Abstract

The cores of stars are the cosmic furnaces where light elements are fused into heavier nuclei [1-3]. The fusion of hydrogen to helium initially powers all stars. The ashes of the fusion reactions are then predicted to serve as fuel in a series of stages, eventually transforming massive stars into a structure of concentric shells. These are composed of natal hydrogen on the outside, and consecutively heavier compositions inside, predicted to be dominated by helium, carbon/oxygen, oxygen/neon/magnesium, and oxygen/silicon/sulphur [4, 5]. Silicon and sulphur are fused into inert iron, leading to the collapse of the core and either a supernova explosion or the direct formation of a black hole [6–9]. Stripped stars, where the outer hydrogen layer has been removed and the internal He-rich layer (in Wolf-Rayet WN stars) or even the C/O layer below it (in Wolf-Rayet WC/WO stars) are exposed [10], provide evidence for this shell structure, and the cosmic element production mechanism it reflects. The types of supernova explosions that arise from stripped stars embedded in shells of circumstellar material

(most notably Type Ibn supernovae from stars with outer He layers, and Type Icn supernovae from stars with outer C/O layers) confirm this scenario [11-15]. However, direct evidence for the most interior shells, which are responsible for the production of elements heavier than oxygen, is lacking. Here, we report the discovery of the first-of-its-kind supernova arising from a star peculiarly stripped all the way to the silicon and sulphur-rich internal layer. Whereas the concentric shell structure of massive stars is not under debate, it is the first time that such a thick, massive silicon and sulphur-rich shell, expelled by the progenitor shortly before the SN explosion, has been directly revealed.

On 7 September 2021 at 09:56 (UTC dates are used throughout this paper), the public Northern Sky Survey of the Zwicky Transient Facility (ZTF) [16, 17] discovered the supernova (SN) 2021yfj at right ascension $\alpha = 01^{h}37^{m}46^{s}171$ and declination $\delta = -01^{\circ}15'17''.78$ (J2000.0; Methods Section Discovery) [18]. A spectrum obtained with Keck/LRIS 24 hours after discovery shows a large number of narrow emission lines and P Cygni profiles from ionised silicon, sulphur, and argon (Si III–IV, S III–IV, and Ar III; Figure 1) superimposed on a hot blackbody spectrum ($T \approx 15,000$ K; Methods Section Bolometric Light Curve), previously unobserved in any supernova [13, 19, 20]. Lines of lighter elements, which are much more common in the Universe [3] and usually detected in spectra of infant SNe [13, 21, 22], are either very weak (carbon and helium) or even completely absent (e.g., hydrogen, nitrogen). This prompted us to monitor the photometric and spectroscopic evolution at optical and ultraviolet (UV) wavelengths for the next 120 days until SN 2021yfj faded below the brightness of the host galaxy (Supplementary Material Observations and Data Reduction). The early spectra also reveal narrow absorption and emission lines from the interstellar medium (ISM) in the host galaxy at a redshift of $z = 0.13865 \pm 0.00004$, placing SN 2021yfj at a luminosity distance of ≈ 676.4 Mpc, assuming Planck cosmology (Methods Section Distance; [23]). Hereafter, all times are given with respect to the discovery time and in the rest-frame.

The SiIII–IV, SIII–IV, and ArIII lines are visible up to day 7.7 (i.e., up to ≈ 5.4 days after the time of the g-band maximum). With time, these lines become weaker, and emission lines from singly-ionised silicon and sulphur emerge (Extended Material Figure 1). Some lines exhibit P Cygni profiles (Extended Material Figure 2), which can be produced either in the SN ejecta, an expanding shell of gas expelled by the progenitor prior to the explosion, or a stellar wind. The absorption minima are at a velocity of $1,000-1,500 \text{ km s}^{-1}$ and the blue edge of the absorption component reaches merely $3,000 \text{ km s}^{-1}$. This is significantly slower than typical SN ejecta velocities ($\sim 10,000 \text{ km s}^{-1}$; [24]), but comparable to the wind velocities of Wolf-Rayet (WR) stars [10] and similar to the velocities of expanding shells of circumstellar material (CSM) around some SNe [e.g., 11–14]. Between day 11 and 20, the blackbody spectrum subsides, and a blue pseudocontinuum dominates the emission in the optical, a tell-tale sign of interaction with CSM [25]. Superimposed are emission lines from SiII, SII, MgI–II, HeI, and OI that remain visible through our last spectrum at day 49.8 (Extended Material Figure 1). Considering that silicon, sulphur, and argon are the ashes of the ephemeral oxygen-burning phase that takes place less than a few years before a massive star dies [e.g., 5], it is puzzling that the early and late spectra also show helium (Methods Section Hydrogen and Helium Content). Helium should have been consumed during the earlier burning stages, and it is not a daughter product of the oxygen-burning phase [5].

SN 2021yfj's unique properties vividly stand out when comparing its spectroscopic sequence to those of stripped-envelope supernovae (SESNe) that strongly interact with CSM rich in either He (Type Ibn) or C/O/Ne (Type Icn; *Figure 2, Methods Section* Comparison With Interaction-powered SESNe). Spectra of SNe Ibn and Icn obtained shortly after explosion exhibit narrow emission lines from carbon, nitrogen, oxygen, helium, or hydrogen, but no silicon and no sulphur. These differences remain well visible in the spectra obtained around maximum light. The Type Icn SNe 2019hgp and 2021csp also show P Cygni profiles with velocities similar to those of SN 2021yfj, which were interpreted as originating from a fast stellar wind [13, 14]. At late times, all objects are characterised by a blue pseudocontinuum with superimposed emission lines. Yet again, SN 2021yfj displays striking differences: conspicuous silicon and sulphur emission lines but no Ca near-infrared (NIR) triplet at ~ 8,500 Å in emission. Therefore, the discovery of silicon and sulphur in SN 2021yfj is not due to differences in the data quality, the timing of the observations, or the blackbody temperature. Instead, the presence of silicon and sulphur reflects true differences in the elemental composition of the CSM and, therefore, the SN progenitor. This lets us conclude that SN 2021yfj is embedded in a thick, extended CSM rich in silicon and sulphur, never observed

in any supernova before. Since SN classes are defined by the absence or presence of particular chemical elements in their spectra [26, 27], SN 2021yfj is the first member of a previously unknown SN class: Type Ien (*Methods Section* A New Type of Supernova; [28]).

SN 2021yfj is > 2 mag more luminous than a typical SESN ($M_g = -19.0$ mag for SN 2021yfj compared to $M_q = -17.3$ mag for a typical SESN), and it has a shorter rise time from 50% peak flux (2.3 days vs. 8 days). The combination of being more luminous with a shorter rise time is inconsistent with Nipowered SNe. The modelling of the light curve corroborates this. Solely powering by radioactive 56 Ni or a central engine, such as a spindown of a rapidly spinning, highly magnetised neutron star, can be excluded (Methods Section Light-Curve Modelling). Owing to the assumptions of the two models, they do not simultaneously capture the rise, peak luminosity, and decline. The bolometric light curve (Figure 3), constructed from the multiband data is akin to those of interaction-powered SNe Ibn and Icn. At peak, SN 2021yfj reached $\gtrsim 3 \times 10^{43}$ erg s⁻¹, and integrating over the entire light curve yields a radiated energy of $0.6 \sim 1 \times 10^{50}$ erg. Both values are strict lower limits because the true bolometric peak likely occurred before our multiwavelength campaign started (Methods Section Bolometric Light Curve). Fitting the bolometric light curve with the model of ejecta-CSM interaction from Ref. [29, 30] reproduces the photometric evolution of SN 2021yfj (Methods Section Light-Curve Modelling). The fit points to an ejecta mass of ~ 5 M_{\odot} , a CSM mass of > 1 M_{\odot} and < $M_{\rm ejecta}$, and an explosion energy of (1.5–2) ×10⁵¹ erg (Extended Material Figure 5). The slight tension between the model and the observations during the rise could be mitigated by more complex CSM geometries and density profiles than the ones used here.

The ubiquity of silicon and sulphur lines in the blue part of the optical spectra at early times raises the question of the silicon and sulphur abundance in the spectrum formation region. Would a low abundance be sufficient, as can happen with iron-group elements? (For example, solar-metallicity iron can easily explain the strong blanketing observed in SNe II at the recombination epoch; see, e.g., observations [31] and models [32–34].) Or, would a high abundance be necessary, as can happen for helium in SNe Ib [e.g., 35]? To address these questions, we perform exploratory radiative-transfer simulations using mock ejecta with an elemental composition similar to the O/Si shell in massive helium stars, which is the outermost shell containing a significant amount of freshly nucleosynthesised silicon and sulphur. Our model consists of an ejecta with 3.24 M_{\odot} , a steep density profile with a power-law exponent of -10 (a wind profile is excluded because of the weakness of emission lines), and a base velocity of 1000 km s⁻¹, yielding a total kinetic energy of a few 10^{49} erg at that time. Furthermore, we deposit a power of 3×10^{43} erg s⁻¹ at a velocity of 1000 km s⁻¹ (Methods Section Spectral Modelling). This simple model (shown in red in Figure 4) can explain the observed features (shown in black in the same figure) at < 4,800 Å in the discovery spectrum in terms of the relative and absolute strength as well as the line width. Increasing the mass fraction from a few percent to 30-50% yields slightly stronger features from silicon and sulphur but in growing tension with the observations (*Methods Section Spectral Modelling*). Likewise, decreasing the mass fraction below 1% gives weaker features and is, therefore, inconsistent with the observations. Based on these simulations, we conclude that a mass fraction of a few $\times 0.01$ suffice to explain the observed features. Furthermore, to have an optically thick CSM out to 10^{15} cm requires a large CSM mass of $\sim 3 M_{\odot}$. This strongly suggests that SN 2021yfj is the product of a massive star that was stripped all the way to the silicon- and sulphur-rich internal layer prior to explosion. The presence of helium cannot be explained by this model. In fact, no O- or Si-rich material in massive-star models is rich in He.

In the framework of wind-driven mass loss, the stripping of a star all the way to the O/Si shell is very challenging to explain. Pulsational pair instabilities might accomplish that [9, 36–38]. This phenomenon is predicted to occur in stars with an initial mass of 70–140 M_{\odot} , which experience a recurrent instability from producing e^-e^+ pairs during the oxygen-burning phase. The interaction between CSM shells can produce luminous transients [9, 39, 40] with properties qualitatively matching those of SN 2021yfj. In this scenario, SN 2021yfj could be the product of collisions between the last shells ejected before the star collapses into a black hole. While this model has appeal, the detection of helium cannot be readily explained and may require, for example, a binary helium star companion. The presence of helium is also an issue for the other massive-star scenarios discussed in the Methods Section Progenitor Scenarios, which are motivated by the star-forming host of SN 2021yfj (Methods Section Host Galaxy). A review of literature models involving accretion and burning of helium on the surface of a compact object does not reveal a suitable Si/S-forming scenario (Methods Section Progenitor Scenarios). All these models merit additional theoretical studies.

