#### **ABSTRACT**

In the present paper we consider the full nonlocal thermodynamic equilibrium (non-LTE) radiation transfer problem. This formalism allows us to account for deviation from equilibrium distribution of both the radiation field and the massive particles. In the present study two-level atoms with broadened upper level represent the massive particles. In the absence of velocity-changing collisions, we demonstrate the analytic equivalence of the full non-LTE source function with the corresponding standard non-LTE partial frequency redistribution (PFR) model. We present an iterative method based on operator splitting techniques to numerically solve the problem at hand. We benchmark it against the standard non-LTE transfer problem for a two-level atom with PFR. We illustrate the deviation of the velocity distribution function of excited atoms from the equilibrium distribution. We also discuss the dependence of the emission profile and the velocity distribution function on elastic collisions and velocity-changing collisions.

**Key words.** Radiation mechanisms: general – Radiative transfer – Line: profiles – Methods: numerical

## **1. Introduction**

In a series of two papers [\(Paletou & Peymirat 2021;](#page-11-0) [Paletou](#page-11-1) [et al. 2023\)](#page-11-1), we have been revisiting the problem of so-called "full" nonlocal thermodynamic equilibrium (non-LTE) radiation transfer originally formulated by [Oxenius](#page-11-2) [\(1986\)](#page-11-2). This formalism not only accounts for deviation of the radiation field from the Planckian equilibrium distribution, but also for the deviation of the velocity distribution of massive particles from the Maxwellian equilibrium distribution. While [Paletou & Peymirat](#page-11-0) [\(2021\)](#page-11-0) focused on setting the stage, [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1) considered the numerical solution of the problem for the case of coherent scattering in the atom's frame, which corresponds to scattering on a two-level atom with (putative) infinitely sharp energy levels. In the present paper, we further extend these works for scattering on a two-level atom with infinitely sharp lower level and a more realistic broadened upper level (which may already be suitable for the modeling of strong resonance lines).

The full non-LTE radiation transfer formalism is based on the kinetic theory of particles and photons [\(Oxenius 1986\)](#page-11-2). In particular, it is founded on a semi-classical description of light scattering in spectral lines. As described in [Hubeny & Mihalas](#page-11-3) [\(2014\)](#page-11-3), the semi-classical picture combines concepts from classical and the more exact quantum mechanical description of the problem at hand, thereby providing a very intuitive and compelling approach to the problem. Clearly, the semi-classical picture is not a self-consistent theory and therefore contains a number of not fully defined concepts. However, it has been very successful in describing several of the line scattering mechanisms in astrophysical conditions (see the above-cited books for details). For the problem considered in this paper, the poorly defined concepts from the physical point of view are those related to the rate of velocity-changing collisions and a clear distinc-

tion between the elastic and velocity-changing collisions. However, despite this, we introduce separate rates for the elastic and velocity-changing collisions. Although it is not completely clear how they would be evaluated for actual cases, and even a proper quantum-mechanical definition of these quantities is uncertain, their introduction and usage in the present paper is fully in the spirit of the semi-classical picture that we adopt here. Indeed this semi-classical theory provides a way to treat the problem, namely including a self-consistent determination of the velocity distribution of atoms in the upper level of the transition. For a more detailed outline of the semi-classical picture, we refer the reader to [Hubeny & Mihalas](#page-11-3) [\(2014,](#page-11-3) see their Chapter 10, specifically pp. 291–294).

In the full non-LTE formalism, the kinetic equation for the velocity distribution of the massive particles (namely, the atoms or ions and free electrons) and that for the photons (namely, the radiative transfer equation for the intensity of the radiation field) have to be formulated and solved simultaneously and selfconsistently. Since the velocity distribution functions (VDFs) of the atomic levels are not known a priori, the absorption and emission profiles that enter the radiative transfer equation need to be obtained by convolving the corresponding atomic quantities with the VDFs, wherein the velocity of the massive particle is measured in the observer's frame. An evaluation of the need to use this formalism had remained unexplored because of the numerical complexity involved in its implementation. The present series of papers aim to clarify this question through detailed numerical calculations. For this purpose, we have embarked upon developing suitable numerical techniques to implement this formalism. As a first step [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1) considered the two-distribution problem, namely the intensity of the radiation field and the VDF of the excited atoms are the only two

distributions that need to be determined simultaneously and selfconsistently. In other words, two-level atoms represent the massive particles with their lower (ground) level having the equilibrium Maxwellian distribution [\(Oxenius 1986;](#page-11-2) [Paletou & Peymi](#page-11-0)[rat 2021\)](#page-11-0). Furthermore, stimulated emission was neglected, and the free electrons that are responsible for inelastic collisions between the two levels of the atom were also assumed to obey the equilibrium Maxwellian distribution. In the present paper we continue to consider this two-distribution problem, with the important difference that the lower level of the atom continues to be infinitely sharp, while the upper level is broadened. In this case, the atomic absorption profile is a Lorentzian and the atomic emission profile already depends on the radiation field. This introduces some difficulties in the numerical solution of the corresponding full non-LTE problem, namely we need to accurately compute Voigt-like function which involves a Lorentzian function in its integrand [\(Paletou et al. 2020\)](#page-11-4). Following a method developed previously by [Bommier](#page-10-0) [\(1997a](#page-10-0)[,b\)](#page-10-1), in the present paper we device a simple and efficient technique to compute such an integral involving Lorentzian function.

The basic equations of the two-distribution problem are detailed in [Paletou et al.](#page-11-1) [\(2023,](#page-11-1) see also [Paletou & Peymirat 2021\)](#page-11-0). Hence, we do not repeat them here, and only the equations relevant to the two-level atom with broadened upper level are discussed. Outline of the present paper is as follows. In Section [2](#page-1-0) we discuss the explicit forms of the absorption and emission profiles for a two-level atom with broadened upper level. The full non-LTE source function is presented in Section [3,](#page-3-0) wherein we also demonstrate the analytic equivalence with the corresponding standard non-LTE source function in the absence of velocitychanging collisions. In Section [4,](#page-3-1) we describe and clarify the three different types of collisions (namely, the inelastic, elastic, and velocity-changing collisions) considered in this paper. Section [5](#page-5-0) is devoted to the numerical method of solution for the full non-LTE problem considered here. Numerical results are illustrated and discussed in Section [6.](#page-6-0) Conclusions are presented in Section [7.](#page-9-0)

#### <span id="page-1-0"></span>**2. The absorption and emission profiles**

Like in the standard non-LTE formalism (see e.g., [Hubeny &](#page-11-3) [Mihalas 2014,](#page-11-3) who also adopt the semi-classical picture), the absorption and emission profiles (and also the frequency redistribution functions) are first determined in the atomic rest frame, and then transformed to the observer's frame to account for the Doppler motion of the atoms in a stellar atmosphere. In the standard non-LTE formalism with complete frequency redistribution (CFR), the VDF of all the atomic levels is assumed to be the equilibrium Maxwellian distribution, while when partial frequency redistribution (PFR) is included this assumption is limited to only the lower level. However, the standard non-LTE formalism with PFR does not provide access to the VDF of the upper level. This is provided by the full non-LTE formalism. Therefore, in this section we discuss the absorption and emission profiles first in the atomic frame and then in the observer's frame.

For the case of a two-level atom with broadened upper level, the atomic absorption profile is given by (see Appendix B.2 of [Oxenius 1986,](#page-11-2) see also [Paletou & Peymirat 2021\)](#page-11-0)

$$
\alpha_{12}(\xi) = \frac{\delta_w}{\pi} \frac{1}{(\xi - \nu_0)^2 + \delta_w^2},\tag{1}
$$

where  $\xi$  is the photon frequency in the atomic frame,  $v_0$  is the line-center frequency and the damping width  $\delta_{\theta} = (A_{21} + O_1 +$ line-center frequency, and the damping width  $\delta_w = (A_{21} + Q_I +$ 

 $Q_E$ )/(4 $\pi$ ), with  $A_{21}$  being the Einstein coefficient for spontaneous emission or radiative deexcitation rate,  $Q_I$  the inelastic collisional deexcitation rate (denoted as *C*<sup>21</sup> in [Paletou & Peymi](#page-11-0)[rat 2021\)](#page-11-0), and  $Q_E$  the total elastic collision rate.

