R)$ reaches its local maximum. The structural hypergraphs have Poisson hyperdegree distribution with average hyperdegree c = 10 and hyperedges with cardinality distribution Q(m) given by Eq. 38. Here r indicates the ratio between the number of hyperedges of cardinality m = 2 and the number of hyperedges of cardinality m = 3. The hypergraphs have regulatory degree distributions with average degrees $c^+ = 4$ and $c^- = 4.5$. The adopted value of r are r = 1 (panels (a),(d),(g)), r = 0.6 (panels (b),(e),(h)) and r = 0.4 (panels (c),(e),(i)). The critical value of $r = r_H^c$ of this model is $r_H^c = 2/3$ see Eq. 40. Panels (a)-(f) are plotted for p = 0.6.

and let us adopt again the notation

$$R^{(t)} = h_{m,p}(R^{(t-1)}) = f_m(g_p(R^{(t-1)})).$$
(37)

We consider structural hypergraphs with a Poisson hyperdegree distribution P(k) with average hyperdegree c and hyperedges of cardinality given either by m = 2 or m = 3. Specifically we consider the cardinality distribution Q(m) given by

$$Q(m) = q_2 \delta_{m,2} + q_3 \delta_{m,3}, \tag{38}$$

where we denote with r the ratio between the number of hyperedges of cardinality m = 2 and the number of hyperedges of cardinality m = 3, i.e. $r = q_2/q_3$. It is known [14] that in this ensembles of hypegraphs, interdependent hypergraph percolation displays a tricritical point at $r = r_H^c$, $p = p_H^c$ given by

$$r_H^c = 2/3, \quad p_H^c = 3/2c.$$
 (39)

For $r > r_H^c$ interdependent hypergraph percolation displays a continuous percolation transition while for $r < r_H^c$ the model displays a discontinuous percolation transition.

It is thus instructive to investigate the behavior of IHOTP in this scenario (see Fig. 12). Recall that the dynamics of IHOTP encoded in the map $h_{m,p}(R)$ defined in Eq. 37 is initialized as that at time t = 0, when all hyperedges are active with probability p_{H}^{0} . When the percolation transition is discontinuous, there will be an

interval of values of R from 0 to a finite value \mathcal{R} that is not physical, i.e. cannot be achieved (see Fig. 12(b) and (c)). Thus the corresponding map $h_{m,p}(R)$, is not defined in the entire range [0,1] as it does not have compact support (see Fig. 12 (e) and (f)). This effect significantly changes the dynamical properties of IHOTP. In particular the map $h_{m,p}(R)$ might no longer display a local maximum. As discussed in the case of HOTP, (see Appendix A) in the situation in which $f_m(p_H)$ is a continuous function, i.e. when the percolation transition is continuous, the map $h_{m,p}(R)$ displays a local maximum for $R = \tilde{R}$ where $g'_p(\tilde{R}) = 0$. Therefore the position of this maximum is independent of the percolation process under consideration. Specifically, for Poisson positive and negative regulatory degree distributions with averages c^+ and c^- we have that R is given by Eq. 28 as for HOTP. When the considered percolation process displays instead a discontinuous phase transition at $p = p_c$ with a discontinuous jump $R = \mathcal{R}$ we cannot observe a local maximum of the map $h_{m,p}(R)$ as long as

$$\mathcal{R} > \tilde{R}.\tag{40}$$

In addition, to have a non-trivial dynamic, there must be at least one fixed point satisfying $R = h_{m,p}(R)$. Therefore \mathcal{R} should further satisfy

$$\mathcal{R} < \max g_p^{-1}(p_c). \tag{41}$$

The critical value of r at which we have $\mathcal{R} = \tilde{R}$ is here indicated as $r = r_c$. Thus for $r < r_c$ we cannot observe a route to chaos of the order parameter of IHOTP and only stationary states and period-2 oscillations are allowed. In Fig. 16 we show that r_c is an increasing function of the average negative regulatory degree c^- . This can be explained as follows. First we observe that \tilde{R} given by (Eq. 28) is a decreasing function of c^- . This indicates that a smaller discontinuity of the interdependent percolation order parameter will be enough to impede the route to chaos. Thus this it is consistent with the monotonically increasing behavior of r_c as a function of c^- .