Stellar evolution theory predicts that stars nearing the end of their lives should consist of concentric shells, with hydrogen in the outermost shell and iron at the core [1–5]. However, direct observations of this shell structure are rare. WR stars experience significant mass loss toward the end of their lives, which can expose their He (WN stars) and C/O (WC/WO stars) shells [10]. Interaction-powered SNe provide an independent view of the shell structure of stars. The CSM they interact with encodes information on the surface composition of the dying star just before it explodes, free from contamination by explosion products [41–43]. Type IIn, Ibn, and Icn supernovae probe the H, He, and C/O shells, respectively. These SNe not only complement observations of Wolf-Rayet stars but also reveal how dying stars can lose part of their outer layers just before the terminal explosion. The discovery of SN 2021yfj has three important implications for stellar evolution theory: (i) it reveals a formation site of argon, silicon, and sulphur; (ii) it likely directly confirms the complete sequence of concentric shells in massive stars; and (iii) it requires the operation of processes that can strip stars down to their inner shells.

The lack of known SNe that show any similarity to the early- or late-time spectra of SN 2021yfj suggests that Type Ien SNe are intrinsically rare. The ZTF Bright Transient Survey [BTS; 44, 45], which aims to spectroscopically classify all ZTF transients that peak brighter than m = 18.5 mag and is nearly 100% complete, has not identified a single SN 2021yfj-like event during its six years of operation. Thus, from the BTS, we conclude that the rate of SN 2021yfj-like events is $< 30 \text{ Gpc}^{-3} \text{ yr}^{-1}$ [95% confidence], < 1/1,000 the rate of SNeIb/c [Methods Section Event Rate; 46]. As future facilities, such as the Vera C. Rubin Observatory, continue to expand the discovery space for the transient Universe, there is a great deal of hope that these surveys will uncover new classes of explosive events. SN 2021yfj represents one of these rare new transients, but it is important to note that it does not significantly stand out from the population of extragalactic transients based on its photometric evolution alone (Extended Material Figure 4). Instead, it is the spectra that uniquely identify SN 2021yfj as belonging to an entirely new SN class: narrow silicon and sulphur lines at early times and a blue pseudocontinuum with silicon and sulphur lines at late times. This highlights the importance of spectroscopic observations and lays plain evidence that even sophisticated artificial-intelligence-powered anomaly-detection algorithms running on light curves from the Rubin Legacy Survey of Space and Time [LSST; 47] will not be able to recover every new type of transient in the LSST data stream. To detect additional SN 2021yfj-like events or discover the predicted but yet not discovered Type Id/Idn/Ie SNe (Extended Material A New Type of Supernova), efforts are needed that tightly couple high-throughput, medium-resolution spectrographs with long-duration, highcadence time-domain surveys, which will naturally be provided by existing and future medium-deep surveys [16, 48–53] and the deep Rubin Legacy Survey of Space and Time [47]. The discovery of any additional SN 2021yfj-like objects will have a profound impact on our understanding of their nature.

Fig. 1: Spectrum obtained 1.0 days after the first ZTF detection with Keck/LRIS in the range from 2,720 to 4,800 Å, after subtracting the blackbody continuum. The spectrum reveals narrow emission lines of highly ionised species of silicon, sulphur, and argon, which have never been seen in any SN before, as well as doubly ionised carbon, singly ionised magnesium, and neutral helium. A number of the highly ionised silicon and sulphur lines also exhibit P Cygni profiles with a maximum velocity of $\sim 3,000 \text{ km s}^{-1}$ (*Extended Material Figure* 2), indicating that these lines are produced in a fast-moving, metal-rich CSM (e.g., a wind or a shell expelled by the progenitor shortly before the explosion). The spectrum is rebinned for illustration purposes. The lower bound of the ordinate axis was cropped for illustration purposes.

Fig. 2: Comparison of SN 2021yfj with other interaction-powered SESNe a few days after the explosion (top), the time of maximum light (middle), and late times (bottom). The earliest spectra of Type Ibn and Icn SNe are characterised by a hot blackbody continuum with a temperature similar to that of SN 2021yfj (*Extended Material Figure* 6). They also show lines of helium, carbon and possibly hydrogen (in SN 2010al) (Ibn), or carbon, oxygen, and neon (Icn), but no silicon, sulphur, and argon. These strong helium, carbon, oxygen, and neon lines are clearly absent in SN 2021yfj. Well after peak brightness, the spectra of SNe Ibn, Icn, and SN 2021yfj are characterised by a blue pseudocontinuum with superimposed intermediate-width (a few 1,000 km s⁻¹) emission lines, due to the interaction of the SN ejecta and CSM. Again, SN 2021yfj shows prominent silicon and sulphur emission lines that are absent in the other objects, and the comparison objects exhibit features that are clearly absent in SN 2021yfj. Therefore, the differences between SN 2021yfj and previously known classes of interaction-powered SESNe reflect true differences in the CSM composition and the progenitor populations, making SN 2021yfj the first member of a previously unknown supernova class. All spectra are rebinned for illustration purposes.

Fig. 3: The bolometric light curve of SN 2021yfj (bottom panel) and the evolution of the blackbody temperature (top right) and radius (top left). The bolometric light curve shown in black covers the wavelength interval from 1,800 to 7,850 Å. Correcting the bolometric flux for the missing far-UV and IR flux increases the luminosity by ~ 0.2 dex. At peak brightness, SN 2021yfj reached a luminosity of $> 3 \times 10^{43}$ erg s⁻¹. Integrating over the entire light curve yields a radiated energy of (0.6–1) $\times 10^{50}$ erg. The smaller value covers the range from 1,800 to 7,850 Å, and the larger value includes an estimate of the contribution from the far-UV and IR. Dotted lines indicate time intervals with incomplete wavelength coverage. The blackbody temperature and radius have typical values for infant interaction-powered SNe, although the gradual evolution of both properties is atypical for infant supernovae and indicative of an optically thick CSM (*Methods Section* Bolometric Light Curve). The shaded bands indicate the statistical uncertainties at the 1 σ confidence level. The vertical dotted line in each panel indicates the date of the last non-detection.

Fig. 4: Comparison of the discovery spectrum of SN 2021yfj (black; Figure 1) with a spectral model (red). The model assumes a power of 3×10^{43} erg s⁻¹, an ejecta mass of 3.24 M_{\odot} , a velocity of 1000 km s⁻¹, and an elemental composition similar to the O/Si shell in massive helium stars: 0.786 (oxygen), 0.1 (neon), 0.05 (silicon), 0.03 (sulphur), 0.01 (argon), 0.01 (magnesium), 0.001 (calcium), and solar abundance for iron, cobalt and nickel. The spectrum is computed with steady-state, non-local thermodynamic equilibrium radiative transfer models (for more details see the *Methods Sections* Spectral Modelling). This model matches the strongest silicon and sulphur lines and also magnesium in terms of absolute and relative strength and line width, corroborating that SN 2021yfj is likely the explosion of a massive star stripped down to its O/Si shell.

Extended material

Extended Material Fig. 1: Spectral evolution from day 1 to 49.8 of SN 2021yfj in the UVoptical (upper panel) and near IR (lower panel). Up to day 11 the spectra are characterised by a blackbody shape with superimposed narrow emission and P Cygni lines from silicon, sulphur, argon, carbon, and helium. As the photosphere cools, the ionisation state of silicon, sulphur, and argon decreases. By day 20, a blue pseudocontinuum dominates the spectrum with superimposed intermediate-width emission lines from magnesium, silicon, sulphur, and helium. The most prominent features of both phases are marked. Regions of high atmospheric absorption are marked, and a near-IR spectrum of the opacity of Earth's atmosphere is shown as black vertical lines (black = high opacity). Host-galaxy emission lines are clipped. The original spectra are in grey, and rebinned versions are in black.

Extended Material Fig. 2: The evolution of the line profiles of selected lines from helium, magnesium, silicon, and sulphur. *Top:* At early times, all lines show well-developed P Cygni profiles. The absorption minima are at ~ 1,500 km s⁻¹. The blue edge, a proxy of the maximum velocity, extends to ~ 3,000 km s⁻¹. These velocities are comparable to velocities of stellar winds as seen in Wolf-Rayet stars [10] and winds around some SNe Icn [13, 14], and much slower than SN-ejecta velocities at similar phases (~ 10,000 km s⁻¹; [54]). The Si III and S IV lines are blended with other lines and exhibit complex line profiles. The Mg II line shows narrow absorption lines from the ISM in the host galaxy. *Bottom:* Up to day 6, the 5,876 Å feature shows a well-developed P Cygni profile and is dominated by He I. At later phases, this feature transitions into a pure emission line with time-variable contributions from silicon, sulphur, and helium. The spectra are rebinned for illustration purposes.

Extended Material Fig. 3: Spectrum obtained 1.6 days after the first ZTF detection with VLT/X-shooter, after subtracting the blackbody continuum. The full spectrum covers the wavelength range from 2,635 to 21,960 Å. The displayed wavelength range is limited to 2,720–11,000 Å where SN features are well visible. The top panel shows the same wavelength interval as the discovery spectrum in *Figure* 1 obtained 12 hours earlier. The evolution between both epochs is gradual at most. In addition to the SN features, the spectrum shows emission lines from star-forming regions in the host galaxy and narrow absorption lines from the host ISM. Strong telluric features are marked with " \oplus ".

Extended Material Fig. 4: SN 2021yfj in a 4-dimensional light-curve feature space, together with 4032 extragalactic transients from the ZTF Bright Transient Survey (79% Type Ia SNe, 11% Type II SNe, and 10% other types of core-collapse SNe and other types of transients). The panels above the diagonal show all measurements in different projections of the feature space, the panels below present the diagonal 2-dimensional kernel-density estimates and the panels on the diagonal display 1-dimensional kernel-density estimates. The locations of SN 2021yfj and Type Ibn/Icn SNe are highlighted in all 2-dimensional projections. SN 2021yfj's light curve shares similarities with interaction-powered SNe Ibn and Icn: a fast rise and a high peak luminosity. However, it sustains a high luminosity for a significantly longer period of time, which is uncommon for interaction-powered SESNe but comparable to regular supernovae. The combination of short rise and long duration places SN 2021yfj in a sparsely populated area of the light-curve parameter space.

Fit of the multi-band light curve with a magnetar and a nickel model

Fit of the bolometric light curve with a CSM model

Days since the first detection (rest-frame)

Extended Material Fig. 5: Fits of the light curve of SN 2021yfj with models of three different powering mechanisms. The panels in the upper half show the results using magnetar and nickel models in the software package Redback [55]. The bottom half shows a fit to the bolometric light curve using a CSM interaction model and the software package CHIPS [29, 30]. The CSM model can describe the observations. The mismatch between the observed and predicted rise can likely be mitigated with more complex CSM geometries and CSM density profiles than the ones considered here. The magnetar and nickel models can be excluded as the primary source of energy. The models do not simultaneously capture the rise, peak luminosity and peak time, and decline. Furthermore, the magnetar fit has an unphysically low opacity, and the nickel model requires an unphysically large nickel fraction. For illustration purposes, we only show the results in three filters. Details about the modelling are provided in the *Extended Material* Light-Curve Modelling. Non-detections are displayed as ' \checkmark '.