<span id="page-1-4"></span>The absorption profile in the observer's frame is given by

$$
\varphi_{\nu} = \int_{\boldsymbol{u}} \alpha_{12} (\nu - \Delta \nu_D \, \boldsymbol{u} \cdot \boldsymbol{\Omega}) f_1(\boldsymbol{u}) d^3 \boldsymbol{u}, \tag{2}
$$

where  $\boldsymbol{u}$  is the atomic velocity<sup>[1](#page-1-1)</sup> normalized to the thermal velocity  $(v_{\text{th}} = \sqrt{2kT/M}$ , with *k* being the Boltzmann constant, *T* the temperature and *M* the mass of the atom) **Q** is the propagation temperature, and *M* the mass of the atom),  $\Omega$  is the propagation direction of the ray, and  $\Delta v_D$  is the Doppler width. In this paper, we do not account for bulk velocities resulting from mass motion of the massive particles. In other words only Doppler motion of atoms is taken into account, so that the corresponding velocities are in the nonrelativistic regime, wherein only the photon frequency is subject to Lorentz transformation between the atomic rest frame and the observer's frame, while the photon direction remains unchanged (i.e., aberration is neglected; see also Eqs. (2.4.3a)–(2.4.3e) in page 54 of [Oxenius 1986\)](#page-11-2). Therefore, in the above equation we have used the Fizeau–Doppler relationship (see Eq. (9) of [Paletou & Peymirat 2021\)](#page-11-0), which relates the frequencies in the atomic  $(\xi)$  and observer's  $(\nu)$  frames. Furthermore, *f*<sup>1</sup> represents the VDF of the lower level of the atom. In the weak radiation field regime  $f_1$  can be assumed to be the equilibrium distribution, namely a Maxwellian *f <sup>M</sup>* [\(Oxenius 1986;](#page-11-2) [Paletou & Peymirat 2021\)](#page-11-0). With this assumption it is straight forward to show that the resulting absorption profile in the observer's frame is a normalized Voigt function  $\varphi(x) = H(a, x)$ , where  $a = \delta_w / \Delta v_D$  and  $x = (v - v_0) / \Delta v_D$ , with  $v_0$  being the line-center frequency.

In the following subsections we discuss the emission profile first in the atomic frame (see Section [2.1\)](#page-1-2) and then in the observer's frame (see Section [2.2\)](#page-2-0).

## <span id="page-1-2"></span>2.1. The atomic emission profile

The explicit form of the atomic emission profile in the absence of velocity-changing collisions is given in Eq. (B.2.26) of [Oxenius](#page-11-2) [\(1986\)](#page-11-2) and in Eq. (4.32) of [Hubeny et al.](#page-11-5) [\(1983a\)](#page-11-5). Although, the notations used in the above-said references are somewhat different, it can be readily shown that both the mentioned expressions are identical. In the presence of velocity-changing collisions, the atomic emission profile is given in [Hubeny et al.](#page-11-6) [\(1983b,](#page-11-6) see their Section 4.1). In their notations, this atomic emission profile is given by

<span id="page-1-3"></span>
$$
\eta_{21}(\xi,\tau) = \frac{B_{12}I_{12}^*j_{121}(\xi,\tau) + [S_{12} + \gamma_2(n_2/n_1)]r_{12}(\xi)}{B_{12}I_{12}^* + S_{12} + \gamma_2(n_2/n_1)},\tag{3}
$$

where  $B_{12}$  is the Einstein coefficient for radiative absorption,  $S_{12}$ is the collisional excitation rate,  $\gamma_2$  is the velocity-changing collision rate,  $n_1$  and  $n_2$  are the number density of the atoms in lower and upper levels, respectively, and  $\tau$  is the line center optical depth. In Eq. [\(3\)](#page-1-3), the generalized redistribution function  $r_{12}(\xi) = \alpha_{12}(\xi)$  (see Eq. (6.3.55) of [Oxenius 1986\)](#page-11-2), the quantity  $I_{12}^*$  is given by

$$
I_{12}^* = \int r_{12}(\xi) I(\nu, \Omega, \tau) d\xi, \qquad (4)
$$

<span id="page-1-5"></span>and

$$
j_{121}(\xi,\tau) = \frac{1}{I_{12}^*} \int r_{121}(\xi',\xi) I(\nu',\Omega',\tau) d\xi', \qquad (5)
$$

<span id="page-1-1"></span> $<sup>1</sup>$  Here the velocity of the atom is measured in the observer's frame.</sup>

Article number, page 2 of 12

with  $\int d\xi = \oint \int dv d\Omega/(4\pi)$ . In the above equations,  $I(v, \Omega, \tau)$  is the specific intensity and  $r_{12}$ ;  $\xi$  is the seneralized atomic is the specific intensity, and  $r_{121}(\xi', \xi)$  is the generalized atomic<br>redistribution function (Hubeny et al. 1983a), which describes redistribution function [\(Hubeny et al. 1983a\)](#page-11-5), which describes the joint probability of absorbing a photon of frequency  $\xi'$  and spontaneously re-emitting a photon of frequency  $\xi$ . spontaneously re-emitting a photon of frequency  $\xi$ .

We remark that the quantity  $I_{12}^*$  introduced by [Hubeny et al.](#page-11-5) [\(1983a,](#page-11-5)[b\)](#page-11-6) is the same as  $I_{12}$  introduced in Eq. (B.2.20) of [Oxe](#page-11-2)[nius](#page-11-2) [\(1986\)](#page-11-2). In the notations of [Paletou & Peymirat](#page-11-0) [\(2021,](#page-11-0) see also [Paletou et al. 2023\)](#page-11-1), we readily identify  $I_{12}^* = J_{12}(u, \tau)$ ,<br> $S_{12} = C_{12}$ , and  $26 = Q_1^2$ . Therefore, we re write Eq. (3) in  $S_{12} = C_{12}$  $S_{12} = C_{12}$  $S_{12} = C_{12}$ , and  $\gamma_2 = Q_V^2$ . Therefore, we re-write Eq. [\(3\)](#page-1-3) in the present notations as follows the present notations as follows

<span id="page-2-2"></span>
$$
\eta_{21}(\xi,\tau) = \frac{B_{12}J_{12}(u,\tau)j_{121}(\xi,\tau) + [C_{12} + Q_V(n_2/n_1)]\alpha_{12}(\xi)}{B_{12}J_{12}(u,\tau) + C_{12} + Q_V(n_2/n_1)},\tag{6}
$$

<span id="page-2-7"></span>where  $J_{12}(u, \tau)$  is defined as (see e.g., Eq. (8) of [Paletou &](#page-11-0) [Peymirat 2021\)](#page-11-0)

$$
J_{12}(\boldsymbol{u},\tau) = \oint \frac{d\Omega}{4\pi} \int_0^\infty \alpha_{12}(\nu - \Delta \nu_D \, \boldsymbol{u} \cdot \boldsymbol{\Omega}) I(\nu, \boldsymbol{\Omega}, \tau) \, d\nu \,. \tag{7}
$$

Also, in our notations, the quantity  $j_{121}(\xi, \tau)$  takes the form

$$
j_{121}(\xi,\tau) = \frac{1}{J_{12}(u,\tau)} \oint \frac{d\Omega'}{4\pi} \int_0^{\infty} r_{121}(\xi',\xi) I(\nu',\Omega',\tau) d\nu' \,. \tag{8}
$$

The atomic frequencies appearing in the above equation are related to their observer's frame counterparts through Fizeau–Doppler relationship, namely,  $\xi' = v' - \Delta v_D u \cdot \Omega'$  and  $\xi = v - \Delta v_D u \cdot \Omega$  $\xi = v - \Delta v_D u \cdot \Omega$ .

#### <span id="page-2-0"></span>2.2. The observer's frame emission profile

The emission profile in the observer's frame is given by

$$
\psi_{\nu}(\Omega,\tau) = \int_{u} \eta_{21}(\nu - \Delta \nu_{D} \mathbf{u} \cdot \Omega,\tau) f_{2}(\mathbf{u},\tau) d^{3} \mathbf{u}.
$$
 (9)

The VDF of the upper-level including the velocity-changing collisions is given in Eq. (3) of [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1). However, for the purpose of deriving the emission profile in the observer's frame, we use the VDF as given in Eq. (19) of [Paletou & Peymi](#page-11-0)[rat](#page-11-0) [\(2021\)](#page-11-0), namely

<span id="page-2-3"></span>
$$
f_2(\mathbf{u}, \tau) = \frac{n_1}{n_2} \frac{B_{12} J_{12}(\mathbf{u}, \tau) + C_{12} + Q_V(n_2/n_1)}{A_{21} + C_{21} + Q_V} f^M(\mathbf{u}).
$$
 (10)

Substituting Eqs. [\(6\)](#page-2-2) and [\(10\)](#page-2-3) into Eq. [\(9\)](#page-2-4), the latter takes the form

<span id="page-2-6"></span>
$$
\psi_{\nu}(\Omega,\tau) = \int_{u} \left\{ \frac{n_{1}}{n_{2}} \left[ \frac{B_{12} J_{12}(u,\tau) j_{121}(\xi,\tau) + C_{12} \alpha_{12}(\xi)}{A_{21} + C_{21} + Q_{V}} \right] + \frac{Q_{V} \alpha_{12}(\xi)}{A_{21} + C_{21} + Q_{V}} \right\} f^{M}(u) d^{3} u.
$$
 (11)

Following Section 5 of [Paletou & Peymirat](#page-11-0) [\(2021\)](#page-11-0), we assume LTE values for  $n_1$  (namely,  $n_1 = n_1^*$ ), and introduce the normalized populations  $\bar{n}_2 = n_2/n_2^*$ . Substituting for  $j_{121}$  (cf. Eq. [\(8\)](#page-2-5)), the first term in the flower brackets of the above equation can be re-written as

$$
\frac{1}{\bar{n}_2}\frac{1}{1+\zeta}\bigg[\varepsilon\alpha_{12}(\xi)+(1-\varepsilon)\iint\frac{d\Omega'}{4\pi}\int_0^\infty r_{121}(\xi',\xi)I(\nu',\Omega',\tau)\,d\nu'\bigg],
$$

