The reconstruction of an inflationary universe considering the parametrization of the scalar spectral index as a function of the number of e−folds in the framework of a modified Friedmann equation is analyzed. In this context, we examine the possibility of reconstructing the Hubble parameter together with the effective potential considering a modified Friedmann equation specified by $\mathcal{F}(H) \propto \rho$, where $\mathcal{F}(H)$ corresponds to an arbitrary function of the Hubble parameter H and ρ denotes the energy density associated with the matter in the universe. To reconstruct the background variables during the inflationary scenario, we develop a new methodology by expressing the spectral index in terms of the Hubble parameter and its derivatives. Thus, we obtain a general formalism for the reconstruction of the inflation, using the slow roll approximation together with the parametrization of the scalar spectral index as a function of the number of e−folds N. As specific examples, we consider the simplest attractor $n_s - 1 = -2/N$ together with different functions $\mathcal{F}(H)$, associated to the modified Friedmann equation, to rebuild the Hubble parameter and the effective potential in terms of the scalar field ϕ . Additionally, we examine the reheating epoch by considering a constant equation of state parameter, in which we determine the temperature and the number of e-folds during this epoch, using the background variables found during the reconstruction of the different $\mathcal{F}(H)$ –models studied. Besides, we constrain the different parameters associated with the reconstructed inflationary $\mathcal{F}(H)$ −models during the epochs of inflation and reheating, using current astronomical data from Planck and BICEP/Keck results.

I. INTRODUCTION

It is widely recognized that during the early universe, the introduction of the inflationary stage, or inflation, remains a possible solution to many long-standing problems of the hot big bang model see e.g., Refs.[\[1](#page-22-0)[–3\]](#page-22-1). However, the most significant characteristic of inflation is that it provides a causal explanation for the origin of the observed anisotropy of the cosmic microwave background (CMB) radiation and the distribution of the large-scale structure observed today $[4–6]$ $[4–6]$.

To describe the inflationary era during the early universe, various inflationary models have been proposed in the context of the theory of general relativity (GR) as well as in modified theories of gravity or alternatives to Einstein's general relativity. The implementation of inflationary models is based on the introduction of a homogeneous scalar field ϕ associated to the matter of the universe. The evolution of this scalar field is governed by the Klein-Gordon equation and together with the Friedmann equation, and they constitute the simplest set of field equations utilized to study the inflationary dynamics of the early universe in the framework of a Friedmann Roberson Walker (FRW) metric. In relation to the modified gravity, we can distinguish those models that utilize a modified Friedmann equation to describe the early universe. In this sense, considering a spatially flat FRW metric, the modified Friedmann equation can be written as

$$
\mathcal{F}(H) = \frac{\kappa}{3}\rho,\tag{1}
$$

where $\mathcal{F}(H) > 0$ is an arbitrary function associated to the Hubble parameter defined by $H = (da/dt)/a$, where a(t) denotes the scale factor. Besides, the quantity $\kappa = 8\pi G = M_p^{-2}$ where M_p represents the Planck mass and ρ corresponds to the energy density relates to the matter of the universe. Thus, we have that the dimension associated to the function $\mathcal{F}(H)$ corresponds to $M_p^2 = \kappa^{-1}$. Also, we note that Eq.[\(1\)](#page-0-2) is reduced to the standard Friedmann equation when the function $\mathcal{F}(H) = H^2$.

The motivation for considering this modification of the Friedmann equation, defined by Eq.[\(1\)](#page-0-2) arises from the fact that various models in the literature, have analyzed this modification to describe the early and present universe. Thus,

[∗] ramon.herrera@pucv.cl

[†] carlos.rios@ucn.cl

some examples are the Friedmann equations in one anti de Sitter bulk with a Gauss Bonnet (GB) term, in which we have three regimes for the history of the brane universe compacted from the function $\mathcal{F}(H) \propto H^{\beta}$ [\[7–](#page-22-4)[10\]](#page-22-5). In this case, when we consider the value $\beta = 3$, we have the GB regime and then the GB term dominates gravity at highest energies. The situation in which we have $\beta = 1$ corresponds to the high energy limit of the brane world cosmology, Randall-Sundrum (RS) regime[\[11\]](#page-22-6) and the case $\beta = 2$ is the standard Friedmann equation. Besides, this class of function of the form power-law type associated to the Hubble parameter is found from the entropy considerations as Tsallis Entopic Proposal or Fractional Entropy (see Refs. [\[12,](#page-22-7) [13\]](#page-22-8)), in which we have $\mathcal{F}(H) \propto H^{\beta}$.

In the framework of the deformed Ho \check{r} ava-Lifshitz gravity from entropic force, we have that the function $\mathcal{F}(H)$ is given by $\mathcal{F} = H^2 + \alpha H^4 [3 - 2 \ln(4 \pi M_p^2 / H^2)]$, where the inverse of the parameter α corresponds to the parameter of Ho˘rava-Lifshitz [\[14\]](#page-22-9). Besides, corrections to the Friedmann equation inspired by Kaniadakis entropy in which adopting the thermodynamics-gravity conjecture was obtained in Ref.[\[15\]](#page-22-10). Here the function $\mathcal{F}(H)$ becomes $\mathcal{F} = H^2 - \gamma H^{-2}$, where γ (with dimensions of M_p^4) is associated to Kaniadakis parameter[\[16\]](#page-22-11), and the Kaniadakis entropy (or Kentropy), is one-parameter extension of the classical Boltzmann–Gibbs–Shannon entropy. It emerges from a coherent and self-consistent relativistic statistical framework, maintaining the fundamental aspects of standard statistical theory while reclaiming it under specific conditions [\[17\]](#page-22-12). Another type of function $\mathcal{F}(H)$ found in the literature corresponds to $\mathcal{F}(H) = H^2 + \alpha H^4$, where α is an arbitrary parameter with dimension of M_p^{-2} . Here the flat Friedmann equation can be derived by considering the Clausius relation to the apparent horizon of FRW universe, in which entropy is defined to be proportional to its horizon area plus a logarithmic correction associated with this area[\[18\]](#page-22-13), see also Ref.[\[74\]](#page-22-14). Also, this function $\mathcal{F}(H) = H^2 + \alpha H^4$ or modified Friedmann equation arises when considering an AdS-Schwarzschild black hole via holographic renormalization, incorporating mixed boundary conditions that correspond to the Einstein field equations in four dimensions [\[20\]](#page-22-15). Additionally this modified Friedmann equation can be found in the framework of a Chern-Simons type of theory [\[21,](#page-22-16) [22\]](#page-22-17), in which the parameter α can be positive or negative[\[23\]](#page-22-18). In this sense, there are several other functions $\mathcal{F}(H)$ or modifications to the Friedmann equation that can be found in the literature, see e.g., Refs.[\[18,](#page-22-13) [24](#page-22-19)[–26\]](#page-22-20).

On the other hand, in the literature several authors have analyzed the reconstruction of the background variables, particularly the effective potential associated with a scalar field in the context of inflation, using observational data, such as, the scalar power spectrum, scalar spectral index n_s , and the tensor to scalar ratio $r[27–30]$ $r[27–30]$ $r[27–30]$. In this respect, an attractive approach to reconstruct the effective potential of the scalar field using the slow roll approximation, is to consider the parametrization of the observational parameters in terms of the number of e -folds N . Specifically, by utilizing the scalar spectral index as a function of N i.e., $n_s = n_s(N)$, often referred to as an attractor, it is possible to rebuild the effective potential as a function of the scalar field [\[31\]](#page-22-23). In this context, the simplest attractor given by $n_s - 1 = -2/N$ for large-N (with $N \sim \mathcal{O}(10) \sim \mathcal{O}(10^2)$), aligns with the Planck data, when the number of e-folds N is set to $N = 60$ [\[32\]](#page-22-24). By assuming this attractor in the framework of the GR, it is feasible to reconstruct an effective potential[\[33\]](#page-22-25) with different limits[\[1,](#page-22-0) [34,](#page-22-26) [35\]](#page-22-27). In relation to warm inflation, the reconstruction of the effective potential and the dissipation coefficient in terms of the scalar field, was necessary to consider two attractors; the scalar spectral index and the tensor to scalar ratio in terms of the number of e -folds N [\[36\]](#page-22-28). Here in the weak dissipative regime, considering the attractors $n_s - 1 \propto N^{-1}$ together with $r \propto N^{-2}$, it was found that the reconstruction of the effective potential and the dissipation coefficient as functions of the scalar field depends on hyperbolic functions. During the strong regime was obtained that the potential and the dissipation coefficient as functions of the scalar field exhibit a power-law behavior under certain conditions[\[36\]](#page-22-28). Analogously, for the construction of the background variables associated with Galilean inflation or G-inflation was necessary to utilize two observational parameters [\[37\]](#page-23-0).

In addition, different analysis for the reconstruction of the background variables using another parametrizations in terms of the number of e−folds N in the context of the slow roll approximation can be found in the literature. Thus, for example, we have the reconstruction of the effective potential as a function of the scalar field using the parametrization on the slow roll parameter $\epsilon = \epsilon(N)$ [\[38–](#page-23-1)[40\]](#page-23-2). Besides, considering the two slow roll parameters $\epsilon(N)$ and $\eta(N)$ as a function of the number of e−folds N, it is possible to rebuild the effective potential and the tensor to scalar ratio in terms of the scalar field[\[41,](#page-23-3) [42\]](#page-23-4). For a review of other methodologies to rebuild the background variables during the inflationary stage, see Refs.[\[43–](#page-23-5)[50\]](#page-23-6).

On the other hand, at the end of the inflationary stage, the universe undergoes a reheating phase to connect with the standard big bang model [\[3,](#page-22-1) [51\]](#page-23-7). During this reheating scenario, matter and radiation are produced through the decay of the inflaton field or other fields. As a result, the temperature of the universe rises, eventually leading to the radiation-dominated era and then connecting with the standard hot big bang model. To explain the reheating scenario during the early universe, various reheating models are employed to increase the temperature in this period. One such mechanism involves the perturbative decay of the scalar field through an oscillatory process at the minimum of the effective potential after the end of inflation [\[52\]](#page-23-8). Additionally, there are mechanisms associated with non-perturbative analysis, such as; the parametric resonance decay of the inflaton, the instant reheating model [\[53\]](#page-23-9) or another field [\[54\]](#page-23-10). Furthermore, some inflationary models do not involve the inflaton field oscillating around the minimum of the potential; these are known as non-oscillating models (NO models). In such cases, reheating occurs through the decay of another field known as the curvaton [\[55,](#page-23-11) [56\]](#page-23-12). For further details, see also Ref.[\[57\]](#page-23-13) for the reheating from tachyonic instability and other reheating models in Ref.[\[58\]](#page-23-14).