Extended Material Fig. 6: Comparison of the light curves and blackbody properties of SN 2021yfj with those of other interaction-powered SESNe and the Type Ic SN 2020oi. Compared to examples of interaction-powered SESN as well as the nickel-powered SN 2020oi, SN 2021yfj has a bright peak luminosity and a fast rise. Its blackbody radius and temperature evolve slowly in time compared to SNe Icn. This gradual evolution is reminiscent of some SNe IIn that are embedded in an optically thick CSM [e.g., 56], whereas the rapid evolution of Type Icn events suggests a CSM that is significantly less optically thick (*Methods Section* Bolometric Light Curve). The vertical dotted line in each panel indicates the date of the last nondetection of SN 2021yfj. The statistical uncertainties at the 1σ confidence level are indicated as vertical error bars in the left panel and as bands in all other panels. Non-detections are displayed as ' \checkmark '.

Extended Material Fig. 7: The properties of SN 2021yfj's host galaxy. Left: The SN position, marked by the crosshair, is located ~ 1.2 kpc south from the centre of its star-forming dwarf host galaxy $(M_r^{\text{host}} \approx -18.1 \text{ mag})$. **Right:** The host of SN 2021yfj is a regular star-forming galaxy, demonstrated by its location with respect to the main sequence of star-forming galaxies (grey-shaded band, [57]). The properties are also consistent with hosts of core-collapse supernovae from the Palomar Transient Factory [58] (grey contours indicate the region encircling 68, 90, and 95%), including interaction-powered SESNe (Type Ibn and Icn SNe). The properties of all hosts were inferred from photometry using the software package Prospector [59]. The statistical uncertainties at the 1σ confidence level are indicated.

Extended Material Table 1: The extension of the SN classification scheme after the discovery of SN 2021yfj.

Ejecta composition	CSM composition	SN Type	SN Type[27]
Н	Н	SN IIn	SN 0 i0
He	He, (H)	SN Ibn	SN 1 i1
C/O	C/O	SN Icn	SN 2 i2
O/Ne/Mg	O/Ne/Mg	SN Idn	SN 3 i3
O/Si/S	O/Si/S	SN Ien	SN 4 i4

The SN classification scheme from Ref. [27] (last column) is a progression of the traditional system (second last column) The first number is the spectroscopic classifier of the ejecta composition: 0 = strong H features; 1 = strong H features but no H; 2 = strong C and O but no H and He; 3 = strong O, Ne, Mg, but no C, He, H; and 4 = strong Si, S, O but no Mg, Ne, He and H. The tag "i" stands for interaction followed by the composition of the material with which the SN interacts: 0 = strongH features, etc. The value of ejecta and CSM composition can take fractional values to indicate transitional objects. The rows marked in grey are the new SN classes. SN 2021yfj belongs to the hitherto unknown class of Type Ien SNe (bold).

Methods

Discovery

SN 2021yfj, located at $\alpha = 01^{h}37^{m}46^{\circ}171$ and $\delta = -01^{\circ}15'17''.78$ [J2000.0], was discovered by the public ZTF Northern Sky Survey as ZTF21abzbmhz at 09:56 (UTC dates are used throughout this paper) on 7 September 2021 with an apparent magnitude of $r = 20.82 \pm 0.30$ mag, about 1.7 rest-frame days after the last nondetection [18]. The ZTF image-processing pipeline [60] generated an alert [61] based on image subtraction [62] with respect to a reference image. The alert was picked up by our custom "infant supernovae" filter [21, 63] running on the ZTF Fritz Marshal system [64, 65]. It was identified by a duty astronomer, and follow-up observations were triggered using our standard methodology [21, 66]. The ALERCE broker [67] team independently discovered ZTF21abzbmhz in the ZTF alert stream. They were also the first to report ZTF21abzbmhz to the IAU Transient Name Server¹ (TNS) [18]. ZTF21abzbmhz was allocated the name 2021yfj on 7 September 2021. Later detections were reported by the Asteroid Terrestrial-impact Last Alert System (ATLAS; [48]) survey on 12 September 2021 (internal name: ATLAS21bipz) and the Pan-STARRS Survey for Transients (PS; [68]) on 5 October 2021 (internal name: PS21ktg). On 3 September 2024, 2021yfj was designated the name SN 2021yfj [69, 70]. Unless stated otherwise, all times reported in this paper are with respect to the first detection and in the rest frame.

Distance

The Keck spectrum from day 1 shows emission lines from hydrogen, oxygen and sulphur, produced by the ionised gas in the star-forming regions in the host galaxy, at a common redshift of z = 0.1386. We refine redshift with the higher-resolution spectra obtained with X-shooter at the VLT. These spectra also show emission lines from hydrogen and oxygen. Averaging over all epochs, we measure a redshift of $z = 0.13865 \pm 0.00004$. This is consistent with the redshift inferred from narrow absorption lines from Mg I λ 2852 and Mg II $\lambda\lambda$ 2796, 2803 from the host ISM, detected in the X-shooter spectra up to 6.1 days after discovery, and the redshift inferred from the host emission lines detected in the Keck spectra at days 128.1 and 132.5. We use the redshift of z = 0.13865 as the SN redshift throughout the paper. The redshift translates to a luminosity distance of 676.4 Mpc and a distance modulus of 39.15 mag using a flat Λ CDM cosmology with $H_0 = 67.7$ km s⁻¹ Mpc⁻¹, $\Omega_m = 0.31$, and $\Omega_{\Lambda} = 0.69$ [23], which we use throughout the paper.

Pre-explosion Limits

The ZTF survey started monitoring the SN field ~ 3.2 yr before its explosion. We search the archival ZTF data for pre-SN outbursts following the methods described by Ref. [71]. We download IPAC difference images and compute the forced-photometry light curve at the SN position. After quality cuts, we are left with 612 pre-SN observations (74 points discarded) on 295 different nights in the ZTF g, r, and i bands. We apply a baseline correction to ensure that the pre-SN light curve is centred around zero flux. The error bars are sufficiently large to account for the scatter of the pre-SN light curve and no upscaling of the statistical errors is required. We search for significant detections in unbinned and binned observations. Since the durations of the pre-explosion outbursts are unknown, we try seven different bin sizes between 1 and 90 days. We do not obtain 5σ detections for any of the searches. For week-long bins, the median limiting magnitude is M > -18.8 mag in g and r and M > -19.5 mag in i. We can exclude outbursts that are brighter than those limits 50 (40) weeks before the explosion in r(g). These limits are $\gtrsim 1$ mag brighter than the most luminous precursors known [71], and hence do not pose meaningful limits on the outburst activity of SN 2021yfj's progenitor shortly before the explosion.

Light-Curve Properties

The first detection is recorded at 09:56 on 7 September 2021, about 1.7 rest-frame days after the last nondetection. At the time of the discovery, SN 2021yfj is very faint, $r = 20.73 \pm 0.30$ mag [Milky Way (MW)-extinction corrected], but already luminous, -18.3 mag, owing to its large distance (*Extended Material Distance*). It reaches its peak brightness in 2.3 and 5.8 rest-frame days in the g and r band, respectively. The MW-extinction corrected peak apparent magnitudes are $m_g \sim 19.5 \pm 0.1$ mag and

 $^{^{1} \}rm https://wis-tns.weizmann.ac.il/object/2021yfj$

 $m_r \sim 19.7 \pm 0.1$ mag and translate to MW-extinction corrected, K-corrected [72] absolute magnitudes of $M_g = -19.4 \pm 0.1$ mag and $M_r = -19.1 \pm 0.1$ mag. At the peak of the g-band light curve, SN 2021yfj has a blue g - r colour of ~ -0.3 mag, K-corrected and corrected for MW extinction. The high absolute magnitude at the time of discovery precludes estimating the explosion time as is commonly done for infant SNe (e.g., [19, 21, 73]).

To put SN 2021vfi in the context of other SN classes, we also compute the rise time from 50% peak flux and how long the brightness stayed above 50% of the peak flux in the g band. We measure a rise time of 3 days and a duration of 21.7 days. Both measurements have an uncertainty on the order of a few days. For comparison, we choose an extended sample of extragalactic transients from the ongoing ZTF Bright Transient Survey. We apply the following selection criteria: (i) no active galactic nuclei (AGNs), (ii) the passing of the BTS data-quality cuts presented in Ref. [45], (iii) well-sampled g and r light curves before, around, and after maximum brightness, (iv) a peak magnitude of < 19 in g and r before MW-extinction correction, (v) a well-measured rise and decline timescale in both bands, (vi) a spectroscopic classification, and (vii) redshift information from either catalogues or the transient spectrum. In total, 4032 transients fulfil these criteria. The vast majority are Type Ia SNe (3178 objects, 79%; e.g., [74]) and Type II SNe (425 objects, 11%; e.g., [75]). The remaining 10% are other types of core-collapse supernovae (407 objects; e.g., 26, 27), tidal disruption events (16 objects; e.g., [76]), intermediate luminosity red transients (3 objects; e.g., [77]), fast blue optical transients (1 object; e.g., [78]), gap transients (1 object; e.g., [79]) and luminous red novae (1 object; e.g., [80]). Among those objects, 22 objects are interaction-powered SESNe (Ibn: 20; Icn: 2). Their light curve properties (rise-time, duration, absolute peak magnitude and q-rcolour at peak) are computed following Ref. [45]. This comparison sample and SN 2021yfj are shown in a 4-dimensional corner plot in the Extended Material Figure 4. Relative to the bulk population of SNe, the fast rise of SN 2021yfj (~ 3 days) represents its most extreme property. This, plus its relatively blue colour at peak $(g - r \approx -0.3 \text{ mag})$ and moderately high luminosity $(M_q \approx -19.6 \text{ mag})$ is largely consistent with the known population of SNeIbn/Icn. Relative to the class of interacting SESNe, SN 2021yfj, however, stands out for its long duration (~ 22 days). In sum, aside from the short rise, SN 2021yfj has a light curve that is largely consistent with the general properties of Type Ia SNe and regular core-collapse supernovae.

To quantify the peculiarity of the photometric evolution of SN 2021yfj, we apply the Isolation Forest anomaly detection algorithm [81] to determine whether SN 2021yfj can be considered an outlier relative to other BTS sources. Briefly, an Isolation Forest builds a collection of decision trees and isolates individual sources by selecting a split point at random for a randomly selected feature within the feature space (4D as shown in the *Extended Material Figure* 4). Rare sources are, on average, isolated with fewer branch splittings within a tree than more common sources. Using the scikit-learn implementation of Isolation Forest [82] with the default settings, we train the forest on the 4032 BTS sources. We then apply the forest to SN 2021yfj and find that not only is it not an outlier, but also that $\approx 15\%$ of the BTS sources are more "rare" than SN 2021yfj in the 4D light-curve property feature space.

Bolometric Light Curve

Following the procedure outlined in Refs. [83, 84], we compute the bolometric light curve over the wavelength range from 1,800 to 7,850 Å (rest-frame), defined by the wavelength range of our photometric campaign from w2 to z band. Figure 3 shows the final bolometric light curve in black. A tabulated version is provided in the Supplementary Material Table 7.