B. Generalization to regulated nodes

An important generalization of HOTP is higher-order node dynamic percolation (HONDP) where the nodes are regulated instead of the hyperedges. In the context of networks, the regulation of the nodes instead of the edges has been already considered in Ref. [13] where it was demonstrated that this generalization of triadic percolation still leads to a route to chaos of the order parameter. Here we explore HONDP on hypergraphs emphasizing the peculiar properties of this dynamical percolation process. First of all we observe a major difference between regulating hyperedges and regulating nodes: while hyperedges allows can be hierarchically regulated, nodes cannot. Thus we cannot define the node-regulation version of HHOTP. The second observation that we make is that

FIG. 13. The critical value r_c (satisfying Eq. 40) of the fraction between the number of hyperedges of cardinality m = 2 and the number of hyperedges of cardinality m = 3, is plotted as a function of the average negative regulatory degree c^- . Thus if if $r < r_c$ a route to chaos cannot be observed in IHOTP. The plot is obtained by considering a random hypergraph with Poisson hyperdegree distribution with an average hyperdegree c = 5, cardinality distribution Q(m) given by Eq. 38 and the regulatory interactions have a Poisson distribution with an average $c^+ = 5$ and c^- .

HONDP admits two formulations that depend on the higher-order nature of the hypergraph and have no correspondence in HOTP. Indeed in hypergraphs, the effect of down-regulating a hyperedge is deterministic: it simply deactivates the hyperedge. Instead down-regulating a node can lead to two possible consequences. In hyperedge percolation [14] with random deactivation of the nodes, all the hyperedges involving the down-regulated nodes will reduce their cardinality by one. For instance, in social networks, a meeting can continue to take place also if one participant leaves. Alternatively, down-regulating a node might lead to deactivation of all the hyperedges the node belongs to [52]. This for instance occurs in chemical reactions where if a reactant is missing the reaction cannot take place. Here we call this process cooperative hypergraph percolation (CHP) (see Fig. 14 and Ref. [19] for further details). According to these two definitions of node hypergraph percolation, we can define two versions of HONDP.

The dynamics of HONDP is defined as follows. At time t = 0, every node is active with probability p_H^0 . For $t \ge 1$:

- Step 1: Given the set of active nodes at time t − 1, a node is considered active at time t if it is not deactivated at time (t − 1) and if he belongs to the giant component of (a) hyperedge percolation or (b) cooperative hyperedge percolation.
- Step 2: A node is deactivated if it is regulated by at least one active negative regulator and/or is not regulated by any active positive regulator and it is considered active otherwise. All other nodes are deactivated with probability 1 p.

For completeness recall here the definition of the giant component in hyperedge percolation and in cooperative hypergraph percolation with regulation of the nodes.

FIG. 14. Schematic diagrams demonstrating the effect of node down-regulation in simple and in cooperative node hyperedge percolation. Panel (a) shows a hypergraph. Panel (b) shows the effect of node deactivation in simple node hyperedge percolation. When a node is removed (deactivated), the cardinality of the hyperedges it belongs to decreases. Panel (c) shows the effect of node deactivation in cooperative node hyperedge percolation. When a node is deactivated, all hyperedges it belongs to are also deactivated.

The equations determining the size of the giant component $R^{(t)}$ given the probability $p_N^{(t-1)}$ that the nodes are active depend on the considered percolation process. In the case (a) Step 1 implements hyperedge percolation with regulation of the nodes. In this model nodes and hyperedges satisfy the following self-consistent and recursive conditions [14].

- A node is in the giant component if it
 - (i) it is not down-regulated,
 - (ii) belongs to at least one hyperedge that is in the hypergraph giant component.
- A hyperedge is in the giant component if it includes at least one node that is in the hypergraph giant component.