During the reheating scenario, several important parameters characterize this stage, including the reheating temperature T_{reh} , the equation of state (EoS) defined as $\omega_{\text{reh}} = p/\rho$, which describes the matter content during the reheating era, and the duration of this stage, characterized by the number of e-folds N_{reh} . Here, the quantities p and ρ denote the pressure and energy density of the matter-associated fluid during the reheating scenario. We mention that in the case of the reheating temperature, there is a lower bound imposed by the primordial nucleosynthesis (BBN), given by $T_{\rm BBN} \sim 10$ MeV[\[59\]](#page-23-15). On the other hand, with regard to the EoS parameter, various numerical calculations have been developed to analyze its dynamics based on specific interactions involving the inflaton and other fields related to matter[\[60\]](#page-23-16). In this sense, the dynamics evolution in the cosmological time of the EoS parameter depends on the interaction of the inflaton and the another fields. In particular, the authors of Ref.[\[61\]](#page-23-17) determined that numerically, the EoS parameter exhibited a slow increase from a value of $\omega_{\text{reh}} = 0$ at the end of inflation to $\omega_{\text{reh}} \sim 0.3$ during the reheating epoch. In the case of a massive field, it was found that numerically, the EoS parameter increases from a negative value at the end of inflation in which $\omega_{\text{reh}} = -1/3$, to a value $\omega_{\text{reh}} \simeq 0$ [\[62,](#page-23-18) [63\]](#page-23-19). In this sense, as a first approximation and in order to find analytical expressions to the reheating parameters, such as, the temperature T_{reh} and the number N_{reh} , we can consider that the EoS parameter during the reheating stage remains approximately constant throughout the this epoch[\[64\]](#page-23-20).

The goal of this study is to rebuild inflation in the framework of the generalized Friedmann equation, through the parametrization of an observational parameter in terms of the number of e−folds N. In particular, we will consider an attractor from the parametrization of the scalar spectral index n_s as a function of the number of e–folds N, i.e., $n_s = n_s(N)$. Here we will develop a new methodology based on rewriting the spectral index in relation to the Hubble parameter and its derivatives. In this, sense, we study how using different modified Friedmann equations, these affect the reconstruction of the Hubble parameter together with the effective potential, in terms of the scalar field. We will also establish a general methodology in the context of the slow roll approximation to build the Hubble parameter and the effective potential, by considering as attractor the scalar spectral index $n_s = n_s(N)$. In this form, settling on a specific scalar spectral index $n_s(N)$, we will determine the possibility of rebuilding the Hubble parameter as well as the potential as a function of the scalar field considering different modified Friedmann equations thought various functions $\mathcal{F}(H)$.

Besides, we will study the reheating era and how the parameters associated to this period, such that, the reheating temperature and number of e−folds are changed from the reconstruction of the background variables obtained in the inflationary period (under the slow roll approximation). Thus, from these reheating parameters, we will analyze the reheating temperature and the duration of the reheating in terms of the observational parameter n_s , from Planck data. In addition, we will determine how these reheating quantities are constrained considering different EoS parameters ω_{reh} on the plane $T_{\text{reh}} = T_{\text{reh}}(n_s)$ and $N_{\text{reh}} = N_{\text{reh}}(n_s)$, respectively.

We organize our paper as follows: In Section [II](#page-2-0) we give a brief analyze of the inflationary phase in a generalized Friedmann equation $\mathcal{F}(H)$. Thus, in this section we show the basic equations under the slow roll approximation during the inflationary epoch to rebuild the background variables. Beside, we present the observational parameters such as the scalar spectral index, power spectrum together with the tensor to scalar ratio in this generalized Friedmann equation. Additionally, we obtain under a general formalism, an expression for the Hubble parameter (differential equation) in terms of the number of e−folds N to find the reconstruction from any parametrization related to the scalar spectral index $n_s(N)$. In Section [III,](#page-6-0) we study the reheating stage under a general formalism in the framework of the modified Friedmann equation. In this section, we express for any function $\mathcal{F}(H)$, the reheating temperature T_{reh} together with the number of e−folds N_{reh} during this era.

In Section [IV,](#page-7-0) we assume a specific attractor for the scalar spectral index $n_s = n_s(N)$ given by $n_s = 1 - 2/N$, in order to rebuild both the Hubble parameter $H(\phi)$ as the effective potential $V(\phi)$ in terms of the scalar field ϕ . In this sense, we consider different functions $\mathcal{F}(H)$ to reconstruct the inflationary scenario and the reheating epoch. During the inflationary scenario, we find the different constrains on the parameter-space from Planck data. In relation to the reheating scenario, we determine the reheating temperature together with the number of e−folds in this epoch. In this way, we find these quantities on the plane $T_{\text{reh}} = T_{\text{reh}}(n_s)$ and $N_{\text{reh}} = N_{\text{reh}}(n_s)$ for various values of the EoS parameters to constraint the parameters of our modified model. Finally, in Section [V](#page-21-0) we give our conclusions. We chose units in which $c = \hbar = 1$.

II. RECONSTRUCTING INFLATION IN A MODIFIED FRIEDMANN EQUATION

In this section, we will present a brief analysis of the implications of considering a modified Friedman equation characterized through function $\mathcal{F}(H)$ associated with the Hubble parameter H. To describe the matter, in the generalized Friedmann equation $\mathcal{F}(H) \propto \rho$, we introduce that the energy density ρ is associated to the inflaton field ϕ . In this way, we can write that the energy density associated to scalar field becomes

$$
\rho = \frac{1}{2}\dot{\phi}^2 + V(\phi),\tag{2}
$$

where $V(\phi)$ represents the effective potential related to the inflaton field. Besides, the pressure related to the scalar field is defined by

$$
p = \frac{1}{2}\dot{\phi}^2 - V(\phi).
$$
 (3)

Here we have considered that the scalar field ϕ is a homogeneous scalar field i.e., $\phi = \phi(t)$. Also, in the following the dots mean derivatives with respect to the time.

Further, the continuity equation can be written as

$$
\dot{\rho} + 3H(\rho + p) = 0,\tag{4}
$$

and replacing equations [\(2\)](#page-3-0) and [\(3\)](#page-3-1) in Eq.[\(4\)](#page-3-2), we obtain that the dynamics of the scalar field can be written as

$$
\ddot{\phi} + 3H\dot{\phi} + V_{\phi} = 0,\tag{5}
$$

where V_{ϕ} represents the derivative of $V(\phi)$ with respect to the ϕ field, i.e., $V_{\phi} = \partial V / \partial \phi$. Besides, in the following, we will use that the notation \mathcal{F}_H corresponds to $\mathcal{F}_H = d\mathcal{F}/dH$, \mathcal{F}_{HH} denotes $\mathcal{F}_{HH} = d^2\mathcal{F}/dH^2$, $H_{\phi} = dH/d\phi$, $H_{\phi\phi} = d^2H/d\phi^2$, etc.

From Eqs.[\(1\)](#page-0-2), [\(2\)](#page-3-0) [\(3\)](#page-3-1) and [\(5\)](#page-3-3), we find that the speed of the scalar field ϕ results

$$
\dot{\phi} = -\frac{\mathcal{F}_H}{\kappa} \left(\frac{H_\phi}{H} \right). \tag{6}
$$

On the other hand, introducing the number of e -folds N , provides a way to quantify the amount of inflation required during the expansion of the universe during the inflationary stage. Thus, the number of e -folds N defined between two different values of the time; t (or scalar field ϕ) and t_{end} becomes

$$
\Delta N = N - N_{\text{end}} = \ln \left[\frac{a(t_{\text{end}})}{a(t)} \right] = \int_{t}^{t_{\text{end}}} H dt = \kappa \int_{\phi}^{\phi_{\text{end}}} \left(\frac{H}{\dot{\phi}} \right) d\phi, \tag{7}
$$

where N_{end} and t_{end} denote the number of e-folds and the time at the end of the inflationary era.

On the other hand, introducing the parameters ϵ_H and η_H , in the context of a theory with a generalized Friedmann equation we have [\[26\]](#page-22-20)

$$
\epsilon_H = -\frac{\dot{H}}{H^2} = -\frac{d\ln H}{d\ln a} = \frac{1}{\kappa} \frac{\mathcal{F}_H}{H} \left(\frac{H_\phi}{H}\right)^2, \text{ and } \eta_H = -\frac{\ddot{H}}{H\dot{H}} = -\frac{d\ln H_\phi}{d\ln a} = \frac{1}{\kappa} \frac{\mathcal{F}_H}{H} \frac{H_{\phi\phi}}{H}.
$$
 (8)

Here we have used the equation for the speed of the scalar field given by $Eq.(6)$ $Eq.(6)$.

We note that these parameters coincide with the parameters given by the standard slow roll parameters ϵ and η , when $\mathcal{F}(H) = H^2$, under the slow roll approximation. In this way, during slow roll approximation we have that the quantities ϵ_{SR} and η_{SR} when $\mathcal{F}(H) = H^2$ are reduced to

$$
\epsilon_{SR} = \epsilon_H \simeq \frac{1}{2\kappa} \left(\frac{V_\phi}{V}\right)^2, \quad \eta_{SR} \simeq \frac{1}{\kappa} \left(\frac{V_{\phi\phi}}{V}\right), \quad \text{and} \quad \eta_H = \eta_{SR} - \epsilon_{SR}.
$$

Let us observe that an inflationary scenario of the universe occurs when $\ddot{a} > 0$, which implies that the parameter $\epsilon_H < 1$. Furthermore, the end of the inflationary era takes place when $\ddot{a} = 0$ or equivalently when the parameter $\epsilon_H = 1.$

In relation to the cosmological perturbations, the general perturbed metric about the flat FRW becomes $ds^2 =$ $-(1+2A)dt^2+2a(t)B_{,i}dx^idt+a(t)^2[(1-2\psi)\delta_{ij}+2E_{,i,j}+2h_{ij}]dx^idx^j$, where A, B, ψ and E correspond to the scalar type metric perturbations and the quantity h_{ij} denotes the traverse-traceless tensor type perturbation. In this sense, following Ref.[\[26\]](#page-22-20), the equation for the Fourier modes associated to the scalar perturbations can be written as

$$
\frac{d^2u_k}{d\eta^2} + \left(k^2 - \frac{1}{z}\frac{d^2z}{d\eta^2}\right)u_k = 0,
$$
\n(10)

5

where u_k corresponds to the Mukanov variable defined as $u = z\mathcal{R}$, in which the quantity $z = a\dot{\phi}/H$. Besides, the variable η denotes the conformal time and the quantity $\mathcal R$ is the gauge invariant comovil curvature perturbation.

The term $(1/z)(d^2z/d\eta^2)$ associated to Eq.[\(10\)](#page-3-5) in the framework of the modified Friedmann equation can be written as [\[26\]](#page-22-20)

$$
\frac{1}{z}\frac{d^2z}{d\eta^2} = 2a^2H^2\Big[1 + \frac{1}{2}\epsilon_H\left(5 - 3H\frac{\mathcal{F}_{HH}}{\mathcal{F}_H}\right) - \frac{3}{2}\eta_H + \frac{1}{2}\eta_H^2 + \epsilon_H^2\Big(1 + \frac{H^2}{2}\frac{\mathcal{F}_{HHH}}{\mathcal{F}_H} - H\frac{\mathcal{F}_{HH}}{\mathcal{F}_H}\Big) - \frac{1}{2}\epsilon_H\eta_H\Big(3 - 2H\frac{\mathcal{F}_{HH}}{\mathcal{F}_H}\Big) + \mathcal{O}(\epsilon_H, \ldots). \tag{11}
$$

In the particular case in which the function $\mathcal{F}(H) = H^2$, the different terms given by Eq.[\(11\)](#page-4-0) are reduced to those obtained in Ref.[\[65\]](#page-23-21).