The solid black line in Figure 3 shows the time interval of the bolometric light curve with the best spectral coverage. The blue w2 - r colour of 0.2 ± 0.1 mag at 1.5 days after the discovery of SN 2021yfj points to a substantial contribution from the far UV. Linearly extrapolating the observed spectral energy distribution (SED) to shorter wavelengths yields a missing far-UV fraction of $39^{+10}_{-8}\%$ and $22^{+10}_{-7}\%$ at day 1.5 and day 19.7, respectively. The missing flux contribution beyond 1 μ m is small. Fitting the observed SEDs from w2 to z or from u to z yields a contribution of $\sim 5\%$ between 1 and 10 μ m during the same time interval. The dark-grey curve in the Extended Material Figure 3 shows the bolometric light curve, including the two missing flux fractions. Other epochs have less well-observed SEDs, and we use the data between day 1.5 and day 19.7 to estimate bolometric corrections. The rising light curve was only observed in the g and r bands. This wavelength interval accounts for 15% of the bolometric flux at day 1.5. Since SN ejecta cool with time, a constant bolometric correction will progressively underestimate the true bolometric flux toward earlier epochs. The fading light curve between days 19.7 and 32 was monitored from the u to i bands and in gri between days 32.0 and 34.8. Similar to the data at the previous time

interval, we compute bolometric corrections. The bolometric light curve of these time intervals is shown as dashed lines in the *Extended Material Figure* 3. At > 34.8 days after discovery, SN 2021yfj is only detected in the g band. We omit these data in the bolometric light curve.

Integrating the entire light curve yields a radiated energy of 0.6×10^{50} erg. Including the missing far-UV and IR contributions increases the radiated energy by a factor of ~ 2 . Both values are comparable to those of other interaction-powered SESNe, such as SNe 2019hgp (Icn, $E_{\rm rad} \approx 10^{50}$ erg; [13]), 2020bqj (Ibn, $E_{\rm rad} \approx 10^{50}$ erg; [85]), and 2021csp (Icn, $E_{\rm rad} \approx 10^{50}$ erg; [14]). Up to day 11.1, the spectra show a blackbody-like continuum with superimposed narrow emission lines but no broad metal absorption lines from the SN ejecta (Supplementary Material Spectroscopic Evolution). Fitting the photometry from 2,000 to 10,000 Å (observer frame) with the Planck function yields a temperature of $\sim 16,000$ K at day 1.5 that gradually decreases to $\sim 12,000$ K in ~ 3 weeks and a radius that remains constant at $\sim 10^{15}$ cm. The slow evolution of the bolometric light curve and the blackbody photosphere stand out compared to those of the well-observed interaction-powered SESNe 2010al, 2019hpg, and 2021csp (Extended Material Figure 3). The bolometric flux of SN 2021 $y_{\rm f}$ decreases by less than 0.2 dex during the first two weeks since discovery, whereas the bolometric flux of the two Type Icn SNe faded by 1.0–1.2 dex and SN 2010al grew even brighter. The reasons for this are that SN 2021yfj's photosphere remains at $\sim 10^{15}$ cm at all times and merely gradually cools. Such an evolution has been observed in SNe IIn and was interpreted as the photosphere being located in the unshocked, optically thick CSM [56, 86]. In contrast to that, the photosphere of the Type Icn SNe 2019hgp and 2021csp undergoes a ballistic expansion, which points to a more optically thin CSM and, hence, a rapid decrease of the bolometric flux.

Light-Curve Modelling

We model the multiband light curve with two distinct powering mechanisms using the open-source Bayesian inference software package Redback [55]: (i) radioactive decay of ⁵⁶Ni [87] and (ii) spin-down of a rapidly spinning, highly magnetised neutron star (magnetar; [88]) utilising the generalised magnetar model by Ref. [89]. The two models include a component to account for the loss of γ -ray trapping at late times [90], which can increase the decline rate. Furthermore, we assume a Gaussian likelihood function, and we infer the model parameters with the nessai [91–93] sampler implemented in Bilby [94, 95]. The priors and marginalised posteriors of each model parameter are shown in the Supplementary Material Table 8.

The upper panels of the *Extended Material Figure* 5 show fits with the two magnetar and nickel models in three different bands. Both models are inadequate to describe the observations. The models are not able to fit the rise, peak and decline simultaneously. Furthermore, the magnetar model predicts an unphysically low opacity of $\kappa \approx 0.01 \text{ cm}^2 \text{ g}^{-1}$, and the nickel requires an unphysically high nickel fraction of almost 100%. Therefore, we reject these two powering mechanisms as the primary source of energy.

Motivated by the lines of evidence for CSM interaction [*Methods Sections* Spectroscopic Evolution and Comparison With Interaction-powered SESNe], we model the bolometric light curve using the opensource code CHIPS² [29, 30]. The code uses hydrodynamical calculations, together with radiative transfer, to calculate bolometric light curves powered by SN ejecta colliding with a dense CSM of an arbitrary density profile. We consider homologously expanding ejecta with a density profile [96]

$$\rho_{\rm ej}(r,t) = \begin{cases} t^{-3} \left[r/(gt) \right]^{-n} & (r/t > \upsilon_t), \\ t^{-3} \left(\upsilon_t/g \right)^{-n} \left[r/(t\upsilon_t) \right]^{-\delta} & (r/t < \upsilon_t), \end{cases}$$

where n = 10 and $\delta = 1$, commonly adopted for explosions for SESN progenitors. The constants g and v_t relate to the ejecta mass $M_{\rm ej}$ and energy $E_{\rm ej}$ as [97]

$$g = \left\{\frac{1}{4\pi (n-\delta)} \frac{\left[2 (5-\delta) (n-5) E_{\rm ej}\right]^{(n-3)/2}}{\left[(3-\delta) (n-3) M_{\rm ej}\right]^{(n-5)/2}}\right\}^{1/n}, \ \upsilon_t = \left[\frac{2 (5-\delta) (n-5) E_{\rm ej}}{(3-\delta) (n-3) M_{\rm ej}}\right]^{1/2}.$$

²https://github.com/DTsuna/CHIPS

For the CSM density profile, we adopt a double power law, characterised by a shallow inner core and a steep drop generally found for simulations of envelope eruption [96, 98, 99],

$$\rho_{\rm CSM}(r) = \hat{\rho}_{\rm CSM} \left[\frac{(r/r_{\rm CSM})^{n_{\rm in}/y} + (r/r_{\rm CSM})^{n_{\rm out}/y}}{2} \right]^{-y}$$

where $r_{\rm CSM}$ and $\hat{\rho}_{\rm CSM}$ set the radius and density at the transition of the two power laws, respectively. The remaining parameters $n_{\rm in} \approx 0-3$, $n_{\rm out} \approx 10-12$, and $y \approx 2-4.5$ are set by the envelope structure as well as the detailed hydrodynamics of the mass loss. However, the overall light-curve morphology is sensitive only to $n_{\rm in}$. We fix the other two as $n_{\rm out} = 10$ (as adopted in the Methods Section Spectral Modelling) and y = 2, inferred from simulations of partial envelope ejections from stripped progenitors [100]. CHIPS requires opacity tables for the CSM, which depend on its uncertain abundances. The spectra favour an O-dominant composition with enhanced Si/S/Ar and some He (Methods Sections Spectroscopic Evolution, Hydrogen and Helium Content, and Spectral Modelling). To reproduce this, we take the abundance of the surface of a stripped helium-poor stellar model with an initial mass of 29 M_{\odot} available in CHIPS [30], and enhance the Si, S, and Ar mass fractions to those inferred from the Methods Section Spectral Modelling with carbon correspondingly reduced. The mass fractions adopted are 0.0081 (helium), 0.2041 (carbon), 0.6805 (oxygen), 0.0130 (neon), 0.0027 (magnesium), 0.05 (silicon), 0.03 (sulfur), 0.01 (argon), and small contributions of < 0.001 for heavier metals. We use the Rosseland and Planck mean opacity tables for this composition, generated with TOPS [101]. While the adopted abundance may not exactly reflect that of the CSM, the bolometric light curves mostly depend on the dynamics of the interaction and much less on the composition details. We adopt a homologous CSM flow $(v \propto r)$ as in the Methods Section Spectral Modelling and set the constant of proportionality to the CSM velocity of 2,000 km s⁻¹ at $r = r_{\rm CSM}$, as observed in the early spectra (Methods Section Spectroscopic Evolution).

A successful fit to the bolometric light curve is shown in the bottom panel of Extended Material Figure 5, with the fitting parameters shown in Supplementary Material Table 9. We find that in order to reproduce the bolometric light curve one needs (i) a moderately large explosion energy (~ 2 × 10⁵¹ erg) and CSM mass ($M_{\rm CSM} \gtrsim 1 M_{\odot}$, with the lower limit being the estimated mass of the CSM swept up by the shock at day 30) for the long bright peak, (ii) a shallow ($n_{\rm in} \approx 1$), extended ($r_{\rm CSM} \approx 5 \times 10^{15}$ cm) inner CSM profile for the slow decline (see, e.g., [97]), and (iii) a large $M_{\rm ej}$ ($\gtrsim M_{\rm CSM}$) so that the interaction power does not sharply decay owing to significant ejecta deceleration by the CSM. The inferred high masses and energy for the ejecta and CSM are within the possible range for successive mass ejections in pulsational pair instability (PPI) models [9, 36–38]. A pre-SN mass eruption in a lower-mass star cannot be ruled out, although a mechanism to eject such a large mass is less clear (Methods Section Progenitor Scenarios).

X-ray Emission

The interaction of the SN ejecta with CSM and heating of the SN ejecta by a central engine (e.g., magnetar or black hole) can produce thermal X-ray emission [102, 103]. SN 2021yfj was not detected in our *Swift*/XRT observations (*Supplementary Material Table* 4). The inferred upper limits between 10^{42} and a few 10^{43} erg s⁻¹ (*Supplementary Material Table* 4) are comparable to the absorption-corrected luminosities of the X-ray brightest SNe [104–106], and thus do not place strong constraints on the lack of X-ray emission.

Spectroscopic Evolution

Extended Material Figure 1 shows the spectral evolution from the rest-frame near-UV to near-IR from 1 to 50 days after the SN discovery. The spectra up to day 11 are characterised by a cooling blackbody (from ~ 22,000 to ~ 15,000 K; Figure 3) with superimposed narrow emission lines (width: ~ 2,000 km s⁻¹, Extended Material Figure 2). Following Ref. [107], we use the atomic spectra database from the National Institute of Standards and Technology (NIST; [108]) for the line identifications. We included all elements up to mass number 18 (argon) and created two ranked line lists for each ion sorted by (i) the relative line intensity, and (ii) the Einstein coefficient for spontaneous emission. We identify most lines as transitions from S III–IV, Si III–IV, and Ar III, and a very small minority of lines as transitions from Mg II, C III, and He I (Figure 1, Extended Material Figure 3, Supplementary Material Table 1).