The equations for hypergraphs [14] can be used to obtain the size of the giant component $R^{(t)}$ at of HONDP at time t given the probability $p_N^{(t-1)}$ that nodes are not down-regulated at time t-1. These equations are given by:

$$\hat{S}^{(t)} = \left[1 - G_{1,m}(1 - S^{(t)})\right],$$

$$S^{(t)} = p_N^{(t-1)} \left[1 - G_1(1 - \hat{S}^{(t)})\right],$$

$$R^{(t)} = p_N^{(t-1)} \left[1 - G_0(1 - \hat{S}^{(t)})\right].$$
(42)

In case (b) Step 1 implements cooperative hypergraph percolation [52]. In cooperative hyperedge percolation, nodes and hyperedges that are in the giant component satisfy the following self-consistent relationship:

- A node is in the giant component if
 - (i) it is not down-regulated with probability p_N ,
 - (ii) it is connected to at least one hyperedge that is in the giant component.
- A hyperedge is in the giant component if
 - (i) *all its nodes* are not deactivated by regulatory interactions,
 - (ii) at least one of its node are in the giant component.

We thus have that the equations determining the size of giant component $R^{(t)}$ of HONDP at time t are given by [52]

$$\hat{S}^{(t)} = \sum_{m} \frac{mQ(m)}{\langle m \rangle} \left(p_{N}^{(t-1)} \right)^{m-1} \left[1 - (1 - S^{(t)})^{m-1} \right],$$

$$S^{(t)} = 1 - G_{1}(1 - \hat{S}^{(t)}),$$

$$R^{(t)} = p_{N}^{(t-1)} \left[1 - G_{0}(1 - \hat{S}^{(t)}) \right].$$
(43)

In both cases Step 2 is enforced by the equation implementing the regulation of the nodes, and thus expressing the probability $p_N^{(t)}$ that a node is active as a function of the probability $R^{(t)}$ that its regulator nodes are in the giant component at Step 1, which is given by,

$$p_N^{(t)} = pG_0^- \left(1 - R^{(t)}\right) \left(1 - G_0^+ \left(1 - R^{(t)}\right)\right).$$
(44)

If the hypergraph reduces to a network, i.e. if $Q(m) = \delta_{m,2}$, both versions reduce to the dynamical percolation model with node regulation introduced in Ref. [13].

The dynamics of HONDP, as the dynamics of HOTP, is described by a percolation order parameter $R = R^{(t)}$ that, in presence of both positive and negative regulatory interactions undergoes a route to chaos in the universality class of the logistic map, in both versions of the model. To show this, let us adopt the same notation as for HOTP, and express the results of Step 1 given by the Eqs. 42 in case (a) and Eqs. 43 in case (b) as

$$R^{(t)} = f_m(p_N^{(t-1)}), (45)$$

while we express the Eq. 44 implementing Step 2 as

$$p_N^{(t)} = g_p(R^{(t)}).$$
 (46)

With this notation, the dynamics of HONDP can be reduced to the one dimensional map

$$R^{(t)} = h_{m,p}(R^{(t-1)}) = f_m\left(g_p\left(R^{(t-1)}\right)\right).$$
(47)

As for HOTP, also for HONDP this map is continuous and since the function $f_m(R)$ is monotonous, the map $h_{m,p}(R)$ displays a maximum only when the function $p_N = g_p(R)$ displays a maximum. This implies that only if both negative and positive regulatory interactions are present with finite probability, HONDP displays a route to chaos of its order parameter.

In order to illustrate some specific properties of HONDP we consider here the limiting case in which there are only positive regulations. In this scenario, similary to what we have previously discussed for HOTP, HONDP displays exclusively discontinuous hybrid transitions.

We first compare case (i) of HONP with HOTP. In both cases Step 1, implements hypergraph percolation, however in HONDP the nodes are upregulated with probability p_N , while in HOTP the hyperedges are upregulated with probability p_H . Interestingly, when regulatory interactions are not present, i.e. $p_N = p_H = p$, hypergraph percolation with deactivation of nodes and hypergraph percolation with deactivation of hyperedges displays a continuous phase transition at the same critical threshold [14]. However, in the presence of exclusive positive regulatory interactions, HONDP (i) and HOTP display discontinuous transitions and HONDP (i) has a larger critical threshold than HOTP, indicating a less robust giant component (see Fig. 15).

Secondly we compare the properties of case (a) and case (b) HONDP and we observe that when the hyperedge cardinality is constant, and is given by m, these two models have different responses to the increase on m. Both percolation processes display a discontinuous phase transition, but the critical threshold of monotonically decreasing with m in case (a) where Step 1 is defined in terms of the hyperedge percolation process, while is and increasing function of m in case (b) where Step 2 is defined in terms of the cooperative hyperedge percolation process (see Figure 16). This different behavior is inherently related to the different nature of the two models as the rules of cooperative hyperedge percolation are determining the increased fragility of hypergraphs with hyperedges of larger cardinality.