In this form, following the approach outlined in Ref. [\[26\]](#page-22-20), the primordial curvature perturbation A_s produced during inflation in the context of a generalized Friedmann equation can be written as

$$
A_s(k) = \left(\frac{\kappa H^2}{\mathcal{F}_H H_\phi}\right)^2 \left(\frac{H}{2\pi}\right)^2.
$$
 (12)

In addition, the power spectrum of the scalar perturbations A_s given by Eq.[\(12\)](#page-4-1) can be rewritten as

$$
A_s = \left(\frac{\kappa H^2}{\mathcal{F}_H H_N}\right) \left(\frac{H}{2\pi}\right)^2,\tag{13}
$$

where we have utilized the relation $\dot{\phi}^2 = \mathcal{F}_H H_N/\kappa$. Here the perturbation defined by Eq.[\(12\)](#page-4-1) is a function of the wave number k and it is evaluated for a particular mode, when the cosmological scale exits the horizon i.e., when $k = aH$.

By using the primordial curvature perturbation, we can determine the so-called scalar spectral index n_s , defined as $n_s - 1 = d \ln A_s/d \ln k$. Thus, from Eq.[\(12\)](#page-4-1) the expression for the scalar spectral index is given by [\[26\]](#page-22-20)

$$
n_s - 1 = 2\eta_H - 2\left(3 - H\frac{\mathcal{F}_{HH}}{\mathcal{F}_H}\right)\epsilon_H.
$$
\n(14)

We note that in the special case in which $\mathcal{F}(H) = H^2$, Eq.[\(14\)](#page-4-2) reduces to the standard expression $n_s - 1 = 2\eta_{SR} - 6\epsilon_{SR}$.

Additionally, the tensor perturbation (transverse-traceless) during the inflationary scenario would produce gravitational waves, where the tensor perturbations amplitude is denoted by A_T . Thus from these perturbations we can define an important observational quantity called the tensor to scalar ratio r, defined as $r = A_T/A_s$. In this form, we have that the tensor to scalar ratio can be written as [\[26\]](#page-22-20)

$$
r = 8\frac{\mathcal{F}_H}{H}\epsilon_H.
$$
\n(15)

We note that Eq.[\(13\)](#page-4-3) and Eq.[\(15\)](#page-4-4) are reduced to the standard expressions $A_s = \kappa H^2 / (8\pi^2 \epsilon_{SR})$ and $r = 16\epsilon_{SR}$ when we choose the function $\mathcal{F}(H) = H^2$ (standard Friedmann equation).

A. Reconstructing inflation: General reconstruction of $H(\phi)$ and $V(\phi)$ from $n_s(N)$

In this subsection we consider the methodology to rebuild the background variables, such as, the Hubble parameter and the effective potential in terms of the scalar field, assuming as attractor the scalar spectral index in terms of the number of e-folds N. In this context, we will utilize a new methodology to reconstruct the background variable considering the Hubble parameter and its derivatives in terms of the number of e−folds N. Firstly, we will rewrite the scalar spectral index given by Eq.[\(14\)](#page-4-2) in terms of the Hubble parameter, the function $\mathcal F$ and the derivatives as a function of the number of e-folds N through the parameters ϵ_H and η_H , respectively. In this way, giving the attractor $n_s = n_s(N)$, we should first find the Hubble parameter and the effective potential in terms of the number of e-folds N. Subsequently, using the expression given by Eq.[\(7\)](#page-3-6), we should find the e-folds N in terms of the scalar field ϕ . Finally, considering these equations, we can rebuild the Hubble parameter as a function of the scalar field i.e., $H(\phi)$, and subsequently we can determine the effective potential $V(\phi)$.

From this methodology, we start by rewriting the parameters ϵ_H and η_H associated to the Hubble parameter in terms of the number of e−folds. Thereby, we can now rewrite the Hubble parameter and its derivatives in terms of the number N considering the relation between N and the scalar field from the relation

$$
dN = -Hdt = -\left(\frac{H}{\dot{\phi}}\right)d\phi, \text{ such that } N_{\phi} = \frac{dN}{d\phi} = -\frac{H}{\dot{\phi}}.
$$
 (16)

In this way, we obtain that

$$
H_{\phi} = -\left(\frac{H}{\dot{\phi}}\right) H_N. \tag{17}
$$

Now, using Eq. (6) we find that the Eq. (17) becomes

$$
H_{\phi}^{2} = \frac{\kappa H^{2} H_{N}}{\mathcal{F}_{H}}.\tag{18}
$$

Here we note that the ratio H_N/\mathcal{F}_H is a positive quantity. Besides, as the quantity $\dot{H} = -H H_N < 0$, then we have that $H_N > 0$ and it suggests that the derivative $\mathcal{F}_H > 0$.

Additionally, we can rewrite the quantity $H_{\phi\phi}$ in terms of the derivatives of the number of e-folds N as

$$
H_{\phi\phi} = \frac{\kappa H^2}{\mathcal{F}_H} \left(\frac{H_{NN}}{2H_N} + \frac{H_N}{H} - \frac{\mathcal{F}_{HH} H_N}{2\mathcal{F}_H} \right). \tag{19}
$$

Thus, from these relations we can rewrite the parameters ϵ_H and η_H , respectively. In this context, by replacing Eqs.[\(18\)](#page-5-1) and [\(19\)](#page-5-2) into Eq.[\(8\)](#page-3-7), we obtain that these parameters as a function of \mathcal{F}, H and its derivatives with respect to the number N result

$$
\epsilon_H = \frac{H_N}{H}
$$
, and $\eta_H = \epsilon_H + \frac{H_{NN}}{2H_N} - \frac{\mathcal{F}_{HH}H_N}{2\mathcal{F}_H}$. (20)

Using previous results we can rewrite the spectral index n_s given by Eq.[\(14\)](#page-4-2) as

$$
n_s - 1 = \frac{H_{NN}}{H_N} - \frac{4H_N}{H} + \frac{\mathcal{F}_{HH} H_N}{\mathcal{F}_H} = \frac{d \ln H_N}{dN} + g(H) \frac{d \ln H}{dN},\tag{21}
$$

where we have defined the function $g(H)$ as

$$
g(H) = \frac{H\mathcal{F}_{HH}}{\mathcal{F}_H} - 4.
$$
\n⁽²²⁾

In order to obtain the Hubble parameter in terms of the number of e -folds N, we can solve Eq.[\(21\)](#page-5-3) to find a first integral given by

$$
H_N \exp\left[G(H)\right] = \exp\left[\int (n_s - 1)dN\right],\tag{23}
$$

where the new function $G(H)$ is given by

$$
G(H) = \int \frac{g(H)}{H} dH.
$$
\n(24)

In this way, the Hubble parameter $H = H(N)$ can be obtained from the differential equation given by Eq.[\(23\)](#page-5-4) assuming a specific attractor for the scalar spectral index $n_s = n_s(N)$.

In order to find the effective potential in terms of the number of e -folds i.e., $V(N)$, we can consider the modified Friedmann equation [\(1\)](#page-0-2) obtaining

$$
V(N) \simeq \frac{3}{\kappa} \mathcal{F}(H). \tag{25}
$$

Here we have considered the slow roll approximation in which the scalar potential $V \gg \dot{\phi}^2/2$ during the inflationary stage.

Additionally, to determine a relationship between the number of ϵ -folds N and the scalar field ϕ , we can use the Eqs. (6) , (16) , and (18) to obtain

$$
N_{\phi} = \sqrt{\frac{\kappa}{\mathcal{F}_H H_N}} H. \tag{26}
$$

In this form, integrating Eq.[\(26\)](#page-6-1) we can determine the relation between $N = N(\phi)$ for a specific attractor $n_s = n_s(N)$. Finally, replacing the solution given by Eq.[\(26\)](#page-6-1) into Eq.[\(25\)](#page-5-6), we will rebuild the effective potential as a function of the scalar field ϕ , i.e., $V = V(\phi)$.

III. REHEATING: GENERAL DESCRIPTION

In this section, we will analyze the reheating era in the framework of the generalized Friedmann equation in a general description. In this sense, we will utilize the expressions associated to the background variables to find the reheating parameters, such as, the reheating temperature, as well as, the number of e−folds during this epoch. To start with this study, we can assume that the physical scale cross the horizon during inflation when the wave number k is equal to $k = a_k H_k$. In addition, we can assume that the physical scale crosses the horizon at the current epoch when $k_0 = a_0H_0$. Here, the subscript "k" denotes that the quantities are evaluated when $k = a_kH_k$, and the subscript "0" represents the physical quantities evaluated at the present time. Besides, the ratio between the wave numbers k/k_0 can be written as

$$
\frac{k}{k_0} = \frac{a_k H_k}{a_0 H_0} = \left(\frac{a_k}{a_{\text{end}}}\right) \left(\frac{a_{\text{end}}}{a_{\text{reh}}}\right) \left(\frac{a_{\text{reh}}}{a_{\text{eq}}}\right) \left(\frac{a_{\text{eq}} H_{\text{eq}}}{a_0 H_0}\right) \left(\frac{H_k}{H_{\text{eq}}}\right). \tag{27}
$$

As before, here we have used that the "end" subscript means that the variable is evaluated at the end of inflation. In addition, the notation "reh" corresponds to the reheating era and "eq" denotes the of radiation-matter equality.

In fact, we can write the number of e -folds N in each stage (duration) as a function of the scale factor a as follows

$$
N_k = \ln\left(\frac{a_{\text{end}}}{a_k}\right)
$$
, $N_{\text{reh}} = \ln\left(\frac{a_{\text{reh}}}{a_{\text{end}}}\right)$ and $N_{RD} = \ln\left(\frac{a_{\text{eq}}}{a_{\text{reh}}}\right)$,

respectively. Here, the notation N_{reh} corresponds to the number of e-folds during reheating era and N_{RD} denotes to the number of e-folds in the radiation dominance (RD). By using these different e−folds in each era, we rewrite $Eq.(27)$ $Eq.(27)$ as

$$
\ln\left(\frac{k}{a_0H_0}\right) = -N_k - N_{\rm reh} - N_{\rm RD} + \ln\left(\frac{a_{\rm eq}H_{\rm eq}}{a_0H_0}\right) + \ln\left(\frac{H_k}{H_{\rm eq}}\right). \tag{28}
$$

Besides, we can utilize the EoS parameter $\omega_{\rm reh}$ related to the reheating regime to express the ratio between the energy density at the end of inflation ρ_{end} and the energy density during the reheating stage ρ_{reh} . In this way, the ratio $\rho_{\text{reh}}/\rho_{\text{end}}$ can be written as

$$
\frac{\rho_{\rm reh}}{\rho_{\rm end}} = e^{-3N_{\rm reh}(1+\omega_{\rm reh})}.\tag{29}
$$

For this expression we have considered that during the reheating stage the energy density ρ has a dependence with the scale factor a as; $\rho \propto a^{-3(1+\omega_{\rm reh})}$, in which the parameter $\omega_{\rm reh}$ is assumed a constant.