The SiIII-IV, SIII-IV, and Ar III are visible for ≤ 6 days (i.e., ≈ 4 days after the g-band maximum). As the bolometric luminosity (a proxy of the CSM interaction strength) and the blackbody temperature decrease, the highly-ionised species vanish, and the lines from singly ionised silicon and sulphur emerge. Between days 11 and 20, the spectrum transforms from a blackbody with narrow P Cygni lines to a blue pseudocontinuum, akin to those of interaction-powered SESNe [13, 14, 109], with superimposed intermediate (width: a few 1,000 km s⁻¹) emission lines from neutral and low-ionisation silicon, sulphur, helium, magnesium, and oxygen.

The emission features in the early spectra are visible as either pure emission lines or P Cygni lines (examples shown in the *Extended Material Figure* 2). P Cygni lines can be produced in the expanding SN ejecta, in an expanding shell of gas expelled by the progenitor before the explosion, or in a stellar wind. The absorption minima of the P Cygni profiles are at ~ 1,500 km s⁻¹ and the blue edge of the absorption component is at $\leq 3,000$ km s⁻¹ (best seen in the isolated Mg II $\lambda\lambda$ 2796, 2803 doublet). These velocities are significantly lower than those of typical SN ejecta (e.g., ~ 10,000 km s⁻¹; [24]). Instead, they are comparable to those of Wolf-Rayet stars [10] and the CSM velocities of interaction-powered SESNe [13, 14], meaning that SN 2021yfj's ejecta interact with a fast-moving wind or shell of material that is rich in silicon and sulphur.

Hydrogen and Helium Content

Hydrogen and helium constitute most of the baryonic matter in the Universe [110], and both elements play crucial roles in SN explosion and progenitor models [5]. Hydrogen has strong features at 4,861 and 6,563 Å [108]. Throughout the evolution of SN 2021yfj, we detect no hydrogen, neither in absorption nor emission. The blackbody temperature of SN 2021yfj is similar to that of H-rich Type II SNe (e.g., [111]); therefore, SN 2021yfj's progenitor must have lost its hydrogen envelope well before the SN explosion. He I has its strongest optical transitions at 3,889, 4,471, 5,876, 6,678, and 7,065 Å. The first high-resolution spectrum, obtained at 1.6 days after discovery, (*Extended Material Figure* 3) shows well-defined emission lines at 3,889 and 5,876 Å; the 7,065 Å line is also detected but it is fainter than the 3,889 and 5,876 Å lines. The intrinsically weak He I line at 6,678 Å is not detected, though it is redshifted to the Telluric A band (*Extended Material Figure* 3). At the location of the 4,471 Å line there is a broad emission complex that is likely due to multiple species, meaning we cannot reliably determine whether a He I component exists at that wavelength.

Using the method of Ref. [107], we find that 3,889 and 5,876 Å are expected to be the strongest lines within the wavelength range we consider [108]. A comparison with an early spectrum of the prototypical He-dominated Type Ibn SN 2006 [112] indicates that this event shows only the 3,889 and 5,876 Å lines at early times, further supporting the presence of He I in the spectrum of SN 2021 yfj. The similarity between SN 2021 yfj and SN 2006 jc is maintained during later phases (*Figure 2*), where the broader He I lines at 5,876 Å and 7,065 Å are most prominent in the spectra of both SNe [12, 112]. We also detect an emission line at 10,830 Å at early and late times (*Extended Material Figures 3*, 1), where He I also has a strong transition. At late times, the 5,876-Å feature of SN 2021 yfj reveals time-variable shoulders due to the contribution from singly-ionised silicon and sulphur (*Extended Material Figure 2*).

Therefore, we conclude that the spectroscopic data provide evidence for the existence of helium within the emitting material throughout the SN evolution.

Comparison With Interaction-powered SESNe

To understand the peculiarity of SN 2021yfj, we compare its spectral evolution to that of other interactionpowered SESNe. We chose SNe 2006jc and 2010al (as archetypes of the Type Ibn class; [12, 20, 113]), and SNe 2019hgp and 2021csp (as archetypes of the Type Icn class; [13, 14]). SNe 2019hgp and 2021csp were detected within < 2 days of their explosion dates, and spectra were acquired within hours after their discovery, offering an excellent opportunity to search for silicon, sulphur, and argon in their earliest spectra.

Figure 2 shows snapshots of the spectral evolution before peak light (top), at maximum (centre), and more than one month after peak (bottom). The different SN classes evolve similarly. Up to the time of maximum light, the spectra are characterised by a thermal spectrum cooling from a few 10,000 K to 10,000-15,000 K and a series of narrow emission lines [full width at half-maximum intensity (FWHM) $< 1000 \text{ km s}^{-1}$]. Well after maximum brightness, a blue pseudocontinuum develops, produced by a forest of

iron emission lines in the CSM, and a small number of emission lines with a FWHM of several 1000 km s⁻¹. Depending on the elemental composition of the CSM, different emission lines are visible: Type Ibn – helium (primarily), hydrogen, carbon, and oxygen; Type Icn – carbon, neon, oxygen (primarily) and helium; and SN 2021yfj– silicon, sulphur, argon (primarily) and helium. Furthermore, SNe 2010al and 2021csp show conspicuous emission from Ca II at 8,500 Å. This feature is absent in SN 2021yfj, which is puzzling considering that argon, calcium, silicon, and sulphur are the ashes of the oxygen-burning phase (e.g., [7]).

In conclusion, the nondetection of silicon, sulphur, and argon in Type Ibn and Icn SNe and likewise the nondetection of hydrogen, nitrogen and oxygen and the weak presence of carbon and helium in SN 2021yfj, is not due to differences in the ionising radiation field, insufficient data quality, or the wavelength coverage. Instead, it reflects differences in the elemental composition of the CSM and, therefore, in the progenitor stars (e.g., [25]).

A New Type of Supernova

The classification of SNe is fundamentally based on spectroscopy [26, 27]. The type of a SN is determined by the dominant spectroscopic features in its peak-light spectra: Type II SNe are dominated by hydrogen lines, Type Ib SNe by helium, and Type Ic SNe lack both hydrogen and helium. This sequence is assumed to reflect the amount of stripping of the progenitor stars, with those of SNe II having retained much of their initial hydrogen envelope, those of SNe Ib having lost the hydrogen layer but retaining the He-rich layer below, and those of SNe Ic having lost all or most of the He-rich layer. Adding the suffix "n" to the SN type is used to indicate the presence of relatively narrow spectral lines that arise from the SN progenitor having been surrounded by slowly-moving CSM whose composition reflects that of the outer stellar layer at the time of explosion or shortly prior. Thus, SNe IIn are surrounded by H-rich CSM, SNe Ibn have He-rich CSM, and SNe Icn have C/O-rich CSM. Following the theoretical shell structure of massive stars, one would expect that even further stripping would lead to the formation of stars whose outer layers are dominated by O/Ne/Mg and later O/Si/S, with natural designations of Type Id and Ie; events with narrow CSM lines would then be denoted by Idn and Ien (Extended Material Table 1). Our observations, presented in the Supplementary Material Spectroscopic Evolution, Hydrogen and Helium Content, and Comparison With Interaction-powered SESNe, suggest that SN 2021yfj is indeed the first example of a Type Ien SN [28]. This discovery also implies the existence of Type Id, Idn and Ie SNe. A late-time spectrum of the Type Ic SN 2021ocs [114] may indicate that its progenitor was more rich in O/Mg than the progenitors of other Type Ic SNe. SN 2021ocs could be Id or Ic/Id transitional SN. However, the evidence comes solely from a nebular spectrum, whereas SN classifications are based on their peak-light spectra. While it is too early to claim the detection of a Type Id SN, the discovery of SN 2021ocs is very intriguing.

Spectral Modelling

Using the approach of Ref. [25], we simulate the early-time spectra of SN 2021yfj by adopting ejecta with a density profile of $\rho \propto r^{-10}$, a velocity of 1000 km s⁻¹ at 10¹⁵ cm (together with a homologous flow, i.e., r/v = age = 116 days), and a composition with the following mass fractions: 0.786 (oxygen), 0.1 (neon), 0.05 (silicon), 0.03 (sulphur), 0.01 (argon), 0.01 (magnesium), 0.001 (calcium), and solar abundance for iron, cobalt, and nickel. This composition is representative of the O/Si shell in a massive He-star model at the time of explosion, such as the he12 model used in Ref. [115]. The density is scaled so that the total Rosseland-mean optical depth of the ejecta is 40, assuming a mean opacity of 0.1 cm² g⁻¹, roughly comparable with the results from the radiative-transfer calculation. This yields a total mass of $3.24 M_{\odot}$, which is quite substantial. Finally, a power of $3 \times 10^{43} \text{ erg s}^{-1}$ is injected into the inner regions of these ejecta at $v_{\text{deposition}} = 1000 \text{ km s}^{-1}$ over a characteristic scale of $dv = 200 \text{ km s}^{-1}$. The deposition profile goes as $\exp[-(v - v_{\text{deposition}})^2 / dv^2]$, and the volume-integrated power is normalised to $3 \times 10^{43} \text{ erg s}^{-1}$. Given these initial conditions, the radiative-transfer solution computes the temperature, ionisation, etc. We then compute steady-state, non-local thermodynamic equilibrium (NLTE) radiative-transfer models [25].

The results for the UV-optical spectrum are shown in *Figure* 4. The model spectra contain numerous lines of silicon and sulphur despite the relatively low abundance of a few 0.01, revealing that these elements have a strong absorption power, like iron, even for a modest abundance. Additional tests, in which we

raise the silicon and sulphur abundances until they reach values of 0.3–0.5, yield somewhat stronger silicon and sulphur lines, although not so much stronger, but progressively in tension with the observations. Decreasing the mass fraction below 1% gives weaker features, again in tension with observations. Hence, it seems that a mass fraction of a few 0.01 of silicon and sulphur is sufficient to explain the optical spectra of SN 2021yfj. These explorations remain somewhat short of the true complexity of SN 2021yfj. Indeed, no O-rich or Si-rich material in a massive star is also rich in helium, which is in tension with the presence of He I lines detected in SN 2021yfj (*Methods Section* Hydrogen and Helium Content). One way to accommodate this peculiarity is by invoking an asymmetric configuration in which He-rich material would be present in some "equatorial region" and O/Si-rich material interacts with that material, producing an interacting SN, with emission coming both from that He-rich CSM and the Si/O-rich ejecta. Further work is needed to investigate this aspect thoroughly.