<span id="page-2-8"></span>where we have made use of Eqs.  $(23)$ – $(27)$  of [Paletou & Peymi](#page-11-0)[rat](#page-11-0) [\(2021\)](#page-11-0), and  $I(v', \Omega', \tau)$  is now normalized to the Planck function in the Wien limit. In the above expression tion in the Wien limit. In the above expression

$$
\varepsilon = \frac{Q_I}{A_{21} + Q_I},\tag{12}
$$

<span id="page-2-10"></span>is the usual collisional destruction probability and the quantity

$$
\zeta = \frac{Q_V}{A_{21} + Q_I},\tag{13}
$$

gives the amount of velocity-changing collisions. Similarly the last term in the flower brackets of Eq. [\(11\)](#page-2-6) reduces to  $\zeta \alpha_{12}(\xi)/(1 + \zeta)$ . Using Eq. (29) of [Paletou & Peymirat](#page-11-0) [\(2021\)](#page-11-0), the emission profile can be re-written as

<span id="page-2-5"></span>
$$
\psi_{\nu}(\Omega,\tau) = \int_{u} f^{M}(u) d^{3}u \left\{ \frac{\zeta}{1+\zeta} \alpha_{12}(\xi) + \frac{1}{1+\zeta} \frac{1}{\varepsilon + (1-\varepsilon) \mathcal{J}_{12}(\tau)} \right.\times \left[ \varepsilon \alpha_{12}(\xi) + (1-\varepsilon) \oint \frac{d\Omega'}{4\pi} \int_{0}^{\infty} r_{121}(\xi',\xi) I(\nu',\Omega',\tau) d\nu' \right] \right\}, (14)
$$

where

$$
\mathcal{J}_{12}(\tau) = \int_{\boldsymbol{u}} \bar{J}_{12}(\boldsymbol{u}, \tau) f^M(\boldsymbol{u}) d^3 \boldsymbol{u} . \tag{15}
$$

In the above equation  $\bar{J}_{12}(u, \tau) = J_{12}(u, \tau)/B_W$ , with  $B_W$  denoting the Planck function in the Wien limit Substituting for noting the Planck function in the Wien limit. Substituting for  $J_{12}(u, \tau)$  from Eq. [\(7\)](#page-2-7) and using Eq. [\(2\)](#page-1-4), it can be easily shown that

<span id="page-2-9"></span><span id="page-2-4"></span>
$$
\mathcal{J}_{12}(\tau) = \oint \frac{d\Omega}{4\pi} \int_0^\infty \varphi_V I(\nu, \Omega, \tau) d\nu, \qquad (16)
$$

is simply the frequency integrated mean intensity (also referred to as "CFR scattering integral") appearing in the standard non-LTE problem. Furthermore, we may readily identify that  $\int r_{121}(\xi', \xi) f^{M}(u) d^{3}u = R_{121}(v', \Omega', v, \Omega)$ , namely the angle-<br>dependent generalized redistribution function in the observer's dependent generalized redistribution function in the observer's frame. Furthermore, using Eq. [\(2\)](#page-1-4), we obtain the emission profile in the observer's frame as

$$
\psi_{\nu}(\Omega,\tau) = \frac{\zeta}{1+\zeta}\varphi_{\nu} + \frac{1}{1+\zeta}\frac{1}{\varepsilon + (1-\varepsilon)\mathcal{J}_{12}(\tau)}
$$
\n
$$
\times \left[\varepsilon\varphi_{\nu} + (1-\varepsilon)\oint \frac{d\Omega'}{4\pi} \int_0^\infty R_{121}(\nu',\Omega',\nu,\Omega)I(\nu',\Omega',\tau)\,d\nu'\right].(17)
$$

We remark that the emission profile given above is the same as that originally derived in [Hubeny et al.](#page-11-6) [\(1983b,](#page-11-6) see their Eq. (4.15)), although we have presented it in a slightly different form and also using the notations adopted in this paper. Furthermore, [Hubeny & Cooper](#page-11-7) [\(1986\)](#page-11-7) have demonstrated that the emission profile derived from the semi-classical picture of [Hubeny et al.](#page-11-6) [\(1983b\)](#page-11-6) fully agrees with that derived from a quantum mechanical approach of [Cooper et al.](#page-10-2) [\(1982\)](#page-10-2).

<span id="page-2-11"></span>In the present paper, we consider the angle-averaged emission profile, namely

$$
\psi(x,\tau) = \oint \frac{d\Omega}{4\pi} \psi(x,\Omega,\tau),\tag{18}
$$

Article number, page 3 of 12

<span id="page-2-1"></span><sup>2</sup> In [Paletou & Peymirat](#page-11-0) [\(2021\)](#page-11-0) and [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1), the velocitychanging collision rate  $Q_V$  was denoted by  $Q_2$ . This changed notation has been adopted to avoid the possible confusion with the notation  $Q_2$ used in [Hubeny & Mihalas](#page-11-3) [\(2014,](#page-11-3) see e.g., their Eq. (10.151) in page 327) for the elastic collision rate.

wherein we have transformed from real frequency  $\nu$  to the nondimensional frequency *x*. The resulting angle-averaged emission profile is given by

<span id="page-3-2"></span>
$$
\psi(x,\tau) = \frac{\zeta}{1+\zeta}\varphi(x) + \frac{1}{1+\zeta} \frac{1}{\varepsilon + (1-\varepsilon)\mathcal{J}_{12}(\tau)}
$$

$$
\times \left[\varepsilon\varphi(x) + (1-\varepsilon)\oint \frac{d\Omega'}{4\pi} \int_{-\infty}^{+\infty} R_{121}(x',x)I(x',\Omega',\tau) dx'\right]. \quad (19)
$$

For a two-level atom with broadened upper level and in the absence of velocity-changing collisions, the generalized redistribution function  $R_{121}$  is given by the observer's frame counterpart of the usual atomic frame PFR function derived by [Omont et al.](#page-11-8) [\(1972,](#page-11-8) see [Milkey & Mihalas 1973](#page-11-9) and [Mihalas 1978](#page-11-10) for the corresponding observer's frame expression). In the presence of velocity-changing collisions, the explicit form of the PFR function  $R_{121}$  has been derived in [Hubeny & Cooper](#page-11-7) [\(1986,](#page-11-7) see their Eqs. (3.15) and (3.16)) starting from the quantum mechanical approach of [Cooper et al.](#page-10-2) [\(1982\)](#page-10-2). In this paper, we adopt this PFR function, which in our notations takes the form :

$$
R_{121}(x', x) = \gamma_{\text{coh}, V} R_{\text{II}-\text{A}}(x', x) + (1 - \gamma_{\text{coh}, V}) R_{\text{III}-\text{A}}(x', x), (20)
$$

where  $R_{\text{II-A}}$  and  $R_{\text{III-A}}$  are respectively the type-II and type-III angle-averaged PFR functions of [Hummer](#page-11-11) [\(1962\)](#page-11-11), and the coherence fraction is given by

$$
\gamma_{\text{coh, V}} = \frac{A_{21} + Q_I + Q_V}{A_{21} + Q_I + Q_E}.
$$
\n(21)

Clearly, in the absence of velocity-changing collisions, the coherence fraction as well as the PFR function become identical to those derived by [Omont et al.](#page-11-8) [\(1972\)](#page-11-8).

To clearly bring out the departure of the emission profile from CFR, we may re-write Eq. [\(19\)](#page-3-2) as

<span id="page-3-4"></span>
$$
\psi(x,\tau) = \varphi(x) + \frac{1}{1+\zeta} \frac{(1-\varepsilon)}{\varepsilon + (1-\varepsilon)\mathcal{J}_{12}(\tau)} \times \left[ \oint \frac{d\Omega'}{4\pi} \int_{-\infty}^{+\infty} R_{121}(x',x) I(x',\Omega',\tau) dx' - \mathcal{J}_{12}(\tau)\varphi(x) \right]. \tag{22}
$$

The above equation can easily be deduced from Eq. [\(19\)](#page-3-2) by simply adding and subtracting unity to  $\zeta$  appearing in the numerator of the first term of that equation.<sup>[3](#page-3-3)</sup>

#### <span id="page-3-0"></span>**3. The source function**

<span id="page-3-5"></span>In the full non-LTE formalism, the source function for a twolevel atom with broadened upper level is of the form (see Eq. (7) of [Paletou et al. 2023\)](#page-11-1)

$$
S(x,\tau) = \left[\varepsilon + (1-\varepsilon)\mathcal{J}_{12}(\tau)\right] \left[\frac{\psi(x,\tau)}{\varphi(x)}\right],\tag{23}
$$

where  $\psi(x, \tau)$  is given by Eq. [\(19\)](#page-3-2) or Eq. [\(22\)](#page-3-4) and  $\varphi(x)$  is the normalized Voigt function.