In order to determine the enrgy density of the field at the end of inflation ρ_{end} in Eq.[\(29\)](#page-6-3), we can first rewrite the parameter ϵ_H from Eq.[\(8\)](#page-3-7) as

$$
\epsilon_H = \frac{2\kappa}{H\mathcal{F}_H} \left(\frac{\dot{\phi}^2}{2}\right) = \frac{2\kappa}{H\mathcal{F}_H} \left(\rho - V\right),\tag{30}
$$

where we have used Eqs.[\(1\)](#page-0-2) and [\(2\)](#page-3-0), respectively. Considering that the end of the inflationary era occurs when $\epsilon_H = 1$ (or equivalently $\ddot{a} = 0$), we can find from the above equation that the energy density at the end of the inflationary era ρ_{end} can be obtained from the relation

$$
\rho_{\text{end}} - \frac{1}{2\kappa} \left(\frac{d\mathcal{F}}{d\ln H} \right) \Big|_{\text{end}} = V_{\text{end}}, \tag{31}
$$

where we mention that the second term of Eq.[\(31\)](#page-6-4) is a function of ρ_{end} and it depends of the function $\mathcal{F}(H)$.

In the particular case in which the function $\mathcal{F}(H)$ corresponds to the standard Friedmann equation i.e., $\mathcal{F}(H) = H^2$, we have that the term $(d\mathcal{F}/d\ln H)|_{\text{end}} = (2\kappa/3)\rho_{\text{end}}$. Thus, substituting this result into Eq.[\(31\)](#page-6-4) we find the well known result for ρ_{end} given by $\rho_{end} = (3/2)V_{end}$ [\[64,](#page-23-20) [66,](#page-23-22) [67\]](#page-23-23).

On the other hand, to find the reheating temperature T_{reh} , we can consider the entropy conservation, in which the entropy generated during reheating is preserved in the CMB together with the neutrino background at the current epoch [\[67\]](#page-23-23). In this context, following Ref.[\[67\]](#page-23-23) we can write this conservation as

$$
g_{\rm s,reh}a_{\rm reh}^3 T_{\rm reh}^3 = a_0^3 \left(2T_0^3 + \frac{21}{4}T_{\nu,0}^3\right),\tag{32}
$$

where the quantity $g_{\rm s,reh}$ corresponds to the effective number of relativistic degrees of freedom for entropy at reheating, the temperature T_0 denotes the present CMB temperature i.e., $T_0 \simeq 2.7$ K and the quantity $T_{\nu,0}$ is the present neutrino temperature. Following Ref.[\[67\]](#page-23-23) we can consider that the relation between the temperatures $T_{\nu,0}$ and T_0 is given by $T_{\nu,0} = (4/11)^{1/3} T_0$, and then from Eq.[\(32\)](#page-7-1) we can relate the scale factors during the reheating scenario and at the current era from the expression $a_{\rm reh}/a_0 = \left[\frac{43}{(11g_{\rm s,reh})}\right]^{1/3} T_0/T_{\rm reh}$.

In addition, we can consider that the energy density at the end of reheating $\rho_{\rm reh}$ corresponds to the hot radiation $\rho_{\text{reh}} \propto T_{\text{reh}}^4$, with which we can write

$$
\rho_{\rm reh} = \frac{\pi^2}{30} g_{\star, \rm reh} T_{\rm reh}^4 \,, \tag{33}
$$

where the quantity $g_{\star,rel}$ represents the effective number of relativistic degrees of freedom at the end of reheating scenario.

In this form, utilizing the above expressions, we find that the reheating temperature T_{reh} in terms of the parameters ρ_{end} , ω_{reh} and N_{reh} becomes

$$
T_{\rm reh} = \exp\left[-\frac{3}{4}(1+\omega_{\rm reh})N_{\rm reh}\right] \left[\frac{30\,\rho_{\rm end}}{g_{\star,\rm reh}\pi^2}\right]^{1/4}.\tag{34}
$$

Besides, we find that the duration of the reheating epoch characterized by the number of e -folds N_{reh} results

$$
N_{\rm reh} = \frac{4}{1 - 3\omega_{\rm reh}} \left[-N_k - \ln\left(\frac{k}{a_0 T_0}\right) - \frac{1}{3} \ln\left(\frac{11 g_{\rm s,reh}}{43}\right) - \frac{1}{4} \ln\left(\frac{30 \kappa^2 \rho_{\rm end}}{g_{\star,reh} \pi^2}\right) + \frac{1}{2} \ln\left(\frac{\pi^2 r A_s}{2}\right) \right].
$$
 (35)

Here we note that to obtain the energy density at the end of the inflationary scenario ρ_{end} , we need to solve the Eq.[\(31\)](#page-6-4) for the different functions $\mathcal{F}(H)$, and then to write the density ρ_{end} in terms of the potential at the end of inflation i.e., $\rho_{end} = \rho_{end}(V_{end})$. In this sense, we have analyzed the reheating scenario for any $\mathcal{F}(H)$ −model under one general description. In the following, we will apply our methodology for different functions $\mathcal{F}(H)$ for the simplest attractor for the scalar spectral index in terms of the number of e–folds given by $n_s = 1 - 2/N$.

IV. RECONSTRUCTION FROM THE SCALAR SPECTRAL INDEX $n_s = n_s(N)$

In this section we will make use of the methodology earlier described, considering as attractor one specific parametrization for the scalar spectral index as a function of the number of e−folds N. In this context, assuming different functions $\mathcal{F}(H)$, we will reconstruct the Hubble parameter together with the effective potential in terms of the scalar field. In addition, in this section we will analyze the reheating era, considering the background variables obtained in the preceding section from of different functions $\mathcal{F}(H)$.

In order to give a scalar spectral index n_s as a function of the number of e−folds N, we consider the simplest parametrization (or attractor) $n_s = n_s(N)$ defined by [\[31\]](#page-22-23)

$$
n_s(N) = 1 - \frac{2}{N},\tag{36}
$$

with $N \neq 0$. Here as we mentioned before, this parametrization is in agreement with Planck's measurements, when the number of e−folds becomes $N \simeq 60$ [\[32\]](#page-22-24).

In addition, to test the modified Friedmann model, we will assume that the reconstruction of the background variables will be developed in light of three types of functions $\mathcal{F}(H)$ associated to the Hubble parameter H. First, we will consider that the function $\mathcal{F}(H)$ of the power-law type $\mathcal{F}(H) = \alpha_{\lambda} H^{\beta}$. As a second example, we will assume that the function of type $\mathcal{F}(H) = H^2 - \gamma H^{-2}$ and finally we will choose a function of type $\mathcal{F}(H) = H^2 \pm \theta H^4$ to study the reconstruction and the reheating of these $\mathcal{F}(H)$ –models.

A. Reconstruction example I: $\mathcal{F}(H) = \alpha_{\lambda} H^{\beta}$

The first example that we will consider to reconstruct the background variables is the case in which $\mathcal{F}(H)$ is a function of the power-law type. In this sense, we will analyze the function defined as

$$
\mathcal{F}(H) = \alpha_{\lambda} H^{\beta},\tag{37}
$$

where the parameters α_{λ} and β are positive constants. We mention that the dimension of the parameter α_{λ} is $[\alpha_{\lambda}] = M_{p}^{2-\beta}$ and β is a dimensionless quantity. In particular, for the standard Friedmann equation in which $\mathcal{F}(H) = H^2$, we have that $\beta = 2$ and $\alpha_{\lambda} = 1$. Besides, as we mentioned before this class of function associated to the Hubble parameter $\mathcal{F}(H) \propto H^{\beta}$ is obtained in different limits in a GB theory, as well in entropy considerations.

To rebuild the Hubble parameter in terms of the number of e–folds N, firstly we can replace Eq.[\(37\)](#page-8-0) into Eq.[\(22\)](#page-5-7) to obtain that the function $q(H)$ becomes

$$
g(H) = \frac{H\mathcal{F}_{HH}}{\mathcal{F}_H} - 4 = \beta - 5 = \text{constant.}
$$
\n(38)

Now, introducing this result into Eq.[\(24\)](#page-5-8) and using Eqs.[\(23\)](#page-5-4) and [\(36\)](#page-7-2), we find that the Hubble parameter as a function of the number of e−folds N yields

$$
H(N) = \left[(4 - \beta) \left(\frac{A_1}{N} + B_1 \right) \right]^{1/(\beta - 4)} > 0, \text{ with } \beta \neq 4,
$$
\n
$$
(39)
$$

and the quantities A_1 and B_1 are two arbitrary integration constants which have units of $M_p^{\beta-4}$, since the Hubble parameter has dimension of M_p . In general these integration constants are positives, negatives o zero. However, in what follows, we will assume for simplicity that the integration constant $B_1 > 0$, while the constant A_1 must be positive, as we will see later.

To rebuild the Hubble parameter in terms of the scalar field $H = H(\phi)$, we have to find the number of e−folds N as a function of the scalar field ϕ i.e., $N = N(\phi)$. Thus, from Eq.[\(26\)](#page-6-1) we get

$$
\frac{dN}{d\phi} = N_{\phi} = \sqrt{\frac{\kappa}{\alpha_{\lambda}\beta A_1}} \left(\frac{N}{H}\right) = \sqrt{\frac{\kappa}{\alpha_{\lambda}\beta A_1}} N \left[(4-\beta) \left(\frac{A_1}{N} + B_1\right) \right]^{-1/(\beta - 4)},\tag{40}
$$

and solving this differential equation, we obtain that the solution for the number $N(\phi)$ can be written as

$$
N(\phi) = \mathcal{J}^{-1}(\phi),\tag{41}
$$

where the quantity $\mathcal{J}^{-1}(\phi)$ represents the inverse of the function $\mathcal{J}(\phi)$ defined by

$$
\mathcal{J}(\phi) = \frac{(4-\beta)\binom{\beta-3}{\beta-4}}{(3-\beta)B_1} \left(B_1 + \frac{A_1}{\sqrt{\kappa/(\alpha_\lambda\beta A_1)}\phi + \tilde{c}_1}\right)^{\left(\frac{\beta-3}{\beta-4}\right)} \times
$$

$$
{}_2F_1 \left[1, 1 + \frac{1}{\beta-4}, 2 + \frac{1}{\beta-4}, 1 + \frac{A_1}{B_1(\sqrt{\kappa/(\alpha_\lambda\beta A_1)}\phi + \tilde{c}_1)}\right],
$$
 (42)

where \tilde{c}_1 is a new constant of integration, and the function ${}_2F_1$ corresponds to the hypergeometric function [\[68\]](#page-23-24).