VI. CONCLUSION

In this study, we propose a comprehensive theoretical framework that merges percolation theory with nonlinear dynamics to examine hypergraphs featuring a timevarying giant component. In higher-order triadic percolation (HOTP) the dynamics is orchestrated by higherorder triadic interactions (HOTIs) that can upregulate or downregulate hyperedges turning percolation into a fullyfledged dynamical process. Specifically, the order parameter of HOTP, indicating the fraction of nodes in the giant component, undergoes, in the most general scenario, period-doubling and a route to chaos. Here we provide an in depth study of the critical behavior of this model characterizing the emergence of discontinuous transition when only positive HOTIs are allowed; the emergence of both continuous and discontinuous phase transitions connected by tricritical points when only negative HOTIs are allowed; and proving that, in presence of both positive

FIG. 15. Panel (a) provides a comparison among the phase diagram of ordinary hypergraph percolation with node deactivation, indicated here as node percolation (NP) and with hyperedge deactivation, indicated here as hyperedge percolation (HP). Panel (b) provides a comparison among the phase diagram of HOTP and HONDP. Solid lines indicate theoretical predictions, symbols indicate Monte Carlo simulations conducted on hypergraphs of $N = 10^4$ nodes. The structural hypergraph has a Poisson hyperdegree distribution P(k) with an average hyperdegree c = 4 and the hyperedges with fixed cardinality m = 5. In panel (b) the positive regulatory interactions have a Poisson distribution with an average $c^+ = 4$ while negative regulatory interactions are absent.

and negative HOTIs, the order parameter of HOTP undergoes a route to chaos in the universality class of the logistic map.

Higher-order triadic interactions, however, can also be hierarchically nested giving rise to hierarchical higherorder triadic interactions (HHOTIs) that have been observed for instance in ecological networks. In this scenario, it is important to consider a relevant variation of HOTP that we call hierarchical higher-order triadic percolation (HHOTP). Due to the improved combinatorial complexity of the regulatory interactions allowed in this scenario, we observe that the critical properties of HHOTP can be significantly more complex than those of HOTP. Among the most relevant differences between the two models we mention two. First, HHOTP can display a route to chaos of the order parameter also when only negative HHOTIs are allowed. Secondly, the route

FIG. 16. Phase diagrams of HONDP in case (a) implementing simple node hyperedge percolation (panel (a)) and in case (b) implementing cooperative node hyperedge percolation (panel (b)) for hypergraphs with hyperedges of fixed cardinality mand in absence of negative node regulations. The numerical predictions (solid lines) obtained from Eq. 42 and Eq. 43) are compared with Monte Carlo simulations (symbols). In both cases we observe a discontinuous hybrid transition, however in case (a) the percolation threshold decreases with increasing values of m while in case (b) it increases. This demonstrates that while in case (a) HODNP the hypergraphs become more robust by increasing the value of m in case (b) HODNP the hypergraphs become more fragile. The considered structural hypergraph has $N = 10^5$ nodes and a Poisson hyperdegree distribution P(k) with an average hyperdegree c = 6. The Poisson degree distribution $\hat{P}^+(\kappa)$ has average positive regulatory degree $c^+ = 4$ while the negative regulations are absent.

to chaos associated to HHOTP is not generally in the universality class of the logistic map.

We conclude our work presenting two other generalizations of HOTP: interdependent higher-order triadic percolation (IHOTI) and higher-order node dynamic percolation (HONDP).

The underlying percolation process in IHOTI is the cooperative hypergraph percolation which already displays a discontinuous percolation transition in absence of HO-TIs. This impedes the route to chaos of the order parameter for certain parameter values, where only stationary states of period-2 oscillations of the order parameter can be observed.

In HONDP we do not have HOTIs regulating the hyperedges, but only interactions up-regulating or downregulating the nodes. In this case hierarchical regulation is not possible, we can consider however different underlying percolation processes: the hypergraph percolation with random deactivation of the nodes (case(a)); and cooperative hypergraph percolation (case (b)) which imposes that all the nodes of a hyperedge must be intact for a hyperedge to be intact. The dynamics of HONDP displays interesting effects of the regulatory interactions that are peculiar to the model and distinct from that observed when the hyperedges are regulated by HOTIs.