In the absence of velocity-changing collisions (namely,  $\zeta$  = 0), the source function [\(23\)](#page-3-5) reduces to the corresponding expression for the standard non-LTE PFR model for a two-level atom

with broadened upper level. This can be easily realized, by noting that the emission profile for  $\zeta = 0$  (cf. Eq. [\(19\)](#page-3-2)) takes the following form

<span id="page-3-6"></span>
$$
\psi(x,\tau) = \frac{1}{\varepsilon + (1-\varepsilon)\mathcal{J}_{12}(\tau)}
$$

$$
\times \left[ \varepsilon \varphi(x) + (1-\varepsilon) \oint \frac{d\Omega'}{4\pi} \int_{-\infty}^{+\infty} R_{121}(x',x) I(x',\Omega',\tau) dx' \right]. (24)
$$

Substituting Eq. [\(24\)](#page-3-6) into Eq. [\(23\)](#page-3-5), we readily obtain

$$
S(x,\tau) = \varepsilon + (1-\varepsilon) \oint \frac{d\Omega'}{4\pi} \int_{-\infty}^{+\infty} \left[ \frac{R_{121}(x',x)}{\varphi(x)} \right] I(x',\Omega',\tau) dx',\tag{25}
$$

thereby establishing the equivalence of the source function derived from the full and standard non-LTE models. This is an important result that justifies the use of numerically relatively simpler standard non-LTE formalism in the absence of velocitychanging collisions.

<span id="page-3-8"></span>In the presence of velocity-changing collisions, the source function is obtained by substituting Eq. [\(22\)](#page-3-4) into Eq. [\(23\)](#page-3-5), namely

<span id="page-3-7"></span>
$$
S(x,\tau) = \varepsilon + (1-\varepsilon)\mathcal{J}_{12}(\tau) + \frac{(1-\varepsilon)}{1+\zeta}
$$

$$
\times \left\{ \oint \frac{d\Omega'}{4\pi} \int_{-\infty}^{+\infty} \left[ \frac{R_{121}(x',x)}{\varphi(x)} \right] I(x',\Omega',\tau) dx' - \mathcal{J}_{12}(\tau) \right\} . (26)
$$

We recall that as in [Paletou & Peymirat](#page-11-0) [\(2021\)](#page-11-0) and [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1) the source function and intensity are normalized to the Planck function in the Wien limit. When velocity-changing collisions are significant (namely,  $\zeta \gg 1$ ), the third term in Eq. [\(26\)](#page-3-7) is negligible and the source function tends to the CFR source function.

## <span id="page-3-1"></span>**4. A clarification on collisions**

In the present paper, we consider three types of collisions :

- inelastic collisions,
- elastic collisions, and
- velocity-changing collisions.

For the massive particles (two-level atoms in the present paper), we distinguish between :

- the "internal variables" (the levels energy and quantum numbers), and
- the "external variables" (the position and velocity).

The inelastic collisions are those responsible for collisional transitions between the lower and upper levels. They enter the kinetic (or statistical equilibrium) equation for atoms as inducing transitions, which further lead to the  $\varepsilon$  factor in the radiative transfer equation. In an inelastic collision, the internal variables change, whereas the external variables may or may not change.

The elastic collisions do not modify the level populations. They are responsible for line broadening. In a strictly elastic collision both the internal and external variables remain unchanged before and after the collision. In a weakly elastic collision, the internal variables, namely the energy value of the level and the quantum numbers may change (for example collision between fine-structure or hyperfine structure levels, or between Zeeman sublevels in the presence of a weak magnetic field), while the

<span id="page-3-3"></span><sup>&</sup>lt;sup>3</sup> We remark that Eq. [\(22\)](#page-3-4) can more easily be related to Eq. (4.15) of [Hubeny et al.](#page-11-6) [\(1983b\)](#page-11-6).

external variables remain unchanged. It is also important to note that elastic collisions between degenerate Zeeman sublevels also lead to change in internal variables (as it changes the magnetic quantum number before and after collisions, although not the atomic energy). Indeed in the present paper we consider isolated spectral line and do not consider magnetic fields. Thus the Zeeman sublevels are degenerate. If an elastic collision changes the Zeeman sublevel (namely, the magnetic quantum number *M* is changed to *M'*, with  $M \neq M'$ , then it will have a polarizing or, more frequently, depolarizing effect (note that polarization results from unequal populations between the Zeeman sublevels). On the contrary, if an elastic collision does not change the Zeeman sublevel (namely,  $M \rightarrow M$ ), then it only broadens the line, namely, it is only a line broadening collision. As clarified in [Sahal-Bréchot & Bommier](#page-11-12) [\(2019\)](#page-11-12) line broadening and depolarizing collisions are different and both contribute to the line broadening and hence to the elastic collision rate  $Q_E$ .

Apart from contributing to line broadening, the elastic collisions take part in the frequency redistribution of the scattered radiation in the line as shown for e.g., in [Omont et al.](#page-11-8) [\(1972,](#page-11-8) see also [Bommier 1997a,](#page-10-0)[b;](#page-10-1) [Sahal-Bréchot & Bommier 2019\)](#page-11-12). In particular, they are responsible for CFR in the atomic frame. In the full non-LTE formalism, both these effects of elastic collisions are included following the works of [Omont et al.](#page-11-8) [\(1972,](#page-11-8) see also Appendix B.2 of [Oxenius 1986\)](#page-11-2) and [Hubeny & Cooper](#page-11-7) [\(1986\)](#page-11-7) in the absence and presence of velocity-changing collisions, respectively. This is done by including  $Q_E$  in the total damping width of the absorption profile (see Eq. [\(1\)](#page-1-5)) and using the appropriate PFR function of [Omont et al.](#page-11-8) [\(1972\)](#page-11-8) and [Hubeny](#page-11-7) [& Cooper](#page-11-7) [\(1986\)](#page-11-7) for the generalized redistribution function (see Eq. [\(20\)](#page-3-8)).

On the other hand, in a collision if the internal variables remain unchanged, while the external variables such as atomic velocity (in particular its modulus) is changed, then such type of collisions are called velocity-changing collisions. We think that since the internal variable is unchanged, [Oxenius](#page-11-2) [\(1986\)](#page-11-2) refers to velocity-changing collision as elastic. However, since the atomic velocity is changed during the collision, we feel that it may not be appropriate to refer to this type of collision as "elastic". Indeed [Landi Degl'Innocenti & Landolfi](#page-11-13) [\(2004\)](#page-11-13) do not refer to them as elastic. Also, most likely, the velocity-changing collisions represented by  $O_V$  includes both elastic and inelastic contributions. Furthermore, this type of collisions are close collisions or strong collisions with small impact parameter. For the two-distribution problem considered in this paper, the velocitychanging collisions enter the kinetic equation for excited atoms as a relaxation term as they are responsible for relaxing the VDF of the upper level to its equilibrium distribution function. This relaxation term is of the form given in Eq. (7) of [Paletou &](#page-11-0) [Peymirat](#page-11-0) [\(2021,](#page-11-0) see also Eq. (6.3.12) in page 167 of [Oxenius](#page-11-2) [1986\)](#page-11-2).

In general, a given collision can modify both the internal and external variables. Those collisions which modify only the internal variables are most likely long-range collisions (obviously, short-range collisions can also modify the internal variables), and those collisions which modify the external variable (namely, velocity) are strong or (only) short-range collisions. In this respect,  $Q_V$  is a part of  $Q_E$  (see Sections 4.1.1 and 4.1.2) of [Bommier 2016a,](#page-10-3) see also Section II(a) of [Hubeny & Cooper](#page-11-7) [1986\)](#page-11-7). Even if velocity-changing collisions are part of the linebroadening collisions, the method of calculation of  $Q_V$  is not the same as the method of calculation of  $Q_E$ , because  $Q_E$  addresses the atomic internal variables, while  $Q_V$  addresses the atomic external variables, although the colliding particles are

the same. The velocity-changing collisions are atom-atom collisions, while the elastic and inelastic collisions may also be caused by electron-atom collisions (in addition to atom-atom collisions).

[Hubeny & Cooper](#page-11-7) [\(1986\)](#page-11-7) show that when lower state interaction is negligibly small (namely, the collisional scattering amplitude of the lower level is much smaller than that of the upper level), the total elastic collision rate  $Q_F$  associated with the upper level can be decomposed into two parts, one corresponding to only phase changes without change in velocity (denoted  $q_E$ ) and other corresponding to both phase and velocity changes (denoted as  $\nu$  by [Hubeny & Cooper 1986\)](#page-11-7). Such a decomposition is well suited for resonance lines to which our present full non-LTE approach is applicable. Therefore, following [Hubeny & Cooper](#page-11-7) [\(1986\)](#page-11-7), we write  $Q_E = q_E + Q_V$  after identifying their v as our *Q*<sub>*V*</sub>. Furthermore, [Hubeny & Cooper](#page-11-7) [\(1986\)](#page-11-7) show that  $q_E = \alpha Q_E$ and  $Q_V = (1 - \alpha)Q_E$  with  $\alpha$  in the range 0 to 1. They also give an estimate of  $(1 - \alpha)$ . When  $m \ll M$  (with *m* denoting the mass of the perturber and *M* denoting the mass of the radiator), they show that  $(1 - \alpha) = (m/M)^2$ , and when  $m \sim M$ , they estimate  $(1 - \alpha) = 0.1$  $(1 - \alpha) = 0.1$ .