Thus, from Eqs.[\(39\)](#page-8-1) and [\(42\)](#page-8-2), we find that the reconstruction of the Hubble parameter as a function of ϕ can be written as

$$
H(\phi) = \left[(4 - \beta) \left(\frac{A_1}{\mathcal{J}^{-1}(\phi)} + B_1 \right) \right]^{1/(\beta - 4)}.
$$
 (43)

In this way, using now the Eq.[\(1\)](#page-0-2) in the slow roll approximation, in which $V \simeq 3\alpha_{\lambda}H^{\beta}/\kappa$ (see Eq.[\(25\)](#page-5-6)), we obtain that the reconstruction of the the potential $V(\phi)$ is given by

$$
V(\phi) = \frac{3\alpha_{\lambda}}{\kappa} \left[(4 - \beta) \left(\frac{A_1}{\mathcal{J}^{-1}(\phi)} + B_1 \right) \right]^{\beta/(\beta - 4)}.
$$
\n(44)

Here we note that in the special case in which the parameter $\beta = 2$ and then $\alpha_{\lambda=2} = 1$, the reconstruction of the effective potential in terms of the scalar field defined by Eq.[\(44\)](#page-8-3) is reduced to standard expressions obtained in GR (T-model) [\[31\]](#page-22-23) in which

$$
V(\phi) = \frac{3}{2\kappa B_1} \tanh^2\left[\frac{1}{2}\left(\sqrt{\frac{\kappa B_1}{A_1}}\phi + \bar{c}_1\right)\right].\tag{45}
$$

On the other hand, in order to constraint the free parameters of our model, we will consider the amplitude of the power spectrum of the scalar perturbations given by Eq.[\(13\)](#page-4-3) together with the tensor-scalar ratio given by Eq.[\(15\)](#page-4-4). In this form, we have that the amplitude of the power spectrum of the scalar perturbations results

$$
A_s = \frac{\kappa}{4\pi^2} \frac{N^2}{(\alpha_\lambda \beta A_1)} \Rightarrow \Lambda = (\alpha_\lambda \beta A_1) = \frac{\kappa}{4\pi^2} \frac{N^2}{A_s}.
$$
 (46)

Here we note that since that the parameters α_{λ} and β are positives quantities, then from the above expression we have that the integration constant $A_1 > 0$. If we consider the case in which the number of e-folds during the crossing epoch is $N_k = 60$ and $A_s = 2.2 \times 10^{-9}$, we obtain from Eq.[\(46\)](#page-9-0) that $A_1 \simeq 4.14 \times 10^{10} M_p^{-2}/\alpha_\lambda \beta$. In particular for the standard Friedmann equation in which the parameter $\beta = 2$ and $\alpha_2 = 1$, we obtain the constraint on the parameter $A_1 \approx 2 \times 10^{10} M_p^{-2}.$

On the other hand, the tensor to scalar ratio r is calculated as follows

$$
r = \frac{8\Lambda H^2}{N^2} = \frac{2\kappa}{\pi^2 A_s} \left[(4 - \beta) \left(\frac{A_1}{N} + B_1 \right) \right]^{2/(\beta - 4)},\tag{47}
$$

where we have used Eq. [\(39\)](#page-8-1). Since that the tensor to scalar ratio r is a real and positive quantity, we can constraint the parameter β to $0 < \beta < 4$.

Besides, using Eq.[\(47\)](#page-9-1) we will obtain a constraint for the parameter B_1 . To do this, we consider the fact that r evaluated at the time of crossing is constrained by the value $r(k)|_{k=a_kH_k} = r_k < 0.039$. Thus, from this observational parameter we have

$$
B_1 > \frac{1}{4 - \beta} \left(\frac{2\kappa}{\pi^2 A_s r_k}\right)^{(4-\beta)/2} - \frac{\kappa N_k}{4\pi^2 \alpha \lambda \beta A_s}.\tag{48}
$$

Since $B_1 > 0$, we can obtain a lower bound for the parameter α_{λ} given by

$$
\alpha_{\lambda} > \frac{(4-\beta)\kappa N_k}{4\pi^2 \beta A_s} \left(\frac{2\kappa}{\pi^2 A_s r_k}\right)^{(\beta-4)/2}.\tag{49}
$$

Additionally, to find the number of e−folds at the end of the inflationary epoch Nend, we can consider that the parameter $\epsilon_H(N)$ given by Eq.[\(8\)](#page-3-7) can be rewritten as

$$
\epsilon_H = \frac{H_N}{H} = \frac{A_1}{(4-\beta)N^2} \left(\frac{A_1}{N} + B_1\right)^{-1} = \frac{1}{(4-\beta)(1+\mu N)N},\tag{50}
$$

where we have used Eq. [\(39\)](#page-8-1), and we have defined the dimensionless parameter $\mu = B_1/A_1$. Thus, the above equation can be evaluated at the end of inflation, where $\epsilon_H = 1$ (or equivalently $\ddot{a} = 0$). In this way, we find the number of e−folds at the end of the inflationary era N_{end} becomes

$$
N_{\text{end}} = \frac{\sqrt{1 + \left(\frac{4}{4 - \beta}\right)\mu} - 1}{2\mu}.\tag{51}
$$

Here we note that for the special case in which the parameter $\mu \ll 1$, the number of e−folds at the end of inflation tends to zero, i.e., $N_{\text{end}} \sim 0$. While in the situation in which $\mu \gg 1$ the number of e−folds $N_{\text{end}} \sim [(4 - \beta)\mu]^{-1/2}$.

In Fig[.1](#page-10-0) shows the evolution of the number of e−folds (left panel) and the effective potential (right panel) as a function of the scalar field for two different values of the parameter β . In addition, when $\beta = 1$ (or $\alpha_{\lambda=1} = 1$), we show three values for the brane tension σ , associated to the parameter $\alpha_{\lambda=1}$ from the relation $\alpha_{\lambda=1} = (2\kappa\sigma/3)^{1/2}$. In this form, for $\beta = 1$, we consider the values; $\sigma = 10^{-9} M_p^4$, $\sigma = 10^{-8} M_p^4$ and $\sigma = 10^{-7} M_p^4$, which give the values $\alpha_1 =$ $2.58 \times 10^{-5} M_p$ (purple curve), $\alpha_1 = 8.16 \times 10^{-5} M_p$ (blue curve) and $\alpha_1 = 2.58 \times 10^{-4} M_p$ (green curve), respectively.

Besides, we have obtained for $\sigma = 10^{-9}M_p^4$ the values $A_1 = 1.61 \times 10^{15}M_p^{-3}$ and $B_1 = 1.15 \times 10^{13}M_p^{-3}$ associated to the purple curve, for the brane tension $\sigma = 10^{-8} M_p^4$ the values $A_1 = 5.08 \times 10^{14} M_p^{-3}$ and $B_1 = 2.98 \times 10^{13} M_p^{-3}$ (blue curve) and the values $A_1 = 1.61 \times 10^{14} M_p^{-3}$ and $B_1 = 3.56 \times 10^{13} M_p^{-3}$ for $\sigma = 10^{-7} M_p^4$ (green curve). In addition, we have considered the special case $\beta = 2$ in which $\alpha_2 = 1$ (red curve), which as mentioned before represents the standard Friedmann equation. For this situation we have found the values $A_1 = 2.07 \times 10^{10} M_p^{-2}$ and $B_1 = 8.35 \times 10^8 M_p^{-2}$. In these plots we have considered that the constant $\bar{c}_1 = 0$ for simplicity and the number of e−folds $N_k = 60$. In relation to the right panel of this figure, we note that the reconstructed effective potential in terms of the scalar field shows a maximum value given by a flat region for large- ϕ ($\phi > 15M_p$) in which the number of e-folds N is also large $(N > 30)$, see left panel. In addition, from the right panel, we can note that scalar field begins to roll from the maximum value of the potential (flat region) towards values of the scalar field $\phi \sim 0$ where the number of e−folds at the end of inflation N_{end} is approximately zero.

In Fig[.2](#page-10-1) we show the contours curves associated to the tensor to scalar ratio r , and different combinations of the parameters α_1 and B_1 from Eq.[\(47\)](#page-9-1) for the special case in which $N = 60$. From this plot, given a value of the tensor to scalar ratio from the vertical column we can constrain the parameter space of B_1 - α_1 .

FIG. 1: Evolution of the number of e−folds (left panel) and the effective potential (right panel) versus the scalar field for two different values of the parameter β . In particular for the case in which $\beta = 1$, we have considered three values on the brane tension σ . Also, in both panels we have used that the integration constant $\bar{c}_1 = 0$ and the number $N_k = 60$.

FIG. 2: Contour plot for the tensor to scalar ratio r in terms of the integration constant B_1 and the parameter associated to brane tension α_1 . Here we have fixed the number of e−folds $N_k = 60$ and $\bar{c}_1 = 0$.

On the other hand, we will study the reheating epoch using the reconstruction of the background variables derived during the inflationary scenario. To analyze the reheating era, we find that the energy density at the end of inflation, from $Eq.(31)$ $Eq.(31)$ yields

$$
\rho_{\rm end} = \left(\frac{1}{1 - \beta/6}\right) V_{\rm end}.\tag{52}
$$

Here as mentioned before, we note that if $\beta = 2$, we recover the standard case for the Friedmann equation and the energy density at the end of inflation is reduced to $\rho_{end} = (3/2)V_{end}$. By using Eq.[\(52\)](#page-10-2) and replacing into Eqs.[\(36\)](#page-7-2) and [\(47\)](#page-9-1), we find that the reheating temperature T_{reh} and the number of e−folds during the reheating N_{reh}, given by Eqs.[\(34\)](#page-7-3) and [\(35\)](#page-7-4) as a function of the spectral index n_s become

$$
T_{\rm reh}(n_s) = \exp\left[-\frac{3}{4}(1+\omega_{\rm reh})N_{\rm reh}(n_s)\right] \left[\frac{30 V_{\rm end}}{g_{\star,\rm reh}\pi^2(1-\beta/6)}\right]^{1/4}, \text{ and } (53)
$$

$$
N_{\rm reh}(n_s) = \frac{4}{1 - 3\omega_{\rm reh}} \left[\frac{2}{n_s - 1} - \ln\left(\frac{k}{a_0 T_0}\right) - \frac{1}{3} \ln\left(\frac{11 g_{\rm s,reh}}{43}\right) - \frac{1}{4} \ln\left(\frac{30 \kappa^2 V_{\rm end}}{g_{\star,reh}\pi^2 (1 - \beta/6)}\right) + \tilde{r}_1(n_s) \right],\tag{54}
$$

where $\omega_{\rm reh} \neq 1/3$ and we have defined the function $\tilde{r}_1(n_s)$ as

$$
\tilde{r}_1(n_s) = \ln \left\{ \kappa^{1/2} \left[(4 - \beta) \left(\frac{(1 - n_s)}{2} A_1 + B_1 \right) \right]^{1/(\beta - 4)} \right\}.
$$
\n(55)

The Fig[.3](#page-12-0) shows the evolution of the temperature $T_{\text{reh}}(n_s)$ and the number of e−folds $N_{\text{reh}}(n_s)$ during the reheating epoch versus the scalar spectral index from Eqs.[\(53\)](#page-11-0) and [\(54\)](#page-11-1), respectively. Four graphs have been plotted: three plots represent different values of the brane tension σ in which $\beta = 1$, while one corresponds to $\beta = 2$ reflecting the standard Friedmann equation. In all the panels different values have been used for the EoS parameter $\omega_{\rm reh}$ related to the reheating epoch and these values are; $\omega_{\text{reh}} = \{-1/3, 0, 2/3, 1\}$. In this figure, the different regions are; the light blue shaded region corresponds to the maximum and minimum bounds of the scalar spectral index $n_s = 0.9649 \pm 0.0042$ from Planck data at 1σ limits. Also, the blue shaded denotes to a projected sensitivity from the central value of the scalar spectral index ($n_s = 0.9649$) with an uncertainly of $\pm 10^{-3}$ in the test analyzed by the authors in Ref.[\[69\]](#page-23-25). Besides, the pink shaded region is the electroweak scale where the temperature $T_{\text{EW}} \sim 100 \text{GeV}$ and the purple shaded region corresponds to a temperatures below 10 MeV, and this region is disapproved by primordial nucleosynthesis.