In conclusion, this work provides a comprehensive framework for studying hypergraphs with time-varying connectivity, revealing the complex interplay between higher-order network structures and their dynamics. The results might shed light on the dynamics of climate networks, biological and brain networks.

Appendix A: Universality class of the route to chaos associated with HOTP

In this Appendix our aim is to determine the universality class associated to the route to chaos associated with HOTP. A classic result of chaos theory is that an unimodal continuous one-dimensional map undergoes a route to chaos in the universality class of the logistic map if it has a uniquely differentiable quadratic maximum [49, 50].

The map $h_{m,p}(R)$ determining the dynamics of HOTP is unimodal and displays a maximum at $R = \tilde{R}$ obeying

$$\left. \frac{\partial h_{m,p}(R)}{\partial R} \right|_{R=\tilde{R}} = 0.$$
 (A1)

Here we want to show that the map $h_{m,p}(R)$ around R =

 \hat{R} is quadratic, thus implying that the order parameter R of HOTP undergoes a route to chaos in the universality class of the logistic map. Specifically our aim is to show that for $|\delta R| \ll 1$ we have

$$h_{m,p}(\tilde{R} + \delta R) - h_{m,p}(\tilde{R}) \simeq \frac{1}{2} h_{m,p}''(\tilde{R}) (\delta R)^2.$$
 (A2)

In order to derive this scaling behavior, let us write the derivative explicitly. Starting from the self-consistent equations

$$\begin{aligned} R^{(t)} &= 1 - G_0(1 - \hat{S}^{(t)}) = F_1\left(\hat{S}^{(t)}\right), \\ \hat{S}^{(t)} &= p_H^{(t-1)}\left[1 - G_{1,m}(1 - S^{(t)})\right] = F_2\left(p_H^{(t-1)}, S^{(t)}\right), \\ S^{(t)} &= 1 - G_1(1 - \hat{S}^{(t)}) = F_3\left(\hat{S}^{(t)}\right), \\ p_H^{(t)} &= pG_0^-\left(1 - R^{(t)}\right)\left(1 - G_0^+(1 - R^{(t)})\right) = F_4(R^{(t-1)}). \end{aligned}$$

Differentiating the equations for $\hat{S}^{(t)}$ and $p_{H}^{(t-1)}$ we obtain

$$\frac{d\hat{S}^{(t)}}{dR^{(t-1)}} = \frac{\partial F_2}{\partial p_H^{(t-1)}} \frac{\partial F_4}{\partial R^{(t-1)}} + \frac{\partial F_2}{\partial S^{(t)}} \frac{\partial S^{(t)}}{\partial R^{(t-1)}}$$
$$\frac{\partial S^{(t)}}{\partial R^{(t-1)}} = \frac{\partial F_3}{\partial \hat{S}^{(t)}} \frac{\partial \hat{S}^{(t)}}{\partial R^{(t-1)}}.$$

Thus we can express $d\hat{S}^{(t)}/dR^{(t-1)}$ as

$$\frac{d\hat{S}^{(t)}}{dR^{(t-1)}} = \frac{\partial F_2}{\partial p_H^{(t-1)}} \frac{\partial F_4}{\partial R^{(t-1)}} \left(1 - \frac{\partial F_2}{\partial S^{(t)}} \frac{\partial F_3}{\partial \hat{S}^{(t)}}\right)^{-1}$$

We observe that the derivative $h'_{m,p}(R^{(t-1)})$ can be expressed in terms of $d\hat{S}^{(t)}/dR^{(t-1)}$ as

$$h'_{m,p}(R^{(t-1)}) = \frac{dR^{(t)}}{dR^{(t-1)}} = \frac{dF_1}{d\hat{S}^{(t)}} \frac{d\hat{S}^{(t)}}{dR^{(t-1)}}.$$
 (A3)