It is known that the phase-changing elastic collision rate  $q_E$ can be obtained from Van der Waals approximation or using the more precise semi-classical theory developed in 1990s by Anstee, Barklem, and O'Mara (the so-called ABO theory; see e.g., [Barklem & O'Mara 1998;](#page-10-4) [Barklem et al. 1998,](#page-10-5) and references cited therein). As for the velocity-changing collision rate  $Q_V$ , a precise calculation of the corresponding collision crosssection will depend on the atomic species under consideration. [Landi Degl'Innocenti & Landolfi](#page-11-13) [\(2004\)](#page-11-13) give only a rough order of magnitude for this cross-section (to be on the order of 10 to 100  $\pi a_0^2$ , with  $a_0$  being the Bohr radius). Specific calculations would be necessary for a better precision. There has been a labwould be necessary for a better precision. There has been a laboratory study by [Brechignac et al.](#page-10-6) [\(1978\)](#page-10-6), who measure the effects of the velocity-changing collisions between the excited Kr atoms and the He and/or Ar perturbers. Here the authors show that a "hard-sphere" collision model is suitable for interpreting their experimental measurements. According to this model the collisional cross-section is given by  $\pi (r_A + r_B)^2$ , where  $r_A$  and  $r_B$  are the radii of the atoms participating in the collision. The  $r<sub>B</sub>$  are the radii of the atoms participating in the collision. The atomic radii for any atomic specie (including also the ions) are listed by [Allen](#page-10-7) [\(1973,](#page-10-7) see page 45), which the authors used for computing the collisional cross-section for Kr\*-He and Kr\*-Ar collisions. In the present paper, all the three collisional rates are assumed to be input parameters, and hence we do not compute them using the collisional dynamics. Consequently, we do not determine the velocity distribution of the colliders.

In order to evaluate the importance of velocity-changing collisions in a stellar atmosphere, [Landi Degl'Innocenti & Lan](#page-11-13)[dolfi](#page-11-13) [\(2004\)](#page-11-13) provide a way to estimate the critical density of the perturbers or colliders (see their Eq. (13.6) in page 694). This is done by comparing an order of magnitude rate for velocitychanging collisions (given by *nqv*, where *n* is the number density of the perturbers,  $q$  is the cross section for velocity-changing collisions, and *v* is the average velocity of perturbers relative to the atom) with the rate for spontaneous emission (namely,  $A_{21}$ ). The density for which these two rates are nearly the same gives the critical density :  $n_c \approx 7.8 \times 10^{16} A_{21}/q/\sqrt{T}$  (in units of cm<sup>-3</sup>).<br>Here  $A_{21}$  is in units of  $10^7$  s<sup>-1</sup> temperature T is in units of  $10^4$ Here  $A_{21}$  is in units of  $10^7$  s<sup>-1</sup>, temperature *T* is in units of  $10^4$ K, and *q* is in units of  $\pi a_0^2$ . For densities larger than this crit-<br>ical density velocity-changing collisions are significant Landi ical density velocity-changing collisions are significant. [Landi](#page-11-13)

[Degl'Innocenti & Landolfi](#page-11-13) [\(2004\)](#page-11-13) estimate  $q$  to be in a range<sup>[4](#page-5-1)</sup> that is rarely larger than 10 to 100. Using this, [Bommier](#page-10-3) [\(2016a\)](#page-10-3) provided an estimate of the critical density of colliders to be on the order of  $10^{20}$  cm<sup>-3</sup>. We redid this estimate for the same set of parameters as used by her (namely,  $A_{21} = 1$ ), except for the temperature (chosen here to be  $T = 0.5$ ), which is not mentioned in her Section 4.1.1. We find the critical density  $n_c$  to be in the range  $1.103 \times 10^{16}$  to  $1.103 \times 10^{15}$  cm<sup>-3</sup>. This is about 4 to 5 orders of magnitude smaller than the one mentioned in 4 to 5 orders of magnitude smaller than the one mentioned in [Bommier](#page-10-3) [\(2016a\)](#page-10-3). Since the collisions with neutral hydrogen is expected to be the dominant source of both elastic and velocitychanging collisions in a stellar atmosphere, we compare *n<sup>c</sup>* with the hydrogen density in the solar photosphere, which is on the order of  $10^{17}$  cm<sup>-3</sup>. Clearly, the velocity-changing collisions are important in the lower solar atmosphere, and hence have to be accounted for. Furthermore, the collisional destruction probability  $\varepsilon$  (which depends on the inelastic collision rate  $C_{21}$  or  $Q_I$ ; see<br>Eq. (12)) also becomes non-negligible in the lower solar atmo-Eq. [\(12\)](#page-2-8)) also becomes non-negligible in the lower solar atmosphere (see e.g., Fig. 2(c) of [Anusha et al. 2010\)](#page-10-8). Finally, as discussed in Section 4.1.1. of [Bommier](#page-10-3) [\(2016a\)](#page-10-3), the elastic collision rate  $Q_E$  is also significant in the lower solar atmosphere. Thus the present full non-LTE formalism is applicable in the lower solar atmosphere when velocity-changing collisions are important. In the upper solar atmosphere wherein velocity-changing collisions are negligible, one may use the numerically relatively simpler standard non-LTE PFR formalism.

# <span id="page-5-0"></span>**5. The numerical method of solution**

We solve the full non-LTE transfer problem for the case of a twolevel atom with broadened upper level using a modified version of the Accelerated Lambda Iteration (ALI) method developed by [Paletou & Auer](#page-11-14) [\(1995\)](#page-11-14) for the corresponding standard PFR model. Here we present this ALI method in some detail, focusing on the changes brought about by the full non-LTE nature of the problem at hand. As in the standard PFR model, the source function given by Eq. [\(26\)](#page-3-7) is iterated until convergence using the Approximate Lambda Operator (ALO) which is chosen to be the diagonal of the full lambda operator [\(Olson et al. 1986\)](#page-11-15).

In an one-dimensional planar atmosphere considered here, the radiation field is axisymmetric. Thus the specific intensity depends only on the inclination  $\theta_r$  of the ray about the atmospheric normal. In other words  $I(x, \Omega, \tau) = I(x, \mu, \tau)$ , where  $\mu = \cos \theta_r$ . Thus, the formal solution of the radiative transfer<br>equation can be stated as equation can be stated as

$$
I_{x\mu} = \Lambda_{x\mu}[S_x],\tag{27}
$$

where for notational convenience, we have suppressed the dependence on optical depth, and the dependence on frequency and angular variables appear as subscript. Moreover  $\Lambda_{x\mu}$  denotes the frequency and angle-dependent integral operator. Given an estimate of the source function at the *n*th iteration, the iterative scheme will be given by

$$
S_x^{(n+1)} = S_x^{(n)} + \delta S_x^{(n)},
$$
\n(28)

where  $\delta S_X^{(n)}$  is the iterative correction on the source function.<br>Using the operator splitting technique (Cannon 1973), namely Using the operator splitting technique [\(Cannon 1973\)](#page-10-9), namely,

 $\Lambda_{x\mu} = \Lambda_{x\mu}^* + (\Lambda_{x\mu} - \Lambda_{x\mu}^*)$  with  $\Lambda_{x\mu}^*$  being the ALO chosen here to be diagonal of the full lambda operator after Olson et al. (1986)  $\Delta x_{\mu} = \Delta x_{\mu} + (\Delta x_{\mu} - \Delta x_{\mu})$  with  $\Delta x_{\mu}$  being the AEO chosen field to be diagonal of the full lambda operator after [Olson et al.](#page-11-15) [\(1986\)](#page-11-15), and following a rather standard procedure [\(Paletou & Auer 1995,](#page-11-14) see also [Sampoorna & Trujillo Bueno 2010\)](#page-11-16), we arrive at the following expression for the iterative correction

<span id="page-5-2"></span>
$$
\delta S_x^{(n)} - (1 - \varepsilon) \int_0^\infty \varphi_x \Lambda_x^* [\delta S_x^{(n)}] dx - \frac{(1 - \varepsilon)}{(1 + \zeta)}
$$
  
\n
$$
\times \left\{ \int_0^\infty \left[ \frac{R_{121}(x', x)}{\varphi_x} \right] \Lambda_x^* [\delta S_{x'}^{(n)}] dx' - \int_0^\infty \varphi_x \Lambda_x^* [\delta S_x^{(n)}] dx \right\}
$$
  
\n=  $r_x^{(n)}$ . (29)

For deducing the above equation, we have used Eq. [\(16\)](#page-2-9) and also the fact that for a static atmosphere the radiation field is symmetric about the line-center, so that only half profile can be considered. In the above equation, the frequency dependent ALO is given by

$$
\Lambda_x^* = \int_{-1}^{+1} \frac{d\mu}{2} \Lambda_{x\mu}^*,\tag{30}
$$

and the residual  $r_x^{(n)}$  has the form

$$
r_x^{(n)} = \varepsilon + (1 - \varepsilon) \mathcal{J}_{12}^{(n)}(\tau) + \frac{(1 - \varepsilon)}{1 + \zeta} \times \left\{ \int_0^\infty \left[ \frac{R_{121}(x', x)}{\varphi_x} \right] \Lambda_{x'} [S_{x'}^{(n)}] dx' - \mathcal{J}_{12}^{(n)}(\tau) \right\} - S_x^{(n)}, \quad (31)
$$

where  $\mathcal{J}_{12}^{(n)}(\tau)$  and the integral involving the angle-averaged PFR function are obtained from the formal solver using the *n*th iterate function are obtained from the formal solver using the *n*th iterate source function. For this purpose, we use the short-characteristic method of [Olson & Kunasz](#page-11-17) [\(1987,](#page-11-17) see also [Lambert et al. 2016\)](#page-11-18). At each iteration the system of linear equations [\(29\)](#page-5-2) can be resolved using either a frequency-by-frequency (FBF) method or a core-wing method [\(Paletou & Auer 1995\)](#page-11-14). In the following subsections we briefly describe both these methods for the full non-LTE case considered here.