In the upper left panel of Fig[.3,](#page-12-0) we have considered the parameter $\beta = 1$ in which the Friedmann equation is $H \propto \rho$, and we have chosen that the tension of the brane $\sigma = 10^{-9} M_p^4$ (or equivalently $\alpha_1 = 2.58 \times 10^{-5} M_p$). Here we have determined that the values of the parameters A_1 , B_1 and N_{end} correspond to; $A_1 = 1.61 \times 10^{15} M_p^{-3}$, $B_1 = 1.15 \times 10^{13} M_p^{-3}$ and $N_{\text{end}} = 0.33$. In the upper right panel, we have also $\beta = 1$ and the for the tension of the brane the value $\sigma = 10^{-8}M_p^4$ (or $\alpha_1 = 8.16 \times 10^{-5}M_p$). In this situation, we have found that the values for the parameters are given by $A_1 = 5.08 \times 10^{14} M_p^{-3}$, $B_1 = 2.98 \times 10^{13} M_p^{-3}$ and $N_{\text{end}} = 0.33$, respectively. In the lower left plot we have again used $\beta = 1$ and for the brane $\sigma = 10^{-7} M_p^4$ (or $\alpha_1 = 2.58 \times 10^{-4} M_p$), together with the values $A_1 = 1.61 \times 10^{14} M_p^{-3}$, $B_1 = 3.56 \times 10^{13} M_p^{-3}$ and $N_{\text{end}} = 0.31$. In the lower right plot, we have considered the standard Friedmann equation in which the parameter $\beta = 2$ i.e., $H^2 \propto \rho$, and then $\alpha_2 = 1$. For this case, we have obtained that the values for the parameters A_1 , B_1 and N_{end} become $A_1 = 2.07 \times 10^{10} M_p^{-2}$, $B_1 = 8.35 \times 10^8 M_p^{-2}$ and $N_{\text{end}} = 0.49$, respectively.

We mention that the stage of instantaneous reheating is given when the number of e −folds at the end of inflation N_{reh} approaches zero. In these panels, this corresponds to the point in which all lines converge to the value $N_{\text{reh}} \simeq 0$. From this plot, we note that the scenario of instantaneous reheating the model presents the maximum temperature of the reheating on the order of $T_{\text{reh}} \sim 10^{16} \text{GeV}$ for $\beta = 2$ and for the standard Friedmann equation a little less $T_{\rm reh} \sim 10^{15}$ GeV. Besides, we observe that the stage of instantaneous reheating (when $N_{\rm reh} \simeq 0$) does not depend on the EoS parameter $\omega_{\rm reh}$, since all curves associated to the different $\omega_{\rm reh}$ converge to the same point. Besides, we can note from the different panels that the highest value of the number of e−folds during the reheating takes place when the EoS parameter $\omega_{\rm reh} = 2/3$ independently of the value of β , and this value of $N_{\rm reh}$ becomes $N_{\rm reh} \lesssim 40$.

In relation to the reheating temperature T_{reh} , we note that that the models associated to $\beta = 1$ and $\beta = 2$, present a good compatibility with Planck's 1σ bounds on the index n_s , for the distinct values of the parameter $\omega_{\rm reh}$, excluding the value $\omega_{\rm reh} = -1/3$, when the temperature $T_{\rm reh} < 10^{+12+13}$ GeV. In particular, when the EoS parameter takes the value $\omega_{\rm reh} = -1/3$, the compatibility with Planck's 1 σ bounds is disadvantaged when the temperature $T_{\rm reh} < 10^{+13+14}$ GeV for the case in which $\beta = 2$, and when the temperature $T_{\rm reh} < 10^{+12+13}$ GeV for the standard Friedmann equation ($\beta = 1$).

The summary of the parameter-space of the model $\mathcal{F} = \alpha_{\lambda} H^{\beta}$ can be consulted in the Table[.I.](#page-12-1) Here the permitted values obtained for the integration constants A_1 and B_1 together with the number of e−folds at the end of inflation N_{end} for two different values of the parameter or power $\beta = 1, 2$ are shown in Table [I.](#page-12-1) In particular, for the situation in which $\beta = 1$, we have considered three different values of the tension for the brane σ . Additionally, in this table we have utilized the values $N_k = 60$, $A_{s_k} = 2.2 \times 10^{-9}$ and $r_k = 0.039$. Also, from this table we can observe that the ratio between the integration constants A_1 and B_1 is the order of $\mathcal{O}(10^2)$. Besides, we note from Table I that the number of e−folds at the end of the inflationary era $N_{\text{end}} \sim \mathcal{O}(1)$ independently on the value of the power β .

TABLE I: This table summarizes the parameter-space of the modified Friedmann equation $\mathcal{F} = \alpha_{\lambda} H^{\beta}$, for the specific cases in which the power β takes the values $\beta = 1$ and $\beta = 2$, respectively. In particular for the situation in which $\beta = 1$ we have considered three different values for the brane tension σ .

FIG. 3: The figure shows the number of e−folds during the reheating scenario Nreh (upper panels) and the reheating temperature T_{reh} (lower panels) versus the scalar spectral index n_s for different values of the parameter β . In particular for the special case in which the power $\beta = 1$, we have considered three different values for the brane tension σ . For the case $\beta = 1$ and the brane tension $\sigma = 10^{-9} M_p^4$ corresponds to the upper left panel. The case $\beta = 1$ and $\sigma = 10^{-8} M_p^4$ is for the upper right panel. Again the case $\beta = 1$ and $\sigma = 10^{-7} M_p^4$ corresponds to the lower left panel and the situation in which $\beta = 2$ i.e., the standard Friedmann equation is the lower right panel. Besides, in all the panels we have assumed different values of the EoS parameter $\omega_{\rm reh}$ associated to the reheating epoch; $\omega_{\rm reh} = -1/3, 0, 2/3$ and $\omega_{\rm reh} = 1$, respectively. Also, in each of the panels, we have utilized the parameters shown in Table I.

B. Reconstruction example II: $\mathcal{F}(H) = H^2 - \gamma H^{-2}$

As a second example that we will consider to rebuild the background variables corresponds to the modified Friedmann equation in which the function $\mathcal{F}(H)$ motivated by the Kaniadakis Entropy [\[15\]](#page-22-10) is given by

$$
\mathcal{F}(H) = H^2 - \gamma H^{-2},\tag{56}
$$

where γ is a positive constant with dimensions of M_p^4 . As we comment in the Introduction, the Kaniadakis entropy (or K-entropy), is a one-parameter extension of the classical Boltzmann–Gibbs–Shannon entropy[\[15\]](#page-22-10). Besides, we note that in order to obtain an energy density $\rho > 0$, we have to satisfy that the Hubble parameter $H > \gamma^{1/4}$.

For this type the function $\mathcal{F}(H)$, we find from Eq.[\(22\)](#page-5-7) that the function $g(H)$ becomes

$$
g(H) = -\frac{7\gamma + 3H^4}{\gamma + H^4}.\tag{57}
$$

Thus, introducing this result into Eq.[\(24\)](#page-5-8) and using the attractor $n_s = n_s(N)$ given by Eq.[\(36\)](#page-7-2), we find that from Eq.[\(23\)](#page-5-4), the equation for the Hubble parameter in terms of the number of e−folds N can be written as

$$
\frac{\gamma}{3} + H^4 = 2\left(\frac{A_2}{N} + B_2\right)H^6,\tag{58}
$$

where the quantities A_2 and B_2 are two integration constants. As we will see later the constant $A_2 > 0$ and for simplicity in the following we will consider that integration constant $B_2 > 0$. By making a change of variable, such that $x = H^2$ in the previous equation, then we obtain a cubic equation, whose real solution for the Hubble parameter $H = H(N)$ is given by

$$
H(N) = x^{1/2} = \left[\frac{1}{3f} \left(1 + \mathcal{A}^{1/3} + \mathcal{A}^{-1/3}\right)\right]^{1/2},\tag{59}
$$

where we have assumed that the function $\mathcal{A} = \mathcal{A}(N)$ in terms of the number of e−folds N is a quantity positive and it is defined as

$$
\mathcal{A} = \mathcal{A}(N) = \frac{1}{2} \left[2 + 9\gamma f^2 + \sqrt{(2 + 9\gamma f^2)^2 - 4} \right] \text{ where } f = f(N) = 2\left(\frac{A_2}{N} + B_2\right). \tag{60}
$$

As before, in order to obtain the reconstruction of the background variables, we need to determine the relation between the number of e−folds and the scalar field, i.e., $N = N(\phi)$. In this way, we can use Eq.[\(26\)](#page-6-1) to find the number of e-folds in terms of the scalar field ϕ from the differential equation given by

$$
\frac{dN}{d\phi} = N_{\phi} = \sqrt{\frac{\kappa}{2A_2}} \left(\frac{N}{H}\right) = \sqrt{\frac{3\kappa}{2A_2}} \sqrt{2}N \left(1 + \mathcal{A}^{1/3} + \mathcal{A}^{-1/3}\right)^{-1/2} \left(\frac{A_2}{N} + B_2\right)^{1/2}.
$$
 (61)

Here we note that this differential equation has no analytical solution. In this context and in order to solve the Eq.[\(61\)](#page-13-0), we can assume that during the inflationary scenario the ratio between the integration constants $A_2/B_2 \ll N$. Thus, using this approximation, we obtain that the Hubble parameter as a function of the number of e−folds N i.e., $H = H(N)$ can be approximate to the expression

$$
H(N) \simeq C_1 - \frac{C_2}{N} + \mathcal{O}(N^{-2}),\tag{62}
$$

where the constants C_1 and $C_2 = (\bar{C}_2 + \bar{C}_3)/\bar{C}_4$ are given by

$$
C_1 = \left(1/\sqrt{6B_2}\right) \left[1 + \left(1 + 2\mathcal{B} + 2\sqrt{\mathcal{B}\left(\mathcal{B} + 1\right)}\right)^{1/3} + \left(1 + 2\mathcal{B} + 2\sqrt{\mathcal{B}\left(\mathcal{B} + 1\right)}\right)^{-1/3}\right]^{1/2},\tag{63}
$$

$$
\bar{C}_2 = A_2 \left[1 + \left(1 + 2\mathcal{B} + 2\sqrt{\mathcal{B}(\mathcal{B} + 1)} \right)^{1/3} + \left(1 + 2\mathcal{B} + 2\sqrt{\mathcal{B}(\mathcal{B} + 1)} \right)^{-1/3} \right] \tag{64}
$$

$$
\bar{\mathcal{C}}_3 = \frac{2A_2}{3} \frac{\left[\sqrt{\mathcal{B}(\mathcal{B}+1)} + 2\mathcal{B}\left(1+\mathcal{B}+\sqrt{\mathcal{B}(\mathcal{B}+1)}\right)\right] \left[1 - \left(1+2\mathcal{B}+2\sqrt{\mathcal{B}(\mathcal{B}+1)}\right)^{2/3}\right]}{(\mathcal{B}+1)\left(1+2\mathcal{B}+2\sqrt{\mathcal{B}(\mathcal{B}+1)}\right)^{4/3}}
$$
(65)

$$
\bar{\mathcal{C}}_4 = 2\sqrt{6}B_2^{3/2} \left[1 + \left(1 + 2\mathcal{B} + 2\sqrt{\mathcal{B}(\mathcal{B} + 1)} \right)^{1/3} + \left(1 + 2\mathcal{B} + 2\sqrt{\mathcal{B}(\mathcal{B} + 1)} \right)^{-1/3} \right]^{1/2},\tag{66}
$$

with the quantity \mathcal{B} defined as $\mathcal{B} = 9\gamma B_2^2$.