Host Galaxy

SN 2021yfj's host galaxy was detected in several broad-band filters from the rest-frame UV to near-IR $(m_r \approx 21 \text{ mag}; Supplementary Material Table 5)$. The left panel of the Extended Material Figure 7 shows a false-colour image of the host galaxy, built with gri images from the DESI Legacy Imaging Surveys [116] and the software package STIFF [117] version 2.4.0. The SN explosion site is ~ 1.2 kpc south of the galaxy centre. To infer the mass and star-formation rate of the host, we model the observed SED (Supplementary Material Table 5) with the software package Prospector [59] version 1.1.³ We assume a Chabrier initial-mass function (IMF; [122]) and approximate the star-formation history (SFH) by a linearly increasing SFH at early times followed by an exponential decline at late times [functional form $t \times \exp\left(-t/t_{1/e}\right)$, where t is the age of the SFH episode and $t_{1/e}$ is the e-folding timescale]. To account for any reddening between the expected and the observed SED, we use the Calzetti attenuation model [123]. The priors of the model parameters are set identical to those used by Ref. [58]. The host galaxy has a stellar mass log $M_{\star}/M_{\odot} = 8.9 \pm 0.2$, a star-formation rate of $0.07^{+0.10}_{-0.02} M_{\odot} \text{ yr}^{-1}$, an age of 4^{+4}_{-2} Gyr, and an attenuation of the stellar component of $E(B-V) = 0.05^{+0.07}_{-0.03} \text{ mag} (\chi^2/\text{n.o.f.} = 18.25/11)$, where n.o.f. is the number of photometric fibers used in the CDD is the number of photometric filters used in the SED modelling). The star-formation rate is comparable to typical star-forming galaxies of that stellar mass (grey band in *Extended Material Figure* 7; [57]). The mass and star-formation rate are also similar to the SN host galaxies from the Palomar Transient Factory (grey contours; [124–127]), including interaction-powered SESNe (colour-coded; the values of the SNe Icn were taken from Refs. [13, 14, 128]).

The SN spectra reveal emission lines from the ionised gas in H_{II} regions along the line of sight, summarised in the Supplementary Material Table 6. Their luminosities and flux ratios allow us to determine the metallicity of the gas in the star-forming regions, the metal enrichment, and the level of attenuation. The MW-extinction corrected $H\gamma/H\beta$ and $H\delta/H\beta$ flux ratios are 0.46 ± 0.02 and 0.23 ± 0.02 , respectively. Both values are consistent with the theoretically predicted values of 0.47 and 0.26, assuming typical conditions of star-forming regions: Case B recombination, electron temperature of 10^4 K, and electron density of 10^2 cm^{-3} [129]. The nominal excess in the flux ratio translates to $E_{\text{host}}(B-V) = 0.07 \pm 0.06 \text{ mag}$, assuming the Calzetti attenuation model with $R_V = 4.05$. Owing to the small amount of attenuation and its large statistical measurement error, we assume negligible extinction for all SN properties. The H α luminosity and the level of star formation are tightly correlated [130]. The attenuation-corrected starformation rate is $0.17 \pm 0.03 \ M_{\odot} \ yr^{-1}$ using Ref. [130] and Ref. [131] to convert from the Salpeter IMF (assumed in Ref. 130) to the Chabrier IMF (assumed in our galaxy SED modelling). Both the attenuation and the star-formation rate are consistent with the values derived from the SED modelling. The metallicity of the star-forming region can be determined from the ratios between H α , H β , [N II] λ 6584, and $[O_{III}] \lambda 5007$ [132]. Using this O3N2 diagnostic together with the parameterisation from Ref. [133], we infer a gas-phase metallicity of 0.53 ± 0.01 solar, a normal value for a galaxy of that mass [134].

We note that SN 2021yfj exploded close to the centre of its host galaxy, and the slit covered a large fraction of the host galaxy. The properties reported above are, hence, representative of the SN explosion site and the entire galaxy.

³Prospector uses the Flexible Stellar Population Synthesis (FSPS) code [118] to generate the underlying physical model and python-fsps [119] to interface with FSPS in python. The FSPS code also accounts for the contribution from the diffuse gas based on the Cloudy models from [120]. We use the dynamic nested sampling package dynesty [121] to sample the posterior probability.

Event Rate

The WISeREP archive contains > 400 public spectra for > 70 SNe Ibn/Icn. We examined all spectra to determine whether any of the objects showed narrow silicon or sulphur lines. None of the objects has spectra exhibiting silicon, sulphur, and argon lines. This reveals that SN 2021yfj is the first member of a previously unknown supernova class and that Type Ien SNe are an even rarer class of objects than the already rare Type Ibn and Icn SNe (SNe Ibn, 0.1-0.5%; SNe Icn, 0.005-0.05% of the total CCSN rate; [14]).

The nondetection of Type Ien SNe in the ZTF Bright Transient Survey allows us to place an upper limit on their volumetric rate. Figure 9 in Ref [45] shows the relationship between the volumetric rate as a function of peak absolute magnitude derived from the ZTF Bright Transient Survey. Using the same methodology together with the 6-year BTS sample and assuming that SNe Ien reach an absolute magnitude of < -19 mag at peak, their volumetric rate is < 30 Gpc⁻¹ yr⁻¹ at 95% confidence (Poisson statistics), which is roughly < 1/1,000 the rate of SNe Ib/c [46] and < 1/3,000 of the total CCSN rate [45].

Progenitor Scenarios

Knowing that a moderate amount of silicon and sulphur suffices to explain the features of the early-time spectra of SN 2021yfj, we now explore possible progenitor channels.

A High-mass Massive Star

Massive stars can lose a substantial amount of their birth mass through stellar winds [135, 136], eruptions [136, 137], and interaction with a companion star [138, 139]. First, we focus on stars that have lost their entire hydrogen envelope, so-called He stars, with a pre-supernova mass between 30 and 133 M_{\odot} . During the oxygen-burning phase of such a star, e^+e^- pairs are formed, reducing the radiation pressure that supports the star against gravitational collapse (so-called pair instability; [36–38]). As a result, implosive oxygen burning can produce enough energy to unbind a substantial amount of the stellar envelope. He cores above $\gtrsim 64 \ M_{\odot}$ experience a single violent pulse that unbinds the entire star [140–144]. Lessmassive stars can encounter pair instability a few times and eject shells of increasingly metal-rich CSM. The collisions of shells can produce luminous optical transients, so-called pulsational pair-instability SNe (PPISNe; [9, 145, 146]). The specific mass limits depend on the uncertain rate of the ${}^{12}C(\alpha, \gamma){}^{16}O$ reaction rate [147–149], but for reasonable choices, a qualitatively similar behaviour is observed in the transition region between PPISNe and PISNe, wherever it occurs. PPISN models usually do not produce shells that contain much silicon and sulphur. Usually, the outer layers of helium, carbon, oxygen, magnesium, and neon are ejected. In the transition between PPISN and PISN, the first pulse can eject an arbitrary amount of mass and expose the oxygen convective shell. This extensive convective shell encompasses much of the star and may be mildly enhanced in newly synthesised silicon.

Among the available PPISN models, the He60/61 model of Ref. [9] with a helium-core mass of 60– 61 M_{\odot} is of particular interest. It has an oxygen convective shell with a composition similar to that of the he12 model whose predicted spectral features matched the observed ones at early times (*Methods Section* Spectral Modelling). In the He61 model, the first pulse ejects 19 M_{\odot} , exposing the O/Ne shell. The remaining 42 M_{\odot} are almost unbound, but eventually, the star contracts and reencounters pair instability. Enough nuclear fuel is left for a few final pulses that happen in rapid succession before the iron core directly collapses into a black hole. With each new pulse, a new shell (moving with a velocity of a few 1,000 km s⁻¹) is enriched in increasingly heavier elements, and, eventually, material from the oxygen convective shell, which could be enhanced in silicon, can be expelled. The collisions between the shells (pulse 2 and later) can produce light curves with rise times as short as a few days, durations of several tens of days, and peak luminosities reaching a few 10^{43} erg s⁻¹. Collisions between the shells can radiate up to 5×10^{50} erg and produce spectra that are dominated by interaction [9]. However, the exact properties are more uncertain. They are highly sensitive to the properties of the first pulse, the kinematics of the shells, the mass they carry, the time between the pulses, mixing processes, and details of the simulations [9, 39, 150, 151].

In the PPISN scenario, SN 2021yfj could be the product of a collision between the last shells ejected before the progenitor star collapsed to form a black hole. Qualitatively, the PPI model explains many of the observed properties, such as the wind velocity of $3,000 \text{ km s}^{-1}$, presence of silicon, sulphur, and argon

in the early spectra, interaction-dominated spectra throughout the entire evolution (*Methods Section* Spectroscopic Evolution), the rise time of 3 days, the peak luminosity of $(3-5) \times 10^{43} \text{ erg s}^{-1}$, and the radiated energy of $(0.5-1) \times 10^{50}$ erg (*Methods Section* Light-Curve Properties). It could also provide a mechanism to strip a star to its oxygen convective shell. The host metallicity of ≤ 0.5 solar (*Methods Section* Host Galaxy) and low event rate of SN 2021yfj-like transients (*Methods Section* Event Rate) match further predictions of PPISN models.

The presence of helium (*Methods Section* Hydrogen and Helium Content) in the spectra of SN 2021yfj is puzzling. There was helium on the surface of the 61/62- M_{\odot} models, but it was ejected about a thousand years before the explosion and now resides at ~ 10^{18} cm, maybe less if it collides with dense CSM. Since massive stars tend to live in binary systems, it may not be too unlikely to have a helium-star companion with a strong wind. All stars this massive have nearly the same lifetimes burning hydrogen and helium (3 × 10^6 and 3 × 10^5 yr, respectively), so a coeval star could be in a similar stage of evolution.

A Low-mass Massive Star

In the regime of less-massive He stars, a few scenarios could give rise to SN 2021yfj, as follows.

Scenario A — Helium stars with pre-supernova masses in the range 2.0 to 2.6 M_{\odot} have a complex final evolution that is strongly influenced by electron degeneracy [152, 153]. To make a low-mass helium star, a close interacting binary is a necessary starting point. Both oxygen and silicon burning ignite far off centre in these stars, and the fusion propagates inward as "flames" bounding a molecular-weight inversion that might be unstable [152]. The stars also have unusually large radii ($\sim 10^{13}$ cm) that they develop after core helium depletion. Some also experience strong, degenerate silicon flashes that, while energetically incapable of exploding the entire star, can eject all or part of the matter outside the silicon core. A relevant scenario would be (i) the silicon flash plus any residual binary interaction removes most of the matter external to the oxygen-burning shell; (ii) during the following months, the inwardly propagating flame powers a strong wind that ejects more silicon-rich matter; and (iii) a terminal iron-core collapse creates an outgoing shock with $\sim 10^{50}$ erg. The bright supernova results from the terminal explosion interacting with the wind and ejected shell, as shown in Figure 14 of Ref. [153]. This could be a more common occurrence than a PPISN and does not require low metallicity or a high star-formation rate. Helium would also be present in the recently ejected matter. The difficulty is the many uncertainties surrounding the energy and timing of the silicon flash; the propagation, in more than one dimension (1D), of the flames; and the extent to which the flash and winds uncover silicon-rich material prior to the terminal explosion. We note that based on simulations by Ref. [25], the CSM around such low-mass stars is expected to consist mostly of helium, which leads to strong helium features throughout the entire evolution, inconsistent with observations of SN 2021yfj [Extended Material Figure 3, 1]. This channel might be ideal for Type Ibn SNe [25], but less so for SN 2021yfj.

Scenario B — Some massive stars produce jets during their terminal explosion [154, 155]. The appearance of Si/S material in the outer layer could be the result of a jetted explosion where jets lift and drag material from the stellar interior onto the outer layers. In this scenario, SN 2021yfj would have to be observed from a preferred direction close to on-axis. This might also produce a γ -ray flash as seen in long-duration GRBs, which are connected with the explosion of very massive stars. We found no γ -ray flash or an afterglow in the X-ray or the optical cospatial with SN 2021yfj within 2 days before the discovery of SN 2021yfj (*Supplementary Material* High-Energy Observations).