Thus we obtain

$$h'_{m,p}(R^{(t-1)}) = \frac{dF_1}{d\hat{S}^{(t)}} \frac{\partial F_2}{\partial p_H^{(t-1)}} \frac{\partial F_4}{\partial R^{(t-1)}} \\ \times \left(1 - \frac{\partial F_2}{\partial S^{(t)}} \frac{\partial F_3}{\partial \hat{S}^{(t)}}\right)^{-1}.$$
 (A4)

From this equation, using the fact that

$$\frac{\partial F_1}{\partial \hat{S}^{(t)}} = G'_0 \left(1 - \hat{S}^{(t)} \right) > 0, \tag{A5}$$

$$\frac{\partial F_2}{\partial p_H^{(t-1)}} = \frac{1 - G_{1,m}(1 - S^{(t)})}{1 - p_H^{(t-1)}G'_{1,m}(1 - S^{(t)})G'_1(1 - \hat{S}^{(t)})} > 0,$$

it follows that the map $R^{(t)} = h_{m,p}(R^{t-1})$ has its maximum, at $R = \tilde{R}$ where we have

$$\left. \frac{\partial F_4}{\partial R^{(t-1)}} \right|_{R^{(t-1)} = \tilde{R}} = 0.$$
 (A6)

This implies that the map $h_{m,p}(R)$ admits a maximum only if the equations implementing the regulatory step are not monotonic, i.e. $p_H^{(t)}$ is not a monotonic function of $R^{(t-1)}$. Thus this implies that both positive and negative HOTIs need to be present with a non vanishing density. In order to prove that the maximum $R = \tilde{R}$ is quadratic, we consider the second derivative of the map

$$\begin{split} h_{m,p}''(R^{(t)}) &= \frac{d^2 R^{(t)}}{d(R^{(t-1)})^2} \\ &= \frac{dF_1}{d\hat{S}^{(t)}} \frac{d^2 \hat{S}^{(t)}}{d(R^{(t-1)})^2} + \frac{d^2 F_1}{d(\hat{S}^{(t)})^2} \left(\frac{d\hat{S}^{(t)}}{dR^{(t-1)}}\right)^2. \end{split}$$

Specifically we are interest in proving that the sign of $h''_{m,p}(R^{(t)})$ is negative for $R = \tilde{R}$. Since, for $R = \tilde{R}$ we have $\partial F_4 / \partial R^{(t-1)} = d\hat{S}^{(t)} / dR^{(t-1)} = 0$ we obtain

$$h_{m,p}''(R^{(t)}) = \frac{dF_1}{d\hat{S}^{(t)}} \frac{\partial F_2}{\partial p_H^{(t-1)}} \frac{\partial^2 F_4}{\partial (R^{(t-1)})^2} \left(1 - \frac{\partial F_2}{\partial S^{(t)}} \frac{\partial F_3}{\partial \hat{S}^{(t)}}\right)^{-1}$$

where we have used that

$$\frac{d^2 \hat{S}^{(t)}}{d(R^{(t-1)})^2} = \frac{\partial F_2}{\partial p_H^{(t-1)}} \frac{\partial^2 F_4}{\partial (R^{(t-1)})^2} \left(1 - \frac{\partial F_2}{\partial S^{(t)}} \frac{\partial F_3}{\partial \hat{S}^{(t)}}\right)^{-1}$$

This equation implies that, given the inequalities (A5), the sign of $h''_{m,p}(\tilde{R})$ depends only on the form of $\partial^2 F_4/\partial (R^{(t-1)})^2$. In particular, the map $h_{m,p}(R)$ will always have a quadratic maximum . This demonstrates that the map $h_{m,p}(R)$ will always have a quadratic maximum, if $p_H^{(t)} = F_4(R^{(t-1)})$ displays a quadratic maximum. Thus in such general hypothesis the order parameter $R = R^{(t)}$ of the HOTP displays a route to chaos in the universality class of the logistic map. Note that this implies that the universality class of HOTP is independent of the hypergraph structure and that also changing the regulatory degree distribution might not affect this result as long as $p_H^{(t)} = F_4(R^{(t-1)})$ displays a quadratic maximum at a non-zero value of R.