Under the approximation in which the ratio $A_2/B_2 \ll N$, we have assumed that the early universe suffers an inflationary expansion from a nearly exponential expansion of the scale factor, in which the Hubble parameter is practically a constant and given by Eq.[\(62\)](#page-13-1), (for a quasi-de Sitter inflation, see e.g., Refs.[\[70,](#page-23-26) [71\]](#page-23-27)).

Thus, considering the approximation for the Hubble parameter given by Eq.[\(62\)](#page-13-1), we find that the differential equation given by [\(61\)](#page-13-0) can be approximate to

$$
N_{\phi} = \sqrt{\frac{\kappa}{2A_2}} \left(\frac{N}{H}\right) \simeq \sqrt{\frac{\kappa}{2A_2}} \left(\frac{N}{\mathcal{C}_1 - \mathcal{C}_2/N}\right). \tag{67}
$$

In this form, from Eq.[\(67\)](#page-14-0), we obtain that the number of e-folds in terms of the scalar field ϕ i.e., the solution $N = N(\phi)$ can be written as

$$
N(\phi) \simeq -\frac{\mathcal{C}_2}{\mathcal{C}_1} \left(\frac{1}{\text{ProductLog}\left\{-\frac{\mathcal{C}_2}{\mathcal{C}_1} \exp\left[-\frac{1}{\mathcal{C}_1} \left(\sqrt{\frac{\kappa}{2A_2}} \phi - \tilde{c}_2\right)\right]\right\}} \right),\tag{68}
$$

where \tilde{c}_2 corresponds to a new integration constant. Besides, here the ProductLog function corresponds to a product logarithm, also called the Omega function or Lambert W function, see e.g., Ref.[\[72\]](#page-23-28).

Thus, we find that the reconstruction of the Hubble parameter as a function of the scalar field becomes

$$
H(\phi) \simeq C_1 \left(1 + \text{ProductLog}\left\{ -\frac{\mathcal{C}_2}{\mathcal{C}_1} \exp\left[-\frac{1}{\mathcal{C}_1} \left(\sqrt{\frac{\kappa}{2A_2}} \phi - \tilde{c}_2 \right) \right] \right\} \right). \tag{69}
$$

Besides, the reconstruction of the effective potential in terms of the scalar field under the slow roll approximation yields

$$
V(\phi) \simeq \frac{3}{\kappa} \left[H^2(\phi) - \frac{\gamma}{H^2(\phi)} \right] \simeq \frac{3\mathcal{C}_1^2}{\kappa} \frac{\left[\left(1 + \text{ProductLog} \left\{ -\frac{\mathcal{C}_2}{\mathcal{C}_1} \exp \left[-\frac{1}{\mathcal{C}_1} \left(\sqrt{\frac{\kappa}{2A_2}} \phi - \tilde{c}_2 \right) \right] \right\} \right)^4 - \gamma/\mathcal{C}_1^4 \right]}{\left(1 + \text{ProductLog} \left\{ -\frac{\mathcal{C}_2}{\mathcal{C}_1} \exp \left[-\frac{1}{\mathcal{C}_1} \left(\sqrt{\frac{\kappa}{2A_2}} \phi - \tilde{c}_2 \right) \right] \right\} \right)^2}.
$$
 (70)

On the other hand, we can find a constraint on the integration constant A_2 , using the expression for the power spectrum of the scalar perturbation. In this sense, we have that the amplitude of the power spectrum of the scalar perturbation, given by Eq.[\(13\)](#page-4-3) becomes

$$
A_s = \frac{\kappa}{8\pi^2} \frac{N^2}{A_2} \Rightarrow A_2 = \frac{\kappa}{8\pi^2} \frac{N^2}{A_s}.
$$
\n
$$
(71)
$$

Thus, from Eq.[\(71\)](#page-14-1) and assuming that the number of e−folds $N_k = 60$ and the power spectrum of the scalar perturbation corresponds to $A_s = 2.2 \times 10^{-9}$ we find that the integration constant $A_2 = 2.07 \times 10^{10} M_p^{-2}$.

In addition, using Eq.[\(62\)](#page-13-1), we find that the tensor to scalar ratio in terms of the number of e -folds N yields

$$
r = 16A_2 \frac{H^2}{N^2} \simeq \frac{2\kappa}{\pi^2 A_s} \left(C_1 - \frac{C_2}{N} \right)^2.
$$
 (72)

Here we note that using Eq.[\(72\)](#page-14-2), we will numerically obtain a constraint on the second integration constant B_2 , since the ratio r is evaluated at the horizon exit during the inflationary epoch where it is constrained by $r(k)|_{k=a_kH_k}$ $r_k < 0.039$ together with the number $N_k = 60$. Thus, numerically we will determine the value of the integration constant B_2 .

Besides, by considering that the function $\mathcal{F}(H) = H^2 - \gamma H^{-2} > 0$ or $H^4 > \gamma$, then combining Eqs.[\(71\)](#page-14-1) and [\(72\)](#page-14-2) we obtain an upper bound for the parameter γ given by

$$
\left(\frac{rN^2}{16A_2}\right)^2 > \gamma.
$$
\n(73)

In particular considering the upper limit for the tensor to scalar ratio $r_k = 0.039$ together with the number of e−folds $N_k = 60$ and the constraint found on the integration constant $A_2 = 2.07 \times 10^{10} M_p^{-2}$ we have

$$
1.80 \times 10^{-19} M_p^4 > \gamma. \tag{74}
$$

In Fig[.4,](#page-15-0) the left panel shows the reconstructed effective potential in terms of the scalar field given by Eq.[\(70\)](#page-14-3) for different values of the parameter γ , when we fix the tensor to scalar ratio $r_k = 0.039$. From this panel, we note that for the different values of the parameter γ , which satisfy the upper bound given by Eq.[\(74\)](#page-14-4) in which $10^{-19}M_p^4 > \gamma$, the shape of the reconstructed effective potential $V(\phi)$ does not change, since the different lines associated to γ are overlaid one after the other. This suggests that due to that the parameter $\gamma \ll 1$, the reconstruction of the effective potential $V(\phi)$ is not strongly affected for this parameter. To build this panel, we have used three different values of the parameter γ where we fix the value of the tensor to scalar ratio $r_k = 0.039$. The purple curve corresponds to $\gamma = 10^{-22} M_p^4$, and the values obtained of B_2 , C_1 and C_2 result $B_2 = 5.95 \times 10^8 M_p^{-2}$, $C_1 = 2.90 \times 10^{-5} M_p$ and $\mathcal{C}_2 = 5.05 \times 10^{-4} M_p$, respectively. To obtain the blue curve we have used $\gamma = 10^{-24} M_p^4$, and then $B_2 = 5.94 \times 10^8 M_p^{-2}$, $C_1 = 2.90 \times 10^{-5} M_p$ and $C_2 = 5.06 \times 10^{-4} M_p$. Finally, the green curve is obtained using $\gamma = 10^{-26} M_p^4$, $B_2 =$ $5.94 \times 10^8 M_p^{-2}$, $C_1 = 2.90 \times 10^{-5} M_p$ and $C_2 = 5.06 \times 10^{-4} M_p$. It is useful to remember that the value of the parameter B_2 is obtained numerically from Eq.[\(72\)](#page-14-2), fixing the tensor to scalar ratio r for the different values of γ . In particular for the tensor to scalar ratio $r_k = 0.039$, we find that of the integration constant B_2 does not change significantly for the different values of γ utilized.

In the right panel of the Fig[.4,](#page-15-0) we also show the reconstructed effective potential V as a function of the scalar field ϕ . Here three curves have been drawn for different values of the tensor to scalar ratio at the time of the crossing, when we fix the parameter γ to the value $\gamma = 10^{-24} M_p^4$. In particular, the purple curve corresponds to the value $r_k = 0.039$, and then we numerically find that the integration constant B_2 becomes $B_2 = 5.94 \times 10^8 M_p^{-2}$ and therefore the quantities \mathcal{C}_1 and \mathcal{C}_2 result $\mathcal{C}_1 = 2.90 \times 10^{-5} M_p$ and $\mathcal{C}_2 = 5.06 \times 10^{-4} M_p$, respectively. In the case of the blue curve in which $r_k = 0.02$, we find that the parameters are $B_2 = 1.90 \times 10^9 M_p^{-2}$, $C_1 = 1.62 \times 10^{-5} M_p$ and $C_2 = 8.85 \times 10^{-5} M_p$. Finally, the green curve corresponds to $r_k = 0.01$, and then the values are given by $B_2 = 4.24 \times 10^9 M_p^{-2}$, $C_1 = 1.09 \times 10^{-5} M_p$ and $C_2 = 2.65 \times 10^{-5} M_p$, respectively.

FIG. 4: The left panel shows the reconstructed effective potential in terms of the scalar field for three different values of the parameter γ , when we fix the tensor to scalar ratio to the upper bound $r_k = 0.039$. The right panel also shows the reconstructed effective potential as a function of the scalar field for three different values of the tensor to scalar ratio r , when we now set the parameter $\gamma = 10^{-24} M_p^4$. In both panels we have used that the constant $\tilde{c}_2 = 0$ for simplicity.

On the other hand, we will analyze the reheating era for our second example, in which the function $\mathcal{F}(H)$ associated to the modified Friedmann equation is given by $\mathcal{F}(H) = H^2 - \gamma H^{-2}$. In the same way as in the example I, we solve the Eq.[\(31\)](#page-6-4) using this function $\mathcal{F}(H)$ to find that the energy density at the end of the inflationary epoch becomes

$$
\rho_{\rm end} = \frac{3}{8} V_{\rm end} \left(3 \pm \sqrt{1 + \frac{32\gamma}{\kappa^2 V_{\rm end}^2}} \right). \tag{75}
$$

In order to obtain the standard result of the above expression, in which $\rho_{end} \rightarrow (3/2)V_{end}$, when $\gamma \rightarrow 0$, it is necessary to consider the positive sign of the solution for ρ_{end} given by Eq.[\(75\)](#page-15-1). Thus, in the following we will consider the positive sign of the solution for ρ_{end} of Eq.[\(75\)](#page-15-1).