Considering SN 2021yfj's moderately high redshift, an intrinsically weak γ -ray flash would likely have evaded detection with current γ -ray satellites [156, 157]. Furthermore, a baryon loading of as little as $10^{-4} M_{\odot}$ is expected to stifle the formation of a relativistic jet [158], leading instead to the formation of a nonrelativistic outflow. An outflow should not only dredge up silicon and sulphur; it should also transport carbon, oxygen, and neon from the layers between the inner Si/S shell and the other He shell. However, strong lines from carbon, oxygen, and neon are absent in the spectra of SN 2021yfj.

A Merger of Two Compact Objects

In the following, we explore whether silicon and sulphur could be formed on the surface of a white dwarf or possibly a neutron star. Simulations by Ref. [159] showed that helium burning at low densities

 $(\sim 10^9 \text{ g cm}^{-3})$ and low temperatures $(\sim 10^9 \text{ K})$ produces silicon and sulphur. Helium burning is an exothermal process, though. The temperature increase would cease the production silicon and sulphur and instead continue fusing the ashes to nickel [159]. The excess energy could be dissipated through the expansion of the gas. However, this would also skew the production toward heavier nuclei [159]. Cooling by emitting neutrinos is not possible since silicon and sulphur are stable against β decay in these conditions. Simulations of helium burning on the surface of C/O white dwarfs [160] revealed that the density on their surface is always $\ll 10^9 \text{ g cm}^{-3}$, making the production of silicon and sulphur subdominant to the more common elements, such as calcium, magnesium, and iron-group elements. We note, though, that helium burning on the surface of different types of compact objects (white dwarfs and neutron stars) is underexplored, and detailed simulations are needed.

Data Availability

The reduced spectra and photometry of SN 2021yfj will be made available via the WISeREP archive and the journal webpage after the acceptance of the paper. Data from ESO, Keck, NOT, *Swift*, and ZTF can be obtained from their designated public data repositories.

Code Availability

Much analysis for this paper has been undertaken with publicly available codes. The details required to reproduce the analysis are contained within the manuscript.

Supplementary Material

Observations and Data Reduction

Photometry

Zwicky Transient Facility — The Zwicky Transient Facility (ZTF) uses the Samuel Oschin 48-inch (1.22 m) Schmidt telescope at Palomar Observatory on Mount Palomar (USA). It is equipped with a 47-square-degree camera [161] and monitors the entire northern hemisphere every 2–3 days in the g and r bands to a depth of ~ 20.7 mag (5σ ; [16, 17]) as part of the public ZTF Northern Sky Survey [162]. We retrieved the host-subtracted photometry via the Infrared Processing and Analysis Center (IPAC) ZTF forced-photometry service [163]. This service uses the data-reduction techniques outlined in Ref. [60]. We cleaned and calibrated the data following Ref. [163].

2.56 m Nordic Optical Telescope — We obtained photometry in gri with the Alhambra Faint Object Spectrograph and Camera (ALFOSC)⁴ on the 2.56 m Nordic Optical Telescope (NOT) at the Roque de los Muchachos Observatory on La Palma (Spain). To remove the host contribution, we obtained a final set of gri photometry in August/September 2022, after the SN had faded. We reduced the data with PyNOT⁵ using standard techniques for CCD data processing and photometry. The world coordinate system was calibrated with the software package astrometry.net [164]. The host contribution was removed with custom image-subtraction and analysis software (K. Hinds, K. Taggart, et al., in prep.). The photometry was measured using point-spread-function (PSF) fitting techniques based on methods in Ref. [165].

Palomar 60-inch telescope — We acquired additional ugri photometry using the Rainbow Camera of the Spectral Energy Distribution Machine (SEDM; [166, 167]) on the robotic Palomar 60-inch (1.52 m) telescope (P60; [168]) at Palomar Observatory. The data were reduced using the data-reduction pipeline FPipe [165].

0.76 m Katzman Automatic Imaging Telescope and 1 m Nickel Telescope — We obtained photometry in BVRI and in the *Clear* band (close to the *R* band; [169]) with the 0.76 m Katzman Automatic Imaging Telescope (KAIT) at Lick Observatory on Mount Hamilton (USA) as a part of the Lick Observatory Supernova Search (LOSS; [170]). One additional epoch of photometry was also obtained with the 1 m Nickel telescope at Lick Observatory. We reduced images using a custom pipeline⁶ detailed in Ref. [171]. We performed PSF photometry with the package DAOPHOT [172] from the IDL Astronomy User's Library⁷.

2 m Liverpool Telescope — We acquired photometry in ugriz using the Infrared-Optical Imager (IO:O) on the robotic Liverpool Telescope (LT; [173]) at Roque de los Muchachos Observatory. Reduced images were downloaded from the LT archive and processed with custom image-subtraction and analysis software (K. Hinds, K. Taggart, et al., in prep.). Image stacking and alignment were performed using SWarp [174] where required. Image subtraction was performed using a pre-explosion reference image in the appropriate filter from the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS) Data Release (DR) 1 [175] or Sloan Digital Sky Survey (SDSS) DR9 [176]. The photometry is measured using PSF fitting techniques based on methods in Ref. [165].

Neil Gehrels Swift Observatory — We submitted a target of opportunity request to use the 30 cm Ultraviolet/Optical Telescope (UVOT; [177]) aboard the *Neil Gehrels Swift Observatory* [178] to expand the wavelength coverage to the UV. Between January and February 2022, we obtained deep images in all filters to remove the host-galaxy contamination from the transient photometry. We coadded all sky exposures for a given epoch to boost the signal-to-noise ratio (S/N) using uvotimsum in HEAsoft⁸ version 6.32.2. Afterward, we measured the brightness of SN 2021yfj with the *Swift* tool uvotsource. The source aperture had a radius of 5", while the background region had a significantly larger radius. To remove the host contribution in w2, m2, and w1 from the earlier epochs, we arithmetically subtracted the host flux from the early measurements when the SN was bright.

Final photometry — The datasets were calibrated against stars from the Sloan Digital Sky Survey (SDSS; e.g., P60, LT, NOT observations; [176]) and Pan-STARRS (e.g., ZTF; [60, 175, 179]), and internal zeropoints (*Swift*; [180]). Observations in similar but not identical filters (e.g., SDSS vs. ZTF filters) could

Supplementary Material Fig. 1: The multiband light curves of SN 2021yfj from 1,800 to 7,850 Å (rest frame) corrected for MW extinction. Vertical bars represent the epochs of spectroscopy. The absolute magnitude is computed with $M = m - DM(z) + 2.5 \log (1 + z)$, where DM is the distance modulus and z the redshift. Non-detections are displayed as ' \mathbf{V} '.

introduce measurable, time-dependent colour terms [181]. Convolving spectra between days 1.0 and 49.8 with SDSS and ZTF filter response functions yielded differences in the filter systems between 0.01 and 0.07 mag. They were comparable to, if not smaller than, the measurement uncertainties. Owing to this, we merged the datasets without applying any colour terms.

The final photometric data are shown in the Supplementary Material Figure 1 and the Supplementary Material Table 2. All measurements are reported in the AB system [182]. The measurements in the Supplementary Material Table 2 are not corrected for Galactic extinction along the line of sight, but the Galactic extinction correction is applied to all photometric data shown in the figures and the derived properties. The MW extinction along the line of sight is E(B - V) = 0.03 mag [183]. We assumed the Cardelli parameterisation of the MW extinction [184] and a total to selective extinction ratio of $R_V = 3.1$.

Spectroscopy

We obtained 16 spectra with several 2–10 m-class telescopes. *Supplementary Material Table* 3 shows the observing log. Details about the observations and the data reductions are provided below.

10 m Keck Telescope — We obtained 4 epochs with the Low-Resolution Imaging Spectrometer (LRIS; [185]) on the 10 m Keck I telescope at Maunakea (USA) between days 1.0 and 132.5. The first and the third epochs, acquired on 8 September 2021 (day 1) and 31 January 2022 (day 132.5), used the B600/4000 blue-side grism and the R400/8500 red-side grating, dichroic 5600, and a 1".0-wide slit. For the second and fourth epochs (days 23.8 and 128.1), we utilised the B400/3400 blue-side grism and the R400/8500 red-side grating, dichroic 5600, and a 1".0-wide slit. The integration times varied between 1,200 and 3,600 s depending on the epoch. To minimise slit losses caused by atmospheric dispersion [186], the spectra were acquired with the slit oriented at or near the parallactic angle. All spectra were reduced in a standard fashion with the data-reduction pipeline LPipe [187].

8.2 m ESO Very Large Telescope — We collected seven medium-resolution spectra with the X-shooter instrument [188] at the 8.2 m Very Large Telescope (VLT) at Paranal Observatory (Chile) between

9 September and 11 November 2021 (days 1.6 to 49.8). All observations were performed in nodding mode and with 1."0/0."9/0."9-wide slits (UVB/VIS/NIR arm). Each spectrum covers the wavelength interval from 3,000 to 24,800 Å. The integration times varied between 2,880 and 4,400 s, depending on the arm (UVB/VIS/NIR) and phase. All observations were done with an atmospheric dispersion corrector to minimise any flux losses. The data were reduced following Ref. [189]. In brief, we first removed cosmic rays with the tool astroscrappy⁹, which is based on the cosmic-ray removal algorithm by Ref. [190]. Afterward, the data were processed with the X-shooter pipeline v3.3.5 and the ESO workflow engine ESOReflex [191, 192]. The UVB- and VIS-arm data were reduced in stare mode to boost the S/N. The individual rectified, wavelength- and flux-calibrated 2D spectra files were coadded using tools developed by J. Selsing¹⁰. The NIR data were reduced in nodding mode to ensure good sky-line subtraction. In the third step, we extracted the 1D spectra of each arm in a statistically optimal way using tools by J. Selsing. Finally, the wavelength calibration of all spectra was corrected for barycentric motion. The spectra of the individual arms were stitched by averaging the overlap regions.

Palomar 200-inch Telescope — We obtained one epoch with the Double Spectrograph (DBSP; [193]) on the Palomar 200 inch (5.1 m) telescope at Mount Palomar Observatory on 13 September 2021 (day 5.2). The observations were taken using the D-55 dichroic beam splitter, a blue grating with 600 lines mm^{-1} blazed at 4,000 Å, a red grating with 316 lines mm^{-1} blazed at 7,500 Å, and a 1.75-wide slit. To minimise slit losses caused by atmospheric dispersion, the spectrum was acquired with the slit oriented at the parallactic angle. The data were reduced using the Python package DBSP_DRP¹¹ that is primarily based on PypeIt [194, 195] and utilises common methods in optical spectroscopy.