In this work we focus mostly in the relevant case in which the regulatory (positive and negative) degree distributions are Poisson distributions with average degrees c^{\pm} respectively. This case satisfies the hypothesis for observing a route to chaos of the order parameter of HOTP in the universlaity class of the logistic map. In fact we have

$$\frac{\partial^2 p_H^{(t-1)}}{\partial (R^{(t-1)})^2} \bigg|_{R^{(t-1)} = \tilde{R}} = -p\tilde{c}c^+ e^{-\tilde{c}\tilde{R}} < 0, \qquad (A7)$$

where $\tilde{c} = c^- + c^+$, thus

$$h_{m,p}''(R)\big|_{R=\tilde{R}} < 0.$$
 (A8)

FIG. 17. Illustration of the functions $f_m(p_H)$ (solid line) and $g_p(R)$ (dashed lines) determining the critical properties of HOTP when hyperedges are not regulated with probability ρ_0 . In panel (a) we consider values of ρ_0 above the tricritical point, where a continuous phase transition is observed. In panel (b) we consider values of ρ_0 below the tricritical point where a discontinuous phase transition is observed. In panel (c) we consider values of ρ_0 at the tricritical point. In each panels, p_c indicates the critical threshold for discontinuous transition (panel (a)) continuous transition (panel (b)) and tricritical phase transition (panel (c)). The structural hypergraph has fixed hyperedge cardinality m = 2 and a Poisson hyperdegree distribution with an average c = 3. The regulatory network is formed exclusively by positive regulations with a Poisson regulatory degree distribution with an average $c^{+} = 2.$

Appendix B: HOTP with partial regulation

In the main text we have shown that HOTP in absence of negative regulations can only display a discontinuous hybrid phase transition, while HOTP in absence of positive regulation can display either continuous transition or period-2 oscillations. In order to reveal the nature of the difference between these two scenarios, we discuss here a general scenario of HOTP with partial regulation where hyperedges are not regulated with probability ρ_0 . Finally we discuss also the effect of partial regulation in HONDP.

a. HOTP in absence of negative regulations

Let us consider HOTP where hyperedges are not regulated with probability ρ_0 , i.e. the HOTIs are present with a probability $1 - \rho_0$. the probability of retaining a hyperedge $p_H^{(t)}$ at time t follow the following generalization of Eq. 8,

$$p_H^{(t)} = p \left[\rho_0 + (1 - \rho_0) \left(1 - G_0^+ \left(1 - R^{(t)} \right) \right) \right].$$
(B1)

When $\rho_0 = 1$, we recover ordinary hypergraph percolation with random hyperedge deactivation that displays a second-order continuous phase transition. When $\rho_0 = 0$, we recover the HOTP in absence of negative regulation which displays a discontinuous hybrid phase transition.

Let us investigate the general scenario when $0 < \rho_0 < 1$. First we observe that when R = 0, $p_H = \rho_0 p$. Let us denote the percolation threshold for for simple hyperedge percolation as p_H^c (the blue line in Fig. 17) and let us adopt the map notation for the dynamics,

$$R^{(t)} = f_m\left(p_H^{(t-1)}\right), \quad p_H^{(t)} = g_p\left(R^{(t)}\right)$$
 (B2)

and

$$R^{(t)} = h_{m,p}\left(R^{(t-1)}\right) = f_m\left(g_p\left(R^{(t-1)}\right)\right).$$
 (B3)

If $\rho_0 p \ge p_H^c$, $R^\star = h_{m,p}(R^\star)$ has a unique stable fixed point (see Fig. 17 (a)) and if $\rho_0 p < p_H^c$, $R^\star = h_{m,p}(R^\star)$ could have three fixed points, while the smallest (R = 0)and the largest are stable (see Fig. 17(b)). Therefore, the discontinuous transition takes place when $y = h_{m,p}(R)$ is tangent to y = R at $p_H = p_H^\star$, $R = R^\star$ (see Fig. 17 (b) when $p = p_c$), i.e.

$$J = h'_{m,p}(R^{\star}) = \left. \frac{\partial f_m}{\partial p_H^{(t)}} \right|_{p_H = p_H^{\star}} \left. \frac{\partial g_p}{\partial R^{(t)}} \right|_{R = R^{\star}} = 1.$$
(B4)