#### 5.1. Frequency-by-Frequency method

<span id="page-5-3"></span>For a given depth point the system of equations [\(29\)](#page-5-2) consists of  $N_x$  number of linear equations, with  $N_x$  representing the number of frequency points. In matrix form this system of linear equations can be written as

$$
\mathbf{A}\,\delta\mathbf{S}^{(n)}=\mathbf{r}^{(n)}\,,\tag{32}
$$

where at each depth point,  $\delta S^{(n)}$  and  $r^{(n)}$  are vectors of length  $N_{n}$  and **A** is a matrix of dimension  $N_{n} \times N_{n}$ . Following Pale- $N_x$  and **A** is a matrix of dimension  $N_x \times N_x$ . Following [Pale](#page-11-14)[tou & Auer](#page-11-14) [\(1995\)](#page-11-14) we solve Eq.  $(32)$  using the LU decomposition scheme (see e.g., [Press et al. 1986\)](#page-11-19). As the FBF method involves matrix manipulations such as inversion and multiplication, it is computationally somewhat expensive when compared to the core-wing method presented in the following subsection.

#### <span id="page-5-4"></span>5.2. Core-wing method

Based on the behavior of the type-II PFR function of [Hum](#page-11-11)[mer](#page-11-11) [\(1962\)](#page-11-11), a core-wing method was proposed by [Paletou &](#page-11-14) [Auer](#page-11-14) [\(1995\)](#page-11-14) that allowed the computation of system of linear equations [\(29\)](#page-5-2) through simple algebraic manipulations, thereby considerably reducing the computational costs involved. In this method, the type-II PFR function is approximated by CFR in

<span id="page-5-1"></span><sup>4</sup> We have verified that the range of *q* values suggested by [Landi](#page-11-13) [Degl'Innocenti & Landolfi](#page-11-13) [\(2004\)](#page-11-13) more or less agrees with those determined from the hard-sphere collision model. For example, using the atomic radii listed in [Allen](#page-10-7) [\(1973,](#page-10-7) see page 45), we find *q* for H-H collision to be 7, He-H collision to be 12.9, and Cs-Cs collision to be 137 (note that Cs has the largest atomic radius).

the line core and coherent scattering in the wings for the computation of the source function corrections. An extension of this method for the type-III PFR function was given by [Fluri et al.](#page-10-10) [\(2003\)](#page-10-10), wherein this function is approximated by CFR in the line core and set to zero in the wings. We apply both the above mentioned core-wing approximations to the  $R_{121}$  function appearing in Eq. [\(29\)](#page-5-2). Furthermore, in Eq. [\(29\)](#page-5-2) we make the approximation of computing the frequency integral involving the absorption profile  $\varphi_x$  only in the line core and set it to zero in the wings. This approximation is similar to the core-wing approximation made for type-III PFR function. With these approximations, we can easily deduce the following core-wing approximation for Eq. [\(29\)](#page-5-2) :

$$
\delta S_x^{(n)} = \frac{r_x^{(n)} + (1 - \alpha_x) \Delta T^{\text{core}}}{1 - (1 - \varepsilon) \alpha_x \Lambda_x^*/(1 + \zeta)},
$$
\n(33)

where  $\alpha_x$  is the core-wing separation coefficient given by

$$
\alpha_x = \begin{cases} 0 & \text{in the core } (x \le 3.5), \\ \gamma_{\text{coh}, \, V} R_{\text{II-A}}(x, x) / \varphi_x & \text{in the wings } (x > 3.5), \end{cases} \tag{34}
$$

and

$$
\Delta T^{\text{core}} = (1 - \varepsilon) \int_{\text{core}} \varphi_x \Lambda_x^* [\delta S_x^{(n)}] dx, \qquad (35)
$$

which can be easily evaluated as described in [Paletou & Auer](#page-11-14) [\(1995,](#page-11-14) see their Section 5.1). As in [Sampoorna & Trujillo Bueno](#page-11-16) [\(2010\)](#page-11-16), we find that when the elastic collision rate  $Q_E$  and/or velocity-changing collision rate  $Q_V$ , are large the approximation of setting the type-III PFR function and the  $\mathcal{J}_{12}(\tau)$  integral to zero in the wings leads to convergence problems. In such cases we use the CFR approximation throughout the line profile. This typically occurs for  $Q_E/A_{21} > 1$  and/or  $Q_V/A_{21} > 1$ , when the medium is optically thick or semi-infinite. We have verified that both the core-wing and FBF methods give identical results. Therefore, all the solutions presented in this paper are computed with the core-wing method.

# 5.3. Numerical computation of  $\bar{J}_{12}(u,\tau)$

The full non-LTE formalism gives us access to the VDF  $f_2$  of the upper level, which depends on  $\bar{J}_{12}(\mu, \tau)$  (see Eq. (3) of Pale-<br>tou et al. 2023). In the case of a two-level atom with broadened [tou et al. 2023\)](#page-11-1). In the case of a two-level atom with broadened upper level, the computation of  $\bar{J}_{12}(u, \tau)$  is numerically more complex than the coherent scattering case considered in Palecomplex than the coherent scattering case considered in [Pale](#page-11-1)[tou et al.](#page-11-1) [\(2023\)](#page-11-1). This is because, in the case of coherent scattering the integrand in  $\bar{J}_{12}(u, \tau)$  contained a delta function (see<br>their Eq. (1)) while the integrand in the present case involves a their Eq. (1)), while the integrand in the present case involves a Lorentzian function (see Eq. [\(7\)](#page-2-7)). Integrals involving Lorentzian are known to be notoriously difficult to evaluate due to the sharp peaked nature of the Lorentzian function. Therefore, we need to devise a suitable method to evaluate such integrals accurately. Here we describe such a numerical method following [Bommier](#page-10-0) [\(1997a,](#page-10-0)[b\)](#page-10-1).

<span id="page-6-1"></span>In terms of the adimensional frequency  $x$ , the quantity  $\bar{J}_{12}(u, \tau)$  is given by (cf. Eq. [\(7\)](#page-2-7))

$$
\bar{J}_{12}(u,\tau) = \oint \frac{d\Omega}{4\pi} \int_{-\infty}^{+\infty} \frac{a}{\pi} \frac{1}{(x - u \cdot \Omega)^2 + a^2} I(x,\mu,\tau) dx. \tag{36}
$$

The dot product of the velocity vector  $\boldsymbol{u}$  with the ray direction  $\Omega$  is evaluated using Eq. (9) of [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1), which requires us to construct the corresponding quadratures for polar

angles  $\theta_u$  and  $\theta_r$ . Since the radiation field is axisymmetric, it is sufficient to construct the quadrature directly for the azimuth difsufficient to construct the quadrature directly for the azimuth difference  $(\phi_r - \phi_u)$ . The dot product  $\mathbf{u} \cdot \mathbf{\Omega}$  can take both positive and negative values. Thus, the frequency integral in Eq. [\(36\)](#page-6-1) has to include the entire range from −∞ to +∞. The intensity for the negative *x* values can be easily obtained from the corresponding positive values using the symmetry relation. We have used thirteen Gauss-Legendre nodes for the direction cosines corresponding to both the ray and velocity vector in the [0, 1] domain, and a twenty-point equally spaced quadrature for their azimuth difference  $(\phi_r - \phi_u)$  in the [0, 2 $\pi$ ] domain. For each pair of  $\theta_r$ ,  $\theta_u$ , and  $(\phi_u - \phi_u)$  we first perform the frequency integral and then and  $(\phi_r - \phi_u)$ , we first perform the frequency integral and then the angular integration.

Evaluating integrals involving Lorentzian function poses accuracy issues (see e.g., Fig. 1 of [Paletou et al. 2020\)](#page-11-4). In the present paper, we apply a method originally developed by [Bom](#page-10-0)[mier](#page-10-0) [\(1997a,](#page-10-0)[b\)](#page-10-1) to compute the angle-dependent type-III PFR function of [Hummer](#page-11-11) [\(1962\)](#page-11-11), which is known to involve an integration over the Lorentzian function (see e.g., Eq. (61) of [Bom](#page-10-1)[mier 1997b\)](#page-10-1). Following her method, we compute the frequency integral in Eq. [\(36\)](#page-6-1) by the trapezoidal method with varying integration steps. The integration begins from the center of the Lorentzian (namely, at  $x = u \cdot \Omega$ ), and proceeds symmetrically thereafter. The integration step is originally set as one tenth of the damping width *a* and multiplied by 1.05 at each step of the integration (namely, a geometric progression). As discussed above, the quantity  $\mathbf{u} \cdot \mathbf{\Omega}$  is evaluated as described in [Paletou et al.](#page-11-1) [\(2023,](#page-11-1) see their Eq. (9)). Thus the integration needs to be performed for each value of  $u$  and  $\gamma$  (which is the cosine of the angle between the velocity vector and the ray direction). Since the frequency integration step size is varied as described above, the intensity computed on a standard frequency grid used for radiative transfer needs to be interpolated at every step of the frequency integration. We use the spline interpolation for this purpose.