2.56 m Nordic Optical Telescope — We collected 3 epochs of low-resolution spectroscopy with ALFOSC on the NOT between 7 January and 22 February 2019 (days 4.1 to 11.1). The spectra were obtained with grism #4 and either a 1".0- or 1".3-wide slit, depending on the weather conditions. To minimise slit losses caused by atmospheric dispersion, the spectra were acquired with the slit oriented at the parallactic angle. The data were reduced with PyNOT using standard techniques for CCD data processing and long-slit spectroscopy.

Shane 3 m telescope — We obtained one spectrum with the Kast double spectrograph¹² mounted on the Shane 3 m telescope at Lick Observatory on 11 September 2021 (day 3.5). We utilised a 2"-wide slit, the 600/4310 grism in the blue, and the 300/7500 grating in the red. This instrument configuration has a combined wavelength range of ~ 3,500-10,500 Å. To minimise slit losses caused by atmospheric dispersion, the Kast spectrum was acquired with the slit oriented at or near the parallactic angle. The Kast data were reduced following standard techniques for CCD processing and spectrum extraction [196] utilising IRAF routines and custom Python and IDL codes¹³. Owing to the low quality of the Lick spectrum, it is not shown in any of the figures in the paper, but it can be downloaded from WISeREP like all other spectra.

Flux calibration and host correction — The flux calibration of all spectra was achieved with spectrophotometric standard stars observed during the same nights. We also tied the absolute flux scale to our multiband photometry. As the SN faded, the relative contribution from the host galaxy increased. To remove the host contribution, we used the X-shooter observation obtained at day 49.8, which also covered the host galaxy. The host was detected in the LRIS spectra from January/February 2022, too. While the continua of the three spectra were identical, the spectra differed in the relative amplitude of the emission lines due to the different resolving powers.

High-Energy Observations

While monitoring SN 2021yfj with UVOT between day 1.5 and day 148.7, *Swift* also observed the field with its onboard X-ray telescope XRT between 0.3 and 10 keV in photon-counting mode [197]. We analysed these data with the online tools of the UK *Swift* team¹⁴ that use the software package HEASoft version 6.26.1 and methods described in Refs. [198, 199]. SN 2021yfj evaded detection at all epochs. The median 3σ count-rate limit of each observing block is $6 \times 10^{-3} \text{ s}^{-1}$ (0.3–10 keV). Coadding all data pushes the 3σ count-rate limits to $0.6 \times 10^{-3} \text{ s}^{-1}$. To convert the count-rate limits into a flux, we assume a power-law spectrum with a photon index¹⁵ of $\Gamma = 2$ and a Galactic neutral hydrogen

⁹https://github.com/astropy/astroscrappy

¹³https://github.com/ishivvers/TheKastShiv ¹⁴https://www.swift.ac.uk/user_objects

¹⁵The photon index is defined as the power-law index of the photon flux density $(N(E) \propto E^{-\Gamma})$.

column density of 2.7×10^{20} cm⁻² [200]. The coadded count-rate limit translates to an unabsorbed flux of $< 0.2 \times 10^{-13}$ erg cm⁻² s⁻¹ in the range of 0.3–10 keV and a luminosity of $< 1.2 \times 10^{42}$ erg s⁻¹. Supplementary Material Table 4 shows a list of all limits.

Furthermore, we queried the NASA High Energy Astrophysics Science Archive Research Center (HEASARC¹⁶) to search for any X-ray and γ -ray transient preceding or accompanying SN 2021yfj. The source catalogues of the *Fermi*, *MAXI*, *NICER*, *NuSTAR*, *AGILE*, and *INTEGRAL* space missions returned no detection within 10' from SN 2021yfj's position between 1 August 2021 (32.7 days before the discovery of SN 2021yfj) and 4 February 2022 (131.8 days after the discovery of SN 2021yfj). Placing a detection limit is not possible for this multitude of facilities.

Host-galaxy Observations

We retrieved science-ready coadded images from the Galaxy Evolution Explorer (GALEX) general release 6/7 [201], the DESI Legacy Imaging Surveys (LS; [116]) DR 10, and PS1. We measured the brightness of the host using LAMBDAR (Lambda Adaptive Multi-Band Deblending Algorithm in R; [202]) and the methods described in Ref. [58]. The field was also observed by the VISTA Hemisphere Survey [203] in the near-IR. We measured the brightness with the aperture photometry tool presented in Ref. [127] using an aperture similar to the ones employed for the other images. The GALEX, LS, and PanSTARRS photometry was calibrated against tabulated zeropoints, and the VHS photometry against stars from the 2MASS Point Source Catalogue [204]. Supplementary Material Table 5 summarises the measurements in the different bands.

The SN spectra also showed absorption lines from the ISM in the host and emission lines produced by the ionised gas in H_{II}. *Supplementary Material Table* 6 summarises the rest-frame equivalent widths of the absorption lines extracted from all early X-shooter spectra and the emission-line fluxes from X-shooter spectrum obtained at day 49.8. The flux measurements are not corrected for reddening.

Comparison Objects

We compare the spectra and light curves of SN 2021yfj to those of other objects. Below, we list the relevant references for each object.

- SN 2006jc (Ibn) bolometric light curve, not constructed; spectra, Ref. [12]
- SN 2010al (Ibn) bolometric light curve, built with data from Ref. [205] using the programme Superbol [206]; spectra, Ref. [205]
- SN 2019hgp (Icn) bolometric light curve, Ref. [13]; spectra, Ref. [13]
- SN 2020oi (Ic) bolometric light curve, Ref. [207]
- SN 2021csp (Icn) bolometric light curve, Ref. [14]; spectra, Ref. [14]

All spectra were retrieved from WISeREP.

Notes: We report rest-frame equivalent widths EW_r for absorption lines and fluxes for emission lines. The emission lines are measured from the X-shooter spectrum at day 49.8 and are not corrected for reddening. [†] Measurement has a significance of $< 3\sigma$.

Supplementary Material Table 7: The bolometric light curve and blackbody properties.

Phase (day)	$ \begin{array}{c} \log \ L_{\rm bol} \\ ({\rm erg} {\rm s}^{-1}) \\ (1,800\text{-}7,850 \text{ Å}) \end{array} $	$ \begin{array}{c} \log \ L_{\rm bol} \\ \left({\rm erg s^{-1}} \right) \\ \left(+ {\rm FUV} + {\rm IR} \right) \end{array} $	$T_{\rm BB}$ (K)	$\begin{array}{c} \log R_{\rm BB} \\ (\rm cm) \end{array}$	Bolometric correction?
0	43.38 ± 0.09	43.60 ± 0.08			yes
0.28	43.42 ± 0.07	43.62 ± 0.07			yes
0.78	43.45 ± 0.06	43.64 ± 0.06			yes
1.28	43.49 ± 0.05	43.67 ± 0.05			yes
1.78	43.52 ± 0.04	43.69 ± 0.05	$15,522\pm998$	15.00 ± 0.04	no
2.28	43.52 ± 0.04	43.68 ± 0.05	$15,351\pm936$	15.00 ± 0.04	no

Notes: The phase is reported in the rest frame with respect to the time of the first detection (MJD = 59,464.414). The last column indicates whether a bolometric correction was applied to determine the pseudobolometric luminosity in the wavelength interval 1,800–7,850 Å. Including the missing FUV and IR flux required a bolometric correction for all data (see the *Methods Section* Bolometric Light Curve for details). The blackbody properties are only reported where UV and optical photometry are available and where the spectrum is adequately described by a blackbody. A machine-readable table will be made available via the WISeREP archive and the journal webpage after the acceptance of the paper.

Parameter	Prior	Magnetar	Nickel		
General					
ejecta mass $M_{\rm ej}~(M_{\odot})$	$\log \mathcal{U}\left(0.01, 10 ight)$	$0.3^{+0.3}_{-0.1}$	1.7 ± 0.1		
explosion date t_{exp} (day, observer frame)	$\mathcal{U}\left(-10,0 ight)$	$-4.5^{+1.0}_{-0.3}$	-8.3 ± 0.5		
" γ -ray" opacity $\kappa_{\gamma} (\mathrm{cm}^2 \mathrm{g}^{-1})$	$\log \mathcal{U}(10^{-4}, 10^4)$	$0.09^{+0.06}_{-0.03}$	0.034 (fixed)		
optical opacity $\kappa (\mathrm{cm}^2 \mathrm{g}^{-1})$	$\mathcal{U}\left(0.01,0.5 ight)$	0.01 ± 0.01	0.07 (fixed)		
photospheric plateau temperature T (K)	$\mathcal{U}(5000, 15,\!000)$	$14,600^{+300}_{-400}$	$14{,}200\pm300$		
white-noise parameter σ	$\mathcal{U}(10^{-3},2)$	0.01	0.01		
V-band absorption $A_{\rm V}$ (mag)	$\mathcal{U}\left(0,1 ight)$	$0.08\substack{+0.08\\-0.05}$	0.01 ± 0.01		
Magnetar model					
ejecta nickel mass fraction $f_{\rm Ni}$	$\log \mathcal{U}\left(10^{-3},1\right)$	$0.05_{-0.05}^{+0.32}$			
initial spin-down luminosity $L_0 \ (10^{44} \ \mathrm{erg s^{-1}})$	$\log \mathcal{U}(10^{-4}, 10^6)$	$0.9^{+2.1}_{-0.2}$			
braking index n	$\mathcal{U}(1.5, 10)$	$7.9^{+1.4}_{-1.8}$			
spin-down time $\tau_{\rm sd}$ (s)	$\log \mathcal{U}(10, 10^8)$	$1.3^{+0.8}_{-1.0} \times 10^6$			
supernova explosion energy $E_{\rm SN}$ (10 ⁵⁰ erg)	$\mathcal{U}\left(1,50 ight)$	$1.9^{+1.0}_{-0.6}$			
⁵⁶ Ni model					
ejecta nickel mass fraction $f_{\rm Ni}$	$\log \mathcal{U}(10^{-3}, 1)$		0.97 ± 0.01		
scaling velocity $v_{\rm scale} \left({\rm km s^{-1}} \right)$	$\mathcal{U}(1000, 15,000)$		$14,300\substack{+400\\-600}$		
Fit	quality				
log Bayesian evidence (log Z)		547	518		
number of free parameters		12	7		

Supplementary Material Table 8: Light-curve fits with Redback: models, priors and marginalised posteriors.

Notes: We used uniform (\mathcal{U}) and log-uniform $(\log \mathcal{U})$ priors. The uncertainties of the marginalised posteriors are quoted at 1σ confidence. The explosion date is measured with respect to the time of the first detection. All marginalised posteriors are reported in linear units. The Bayesian evidence is reported in log units. The opacities of the nickel model were taken from Refs. [208, 209].

Supplementary Material Table 9: Light curve fit with CHIPS.

Parameter	Value
ejecta mass $M_{\rm ej}~(M_{\odot})$	5
CSM mass $M_{\rm CSM}$ (M_{\odot})	> 1
explosion energy $E_{\rm ej}$ (erg)	1.6×10^{51}
power-law index of the inner CSM $n_{\rm in}$	1.1
radius at transition $r_{\rm CSM}$ (cm)	5×10^{15}
density at transition $\hat{\rho}_{\rm CSM} \ ({\rm g \ cm^{-3}})$	3×10^{-15}