If $R^* = h_{m,p}(R^*)$ always has a unique stable fixed point, the transition is always continuous. The continuous transition takes place when the fixed point decreases to zero at $p\rho_0 = p_H^c$. In addition, to guarantee the fixed point is stable, it is necessary to have

$$\left. \frac{\partial f_m}{\partial p_H^{(t)}} \right|_{p_H = p_H^c} \left. \frac{\partial g_p}{\partial R^{(t)}} \right|_{R=0} < 1.$$
 (B5)

Thus, the tricritical point separating continuous and discontinuous transition is reached when

$$\frac{\partial f_m}{\partial p_H^{(t)}}\bigg|_{p_H = p_H^c} \frac{\partial g_p}{\partial R^{(t)}}\bigg|_{R=0} = 1, \quad p\rho_0 = p_H^c.$$
(B6)

To illustrate this critical behavior, let us assume that the structural hypergraph has a Poisson hyperdegree distribution with an average c and the hyperedge cardinality m. Thus $p_H^c = 1/c(m-1)$ [14] and

$$\frac{\partial f_m}{\partial p_H^{(t)}}\Big|_{p_H = p_H^c} = 2c, \quad \frac{\partial g_p}{\partial R^{(t)}}\Big|_{R=0} = p(1-\rho_0)c^+.$$
(B7)

Thus the tricritical point is reached when (see Fig. 17 (c))

$$\rho_0 = \frac{2c^+}{2c^+ + m - 1}, \quad p = \frac{2c^+ + m - 1}{2cc^+(m - 1)}.$$
(B8)

We observe that $\rho_0 > 0$ for any c^+ and m. Therefore in the case of *HOTP* in absence of negative regulations, $\rho_0 = 0$, the transition will always be discontinuous.

b. HHOTP in absence of positive regulations

When only negative regulations are present, the probability of retaining a hyperedge is given by

$$p_{H}^{(t)} = p\left[\rho_{0} + (1 - \rho_{0})\left(G_{0}^{-}\left(1 - R^{(t)}\right)\right)\right]$$
(B9)

Similarly, we observe that when R = 0, we have $p_H = p$. Thus the continuous transition is observed when $p = p_H^c$ together with |J| < 1, where p_H^c denotes the critical threshold of hyperedge percolation. The period-2 bifurcation happens when the non-trivial fixed point loses its stability when $p > p_H^c$ and |J| = 1. Thus the tricritical point is reached when

$$J = -1, \quad p_H^c = p \tag{B10}$$

Assuming the hypergraph has a Poisson structural hyperdegree distribution with an average c, a Poisson regulatory degree distribution with an average c^- and a fixed hyperedge cardinality m,

$$J = -2c(1 - \rho_0)pc^- = -1, \quad p = 1/c(m - 1).$$
(B11)

Thus the tricritical point is reached when

$$\rho_0 = 1 - \frac{m-1}{2c^-}, \quad p = \frac{1}{c(m-1)}$$
(B12)

Thus, when $\rho_0 = 0$, we have $c^- = (m-1)/2$. Therefore, in the case of HOTP in absence of positive regulation, as long as $c^- < (m-1)/2$, the transition is always continuous.

c. HONDP with partial regulation

the case (a) as an example. In this case we have

$$\frac{\partial f_m}{\partial p_N^{(t)}} \bigg|_{p_N = p_N^c} = \frac{2c(m-1)}{c(m-1) + (m-2)}.$$
 (B13)

Thus for HONDP in absence of negative regulations, the tricritical point is given by

$$\rho_0 = \frac{2c^+}{2c^+ + c(m-1) + (m-2)},$$

$$p = \frac{c(m-1) + (m-2) + 2c^+}{2c^+ c(m-1)}.$$
(B14)

For HONDP in absence of positive regulation, we have instead that the tricritical point is given by

$$\rho_0 = 1 - \frac{c(m-1) + (m-2)}{2c^-}, \ p = \frac{1}{c(m-1)}.$$
 (B15)

We we discuss also HONP when hyperedges are not regulated with probability ρ_0 observing a critical behavior similar to the one of HOTP with partial regulation discussed in the previous paragraphs of this Appendix. The major difference between HONP and HOTP is that the map $R = f_m(p)$ implements hypergraph percolation (case (a)) or cooperative hypergraph percolation (case (b)) with deactivation of the nodes instead of hypergraph percolation with hyperedge deactivation. Let us discuss