The method described above to compute  $\bar{J}_{12}(\hat{u}, \tau)$  is however, newhat slow. For a typical case of semi-infinite atmosphere somewhat slow. For a typical case of semi-infinite atmosphere with 10 points per decade, 65 frequency points, and the angular quadrature mentioned above it requires about 67 minutes of computing time on a Intel $(R)$  Xeon $(R)$  Gold 5122 processor with 3.6GHz, 10.4 GT/s clock speed. Clearly computing this quantity and subsequently the VDF  $f_2$  of the upper level at every iteration would be computationally very expensive. However, since the ALI method described above does not require us to compute  $\bar{J}_{12}(u, \tau)$  and  $f_2$  at every iteration (see Eq. [\(29\)](#page-5-2), we compute these quantities once the ALI solution has converged which typically quantities once the ALI solution has converged, which typically takes 15 seconds of computing time.

# <span id="page-6-0"></span>**6. The numerical results**

In this section we first validate our iterative method by reproducing the benchmark result of [Hummer](#page-11-20) [\(1969\)](#page-11-20), and then illustrate the new quantities, namely the VDF of the upper level and the emission profiles together with source function with and without elastic and/ or velocity-changing collisions. We also illustrate a comparison of the normally emergent intensity profiles for the cases of a two-level atom with infinitely sharp upper and lower levels considered in [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1), and a twolevel atom with broadened upper level considered in this paper, along with the corresponding CFR standard non-LTE models. For the numerical studies presented here, we consider a onedimensional, isothermal, semi-infinite, planar atmosphere of total optical thickness at line center  $T = 10^6$  and  $\epsilon = 10^{-4}$ .<br>The radiative width of the upper level parameterized as  $a_B =$ The radiative width of the upper level parameterized as  $a_R$  =  $A_{21}/(4\pi\Delta v_D)$  is chosen to be  $10^{-3}$ . It is related to the total damp-

<span id="page-7-0"></span>Fig. 1. Validation of our iterative method for full non-LTE transfer problem (compare with Fig. 3c of [Hummer 1969\)](#page-11-20). The normalized source function is displayed as a function of frequency at different line center optical depths within the atmosphere, namely, at  $\tau = 0, 1, 10, 100, 10^3, 10^4$ . For comparison, we also show the corresponding CFR source function (constant with frequency) as dashed responding CFR source function (constant with frequency) as dashed lines.

ing parameter via  $a = a_R[1 + (Q_I + Q_E)/A_{21}]$ . Unless otherwise mentioned, both the rates  $q_E/A_{21}$  and  $Q_V/A_{21}$  are set to zero.

#### 6.1. Validation

For the atmospheric model described above, the standard non-LTE source function for the  $R_{II-A}$  PFR model is illustrated in Fig. 3c of [Hummer](#page-11-20) [\(1969\)](#page-11-20). For the purpose of validating our numerical method we reproduce this benchmark result in our Fig-ure [1,](#page-7-0) which displays the source function  $S(x, \tau)$  for different optical depths as a function of frequency. These solutions are computed with the ALI method presented in Section [5](#page-5-0) together with the core-wing method (cf. Section [5.2\)](#page-5-4) for calculating the source function corrections. A comparison of our Fig. [1](#page-7-0) with Fig. 3c of [Hummer](#page-11-20) [\(1969\)](#page-11-20), clearly shows that our numerical method satisfactorily reproduces the benchmark solutions thereby validating our iterative method. This is expected, as the source function derived from full non-LTE formalism is equivalent to the corresponding standard non-LTE PFR model when velocity-changing collisions are neglected (cf. Section [3\)](#page-3-0).

Unlike the standard non-LTE PFR model considered by [Hummer](#page-11-20) [\(1969\)](#page-11-20), the full non-LTE model considered here gives access to the VDF of the upper level. The emission profile on the other hand can be obtained from both the above-mentioned formalisms. However, it is rarely shown in the literature. Therefore, in this paper we illustrate both the emission profile and the VDF of the upper level. Figures [2](#page-7-1) and [3](#page-8-0) exhibit respectively the ratios  $\psi(x, \tau)/\varphi(x)$  and  $f_2(u, \tau)/f^M(u)$  for different line center optical denths within the atmosphere Figure 3 in the present paper is depths within the atmosphere. Figure [3](#page-8-0) in the present paper is equivalent to Fig. 3 in [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1), but for the case of scattering on a two-level atom with naturally broadened upper level. For the ease of comparison, in Figs. [2](#page-7-1) and [3,](#page-8-0) we also show as dashed lines the corresponding quantities at  $\tau = 1$  for coherent

<span id="page-7-1"></span>Fig. 2. Departure of emission profile  $\psi(x, \tau)$  from CFR for the case of scattering on a two-level atom with radiatively broadened upper level. Different lines correspond to  $\psi(x, \tau)/\varphi(x)$  at different line-center optical depths within the atmosphere (indicated in the figure legend). For comparison  $\psi(x, \tau = 1)/\varphi(x)$  corresponding to scattering on a two-level atom with infinitely sharp upper and lower levels (namely, coherent scattering – CS in the atomic frame) is shown as dashed line.

scattering (CS) in atomic frame (namely, the case of two-level atom with infinitely sharp lower and upper levels) considered in [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1).

For the standard non-LTE CFR model, the emission and the absorption profiles are identical [\(Hubeny & Mihalas 2014\)](#page-11-3). Thus to bring out the departure of the emission profile from CFR, we plot in Fig. [2](#page-7-1) the ratio  $\psi(x, \tau)/\varphi(x)$  at different line center optical depths within the atmosphere. Clearly, the emission profile departs from CFR for  $x > 1$ . As the optical depth increases this departure from CFR decreases. Furthermore, the differences in  $\psi(x, \tau)/\varphi(x)$  between the present and CS cases are significant (compare green solid and gray dashed lines in Fig. [2\)](#page-7-1).

Because here we consider angle-averaged emission profile, the VDF of the excited atom depending only on the modulus of velocity *u* is illustrated. Like in the CS case, deviation from the Maxwellian distribution is significant for  $u > 2$  and for optical depths close to the surface, which then decreases with increasing optical depth (compare the Fig. [3](#page-8-0) here with Fig. 3 of [Paletou et al. 2023\)](#page-11-1). However, unlike the CS case the overpopulation of excited level for  $u > 2$  is relatively smaller in the present case of two-level atom with naturally broadened upper level (compare green solid and gray dashed lines in Fig. [3\)](#page-8-0). We remark here that departure of the VDF of the upper level from the Maxwellian distribution was also obtained by [Bommier](#page-10-11) [\(2016b,](#page-10-11) see her Section 5.3) through a self-consistent solution of the statistical equilibrium equations for each velocity class of the velocity-dependent atomic density matrix elements and the radiative transfer equation for the polarized radiation in the case of Na I  $D_1$  and  $D_2$  lines. This departure can be attributed to the radiative processes between the interacting atom and the incident radiation field which is spectrally structured (namely, non-flat) within the radiative width of the upper level.

<span id="page-8-0"></span>Fig. 3. Departure of the VDF of the naturally broadened upper level  $(f_2(u, \tau))$  of a two-level atom from the Maxwellian equilibrium distribution  $f^M(u)$  at different line center optical depths within the atmosphere (indicated in the figure legend). For comparison the corresponding quantity at  $\tau = 1$  for the CS case is shown as dashed line. Clearly, overpopulation of  $f_2$  at large *u*'s is relatively more in the CS case than in the present case of two-level atom with naturally broadened upper level.

Figure [4](#page-8-1) displays a comparison of the normally emergent intensity for the CS and the present case of a two-level atom with radiatively broadened upper level. We also plot the corresponding CFR cases, namely for the damping parameter  $a = 0$  and  $a = 10^{-3}$ . While the CS and the corresponding CFR ( $a = 0$ ) cases nearly coincide (compare orange and green lines in Fig. [4\)](#page-8-1), significant differences are seen in the wings for  $x > 3$  between the CS and PFR cases (compare green and blue lines). Moreover, the PFR intensity differs significantly from the corresponding CFR intensity for  $x > 2$  (compare blue and red lines in Fig. [4\)](#page-8-1). In particular, we recover the lowering / dip of emergent intensity in the wings before finally reaching the continuum level, a well-known effect of PFR ( $R$ <sub>II−A</sub>).

#### 6.2. Impact of velocity-changing collisions  $(Q_V/A_{21})$

Unlike the standard non-LTE PFR formalism, the full non-LTE formalism of [Oxenius](#page-11-2) [\(1986\)](#page-11-2) takes into account the influence of velocity-changing collisions characterized here by  $Q_V/A_{21}$ . To bring out the impact of velocity-changing collisions, here we consider the extreme limit of  $\alpha = 0$ , corresponding to the case of strong collisions (in the kinetic sense; see [Hubeny & Cooper](#page-11-7) [1986\)](#page-11-7). When  $\alpha = 0$ , the total elastic collision rate  $Q_E$  gets its contribution solely from  $Q_V$ , which leads to simultaneous phase and velocity changes. In this respect, *Q<sup>V</sup>* here actually represents the effective velocity-changing collision rate. Figures [5,](#page-9-1) [6,](#page-9-2) and [7,](#page-9-3) respectively, display the influence of  $Q_V/A_{21}$  on the source function, emission profile, and the VDF of the upper level at optical depth  $\tau = 1$ . The model parameters used are the same as those for Figures [1–](#page-7-0)[3,](#page-8-0) but we now vary  $Q_V/A_{21}$  from 0 to 50 in much the same way as  $\zeta$  was varied in Section 7 of [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1)

<span id="page-8-1"></span>Fig. 4. Comparison of normally emergent intensity computed using full non-LTE model for a two-level atom with infinitely sharp levels (CS) and radiatively broadened upper level (PFR) and standard non-LTE model with CFR. Notice that the intensity for CS and the corresponding CFR  $(a = 0)$  case nearly coincide.

for the CS case. Since we have chosen  $\epsilon = 10^{-4}$ , the ratio  $Q_I/A_{21}$ <br>is relatively small, such that  $\zeta$  (see Eq. (13)) is nearly the same as is relatively small, such that  $\zeta$  (see Eq. [\(13\)](#page-2-10)) is nearly the same as  $Q_V/A_{21}$ . Thus our Fig. [5](#page-9-1) is equivalent to Fig. 4 of [Paletou et al.](#page-11-1) [\(2023\)](#page-11-1), but for the case of broadened upper level. However, unlike the CS case, the frequency grid is much more extended in the present case. This is to take into account the fact that the absorption profile is now a Voigt function with rather broad damping wings. Like in the CS case, the source function at  $\tau = 1$ approaches the CFR limit with increasing values of  $Q_V/A_{21}$  or  $\zeta$  (see Fig. [5\)](#page-9-1). This is also in general the trend exhibited by the emission profile (see Fig. [6\)](#page-9-2) and the VDF of the upper level (see Fig. [7\)](#page-9-3). As discussed in Section [4,](#page-3-1) the velocity-changing collisions are non-negligible in the lower solar atmosphere, wherein  $Q_V/A_{21}$  or  $\zeta$  may take moderate values when full non-LTE formalism has to be adopted for an accurate determination of the source function (cf. Fig. [5\)](#page-9-1) and the radiation field.

### 6.3. Impact of phase-changing elastic collisions  $(q_E/A_{21})$

The phase-changing elastic collisions that are normally accounted for in spectral line formation theory through their effect on broadening the spectral line and leading to CFR in the atomic frame are characterized by  $q_E/A_{21}$ . By considering  $\alpha = 1$ , here we present its impact on the source function, emission profile, and the VDF of the upper level at  $\tau = 1$ . When  $\alpha = 1$ , the total elastic collision rate  $Q_E$  gets its contribution solely from the phase-changing collisions, which are basically weak collisions [\(Hubeny & Cooper 1986\)](#page-11-7). The dependence of the source function on  $q_E/A_{21}$  is known from the standard non-LTE PFR formalism. Basically with an increase in  $q_E/A_{21}$  the source function approaches the CFR limit, which is indeed the case as seen from Fig. [8.](#page-9-4) This is true also for the emission profile, namely  $\psi(x, \tau) \rightarrow \varphi(x)$  with increasing values of the phase-changing elastic collision rate (see Fig. [9\)](#page-10-12). As for the VDF of the upper

<span id="page-9-1"></span>Fig. 5. Influence of velocity-changing collisions on the normalized source function at  $\tau = 1$ . As expected, with increasing values of  $Q_V/A_{21}$ , the source function approaches the CFR limit, shown as horizontal dashed line.

<span id="page-9-2"></span>Fig. 6. Dependence of the ratio of emission to absorption profile at  $\tau = 1$  (namely,  $\psi(x, \tau = 1)/\varphi(x)$ ) on velocity-changing collisions. As expected, the emission profile approaches the CFR limit, namely  $\psi(x, \tau) \rightarrow \varphi(x)$  with increasing values of  $Q_V/A_{21}$ .

level, its departure from the Maxwellian distribution initially increases until  $q_E/A_{21} = 0.5$  and then decreases with further increase in  $q_E/A_{21}$  (see Fig. [10\)](#page-10-13).

# <span id="page-9-0"></span>**7. Conclusions**

Full non-LTE radiative transfer, although formulated way back in the 1980's [\(Oxenius 1986\)](#page-11-2), remained largely unexplored because of the complexity involved in its numerical implementa-tion (see however [Borsenberger et al. 1986,](#page-10-14) [1987;](#page-10-15) Atanackovič [et al. 1987,](#page-10-16) who considered the limiting case of pure Doppler profile). More recently, [Paletou & Peymirat](#page-11-0) [\(2021\)](#page-11-0) have reconsidered this problem, and expressed its basic elements in terms of the prevailing standard notations in this field of research.

<span id="page-9-3"></span>Fig. 7. Dependence of the ratio of the VDF of the upper-level to Maxwellian distribution at  $\tau = 1$  (namely,  $f_2(u, \tau = 1)/f^M(u)$ ) on velocity-changing collisions. With increasing values of  $O_v/A_{2v}$  the develocity-changing collisions. With increasing values of  $Q_V/A_{21}$  the departure of the  $f_2$  from Maxwellian initially increases for  $Q_V/A_{21} = 0.25$ in the regime of intermediate velocities and then decreases.

<span id="page-9-4"></span>Fig. 8. Influence of phase-changing elastic collision rate  $q_E/A_{21}$  on the normalized source function at  $\tau = 1$ . As expected, the source function approaches the CFR limit (shown as horizontal dashed line) with increasing values of *<sup>q</sup><sup>E</sup>*/*A*21.

[Paletou et al.](#page-11-1) [\(2023\)](#page-11-1) then made a numerical implementation of this formalism for the case of coherent scattering in the atomic frame using the usual numerical iterative methods that are in use for the standard non-LTE transfer problem. In the present paper, we have solved, for the first time, a full non-LTE radiative transfer problem considering the case of a two-level atom with infinitely sharp lower level and broadened upper level. For this purpose, we have applied, after suitable modifications, the well-known operator perturbation methods developed for standard PFR models [\(Paletou & Auer 1995,](#page-11-14) see also [Sampoorna &](#page-11-16) [Trujillo Bueno 2010;](#page-11-16) [Lambert et al. 2016\)](#page-11-18). We validate our iterative method against the standard non-LTE transfer problem with angle-averaged *RII*−*<sup>A</sup>* PFR function [\(Hummer 1962,](#page-11-11) [1969\)](#page-11-20). We

<span id="page-10-12"></span>Fig. 9. Dependence of the ratio of emission to absorption profile at  $\tau = 1$ (namely,  $\psi(x, \tau = 1)/\varphi(x)$ ) on varying values of phase-changing elastic collision rate  $q_E/A_{21}$  (indicated in the figure legend). As expected, the emission profile approaches the CFR limit (namely,  $\psi(x, \tau) \rightarrow \varphi(x)$ ) with increasing phase-changing elastic collision rate.

<span id="page-10-13"></span>Fig. 10. Dependence of the ratio of the VDF of the upper-level to Maxwellian distribution at  $\tau = 1$  (namely,  $f_2(u, \tau = 1)/f^M(u)$ ) on vary-<br>ing values of phase-changing elastic collision rate  $g_E/A_{21}$  (indicated in ing values of phase-changing elastic collision rate  $q_E/A_{21}$  (indicated in the figure legend). With increasing values of  $q_E/A_{21}$  the the departure of the  $f_2$  from Maxwellian initially increases (until  $q_E/A_{21} = 0.5$ ) and then decreases.

illustrate the new quantities, namely, the emission profile and the VDF of the upper level, and also make a comparison with the case of a two-level atom with infinitely sharp lower and upper levels (namely, the coherent scattering case considered in [Pale](#page-11-1)[tou et al. 2023\)](#page-11-1). We clearly demonstrate the influence of phasechanging elastic collisions (*qE*, which lead to spectral line broadening and CFR in the atomic frame) and the velocity-changing collisions  $(Q_V)$  on the source function, emission profile, and the VDF of the upper level. In particular, we show that for moderate values of  $Q_V/A_{21}$  (or equivalently  $\zeta$ ; see Eq. [\(13\)](#page-2-10)), one has to adopt the full non-LTE formalism presented here to accurately determine the source function (see Fig. [5\)](#page-9-1) and the radiation field.

Results presented in this paper would serve as benchmarks for future works in this topic (and would be made available upon request to corresponding author).

In the present paper, we show that in the absence of velocitychanging collisions, the full non-LTE formalism is equivalent to the standard non-LTE PFR formalism, thereby validating the use of numerically relatively simpler standard non-LTE PFR formalism. However, unlike the standard non-LTE formalism, the full non-LTE formalism can also account for the velocity-changing collisions, which may become significant in the lower solar atmosphere (see Section [4\)](#page-3-1). Given this, an accurate determination of velocity-changing collision rates for astrophysical applications become crucial. Until such calculations become available, the hard-sphere collision model would provide an excellent way to determine the cross-section for velocity-changing collisions.

For computational simplicity, in the present paper we have considered the angle-averaged emission profile (cf. Eq. [\(18\)](#page-2-11)), and thereby the angle-averaged redistribution functions (cf. Eq. [\(20\)](#page-3-8)). One of the near future goals would be to relax this assumption, which would allow us to explore the angular dependence of the VDF of the excited level.

The next crucial step will be to consider the full non-LTE transfer problem for multi-level atoms. In particular we intend to take forward this work by considering a three-level atom which would involve dealing with three distributions, one for the photon and two more for the excited atoms. Then another important step would be to relax the usual assumption of Maxwellian velocity distribution for the free electrons.