Besides, as before using Eqs.[\(34\)](#page-7-3), [\(35\)](#page-7-4) and [\(36\)](#page-7-2) and considering Eqs.[\(72\)](#page-14-2) and [\(75\)](#page-15-1), we can rewrite the reheating temperature T_{reh} and the number of e−folds N_{reh} during the reheating epoch as a function of the spectral index n_s . In this way, we find that T_{reh} and N_{reh} in terms of the scalar spectral index can be written as

$$
T_{\rm reh}(n_s) = \exp\left[-\frac{3}{4}(1+\omega_{\rm reh})N_{\rm reh}(n_s)\right] \left[\frac{45 V_{\rm end}\left(3+\sqrt{1+\frac{32\gamma}{\kappa^2 V_{\rm end}^2}}\right)}{4g_{\star,\rm reh}\pi^2}\right]^{1/4}, \text{ and } (76)
$$

$$
N_{\rm reh} = \frac{4}{1 - 3\omega_{\rm reh}} \left[\frac{2}{n_s - 1} - \ln\left(\frac{k}{a_0 T_0}\right) - \frac{\ln}{3} \left(\frac{11 g_{\rm s,reh}}{43} \right) - \frac{\ln}{4} \left(\frac{45\kappa^2 V_{\rm end} \left(3 + \sqrt{1 + \frac{32\gamma}{\kappa^2 V_{\rm end}^2}}\right)}{4 g_{\rm \star,reh} \pi^2} \right) + \tilde{r}_2(n_s) \right], \quad (77)
$$

where $\omega_{\text{reh}}\neq 1/3$ and the function $\tilde{r}_2(n_s)$ is defined as

$$
\tilde{r}_2(n_s) = \ln\left\{\kappa^{1/2}\left[\mathcal{C}_1 - \frac{(1-n_s)}{2}\mathcal{C}_2\right]\right\}.\tag{78}
$$

The Fig[.5](#page-16-0) shows the number of e−folds (upper panel) and the temperature (lower panel) during the reheating scenario as functions of the spectral index for the modified Friedmann equation given by Eq.[\(56\)](#page-13-2). In these panels we have used different values for the tensor to scalar ratio as well different values associated to the EoS parameters $\omega_{\rm reh}$ in each case. Thus, three curves have been plotted, one for each value of r, for each EoS parameter $\omega_{\rm reh}$ with values $\omega_{\rm reh} = \{-1/3, 0, 1, 2/3\}$. As before, we note that the instantaneous reheating of the model takes place when $N_{\rm reh} \sim 0$ and temperature corresponds to a maximum valor. Besides, we note that any temperature between the BBN bound and the instantaneous reheating value is allowed inside the Planck's 1σ bound, independently of the EoS parameter. However, we note that the curve associated with the upper limit for the tensor to scalar ratio $r_k \sim 0.039$ (purple curve) is more centered around the value within the Planck's 1σ . Besides, we observe that the model predicts from Planck data at 1σ limits $(n_s = 0.9649 \pm 0.042)$ a small number of e−folds during the reheating epoch $N_{\text{reh}} < 35$ for the different temperatures T_{reh} .

FIG. 5: The upper panel shows the number of e−folds and the lower panel shows the temperature during the reheating stage versus the scalar spectral index, for different values of the tensor to scalar ratio. In these panels the different curves and shaded regions are similar to the Fig.[\(3\)](#page-12-0). Besides, we have fixed the parameter $\gamma = 10^{-24} M_p^4$.

The Fig[.6](#page-17-0) shows the three-dimensional plot for the number of e−folds in terms of the EoS parameter and the scalar spectral index, given by Eq.[\(77\)](#page-16-1). From this figure, we note that the maximum values of the number of e -folds occur for values of the EoS parameter in the range $0 < \omega_{\rm reh} < 1$ within the Planck's 1σ bound. Besides, from this 3-D plot we observe that the number of the e−folds, during the reheating epoch becomes smaller, when we consider negative values of the EoS parameter $\omega_{\rm reh}$.

FIG. 6: Three-dimensional plot for the number of e−folds versus the EoS parameter $\omega_{\rm reh}$ and the scalar spectral index n_s . Here we have used that the tensor to scalar ratio corresponds to the upper bound $r_k = 0.039$ and $N_k = 60$.

C. Reconstruction example III: $\mathcal{F}(H) = H^2 \pm \theta H^4$

As a final example to reconstruct the inflationary scenario using the scalar spectral index $n_s = n_s(N)$, we will analyze the modified Friedmann equation given by

$$
\mathcal{F}(H) = H^2 \pm \theta H^4,\tag{79}
$$

where θ is a positive constant with dimension M_p^{-2} . This type of modification to the Friedmann equation comes for example, from the Chern-Simons theories of gravity [\[22\]](#page-22-17) or quantum corrections to the entropy of the apparent horizon [\[18\]](#page-22-13) as well black hole entropy in loop quantum gravity [\[73,](#page-24-0) [74\]](#page-22-14) or due to correction to black hole entropy due to thermal equilibrium fluctuation or quantum fluctuation, see also Refs.[\[75,](#page-24-1) [76\]](#page-24-2).

In relation to the Eq.[\(79\)](#page-17-1) and the parameter θ , we need to ensure that the term H^2 should be comparable to the term $|\theta|H^4$. In this form, we can assume that the parameter θ must be of the order $|\theta| \sim H^{-2}$ for both terms to be significant during the early universe.

To begin the reconstruction of the background variables from the modified Friedmann equation defined by Eq.[\(79\)](#page-17-1), we determine the expression of the function $g(H)$ given by Eq.[\(22\)](#page-5-7) yields

$$
g(H) = -\frac{(3 \pm 2\theta H^2)}{(1 \pm 2\theta H^2)}.
$$
\n(80)

Now using Eqs.[\(23\)](#page-5-4), [\(24\)](#page-5-8) and [\(36\)](#page-7-2), we find that the first order differential equation for the Hubble parameter as a function of the number of e −folds N can be written as

$$
(1 \pm 2\theta H^2) \frac{H_N}{H^3} = \frac{A_3}{N^2},\tag{81}
$$

where A_3 is a constant of integration and as we will see later this constant is positive. In the following, by simplicity, we will consider the positive sign of Eq.[\(79\)](#page-17-1) in our analysis.

From Eq. (81) we obtain that the solution for the Hubble parameter as a function of N becomes

$$
H(N) = \frac{1}{\sqrt{2\theta}} \left[\text{ProductLog}\left(\frac{1}{2\theta} e^{\frac{1}{\theta} \left(\frac{A_3}{N} + B_3\right)}\right) \right]^{-1/2},\tag{82}
$$

where B_3 corresponds to a new integration constant. In the following, we will assume that this constant $B_3 > 0$ for simplicity.

To rebuild the background variables, we need to find the number of e -folds N as a function of ϕ . Thus, from Eq.[\(26\)](#page-6-1), we have that the first order differential equation for $N = N(\phi)$ becomes

$$
N_{\phi} = \sqrt{\frac{\kappa}{2A_3}} \left(\frac{N}{H}\right) = \sqrt{\frac{\kappa \theta}{A_3}} N \left[\text{ProductLog}\left(\frac{1}{2\theta} e^{\frac{1}{\theta}\left(\frac{A_3}{N} + B_3\right)}\right) \right]^{1/2}.
$$
 (83)

Nevertheless, we cannot analytically solve this first order differential equation to obtain $N = N(\phi)$. In order to find an analytical solution to Eq.[\(83\)](#page-18-0), we can consider that during inflation the ratio between the integration constants $A_3/B_3 \ll N$. By using this approximation, we obtain that the Hubble parameter in terms of the number of e−folds can be approximate to an expansion quasi de Sitter given by

$$
H(N) \simeq \mathcal{D}_1 - \frac{\mathcal{D}_2}{N} + \mathcal{O}(N^{-2}),\tag{84}
$$

where \mathcal{D}_1 and \mathcal{D}_2 correspond to two constants defined as

$$
\mathcal{D}_1 = \frac{1}{\sqrt{2\theta}} \left[\text{ProductLog}\left(\frac{1}{2\theta} e^{B_3/\theta} \right) \right]^{-1/2}, \text{ and } (85)
$$

$$
\mathcal{D}_2 = \frac{A_3}{2\sqrt{2}\theta^{3/2}} \left[\text{ProductLog}\left(\frac{1}{2\theta} e^{B_3/\theta}\right) \right]^{-1/2} \left[1 + \text{ProductLog}\left(\frac{1}{2\theta} e^{B_3/\theta}\right) \right]^{-1},\tag{86}
$$

respectively. In this context, the differential equation given by Eq.[\(83\)](#page-18-0) is reduced to

$$
N_{\phi} \simeq \sqrt{\frac{\kappa}{2A_3}} \left(\frac{N}{\mathcal{D}_1 - \mathcal{D}_2/N} \right),\tag{87}
$$

and we find that the solution for the number of e-folds N as a function of the scalar field ϕ yields

$$
N(\phi) \simeq -\frac{\mathcal{D}_2}{\mathcal{D}_1} \left(\text{ProductLog} \left\{ -\frac{\mathcal{D}_2}{\mathcal{D}_1} \exp \left[-\frac{1}{\mathcal{D}_1} \left(\sqrt{\frac{\kappa}{2A_3}} \phi - \tilde{c}_3 \right) \right] \right\} \right)^{-1},\tag{88}
$$

where \tilde{c}_3 is a new integration constant. In this form, replacing Eq.[\(88\)](#page-18-1) into Eq.[\(84\)](#page-18-2), we obtain that the reconstruction of the Hubble parameter $H = H(\phi)$, during the inflationary epoch results

$$
H(\phi) \simeq \mathcal{D}_1 \left(1 + \text{ProductLog} \left\{ -\frac{\mathcal{D}_2}{\mathcal{D}_1} \exp \left[-\frac{1}{\mathcal{D}_1} \left(\sqrt{\frac{\kappa}{2A_3}} \phi - \tilde{c}_3 \right) \right] \right\} \right). \tag{89}
$$

Besides, the reconstructed effective potential in terms of the scalar field can be written as

$$
V(\phi) \simeq \frac{\left(3\mathcal{D}_1^2/\kappa\right)\left(1+\text{ProductLog}\left\{-\frac{\mathcal{D}_2}{\mathcal{D}_1}\exp\left[-\frac{1}{\mathcal{D}_1}\left(\sqrt{\frac{\kappa}{2A_3}}\,\phi-\tilde{c}_3\right)\right]\right\}\right)^2}{\left[1-\theta\,\mathcal{D}_1^2\left(1+\text{ProductLog}\left\{-\frac{\mathcal{D}_2}{\mathcal{D}_1}\exp\left[-\frac{1}{\mathcal{D}_1}\left(\sqrt{\frac{\kappa}{2A_3}}\,\phi-\tilde{c}_3\right)\right]\right\}\right)^2\right]^{-1}}.\tag{90}
$$

Additionally, from the power spectrum of the scalar perturbations defined by Eq.[\(12\)](#page-4-1), we can determine a constraint on the parameter A_3 given by

$$
A_s = \frac{\kappa}{8\pi^2} \frac{N^2}{A_3} \implies A_3 = \frac{\kappa}{8\pi^2} \frac{N^2}{A_s} > 0. \tag{91}
$$

Also, we find that the tensor to scalar ratio r in terms of the number of e -folds N becomes

$$
r = 16A_3 \frac{H^2}{N^2} \simeq \frac{2\kappa}{\pi^2 A_s} \left(\mathcal{D}_1 - \frac{\mathcal{D}_2}{N} \right)^2, \tag{92}
$$

From Eq.[\(92\)](#page-18-3), different values of the parameter B_3 can be numerically obtain for various values of the parameter θ . In Fig[.7](#page-19-0) the left panel shows the reconstruction of the Hubble parameter versus the scalar field, for different values of the parameter θ . In order to chose the different values of the parameter θ , we have considered that $\theta \sim H^{-2}$ to ensure that the terms H^2 and θH^4 are the order. Besides, in the right panel we show the reconstruction of the

effective potential in terms of the inflaton field, for various values of the parameter θ . In the two panels we have fixed the tensor to scalar ratio $r_k = 0.039$. Also, in both panels the purple curve is obtained using the following parameters; for $\theta = 10^8 M_p^{-2}$, we determine that the constants B_3 , \mathcal{D}_1 and \mathcal{D}_2 are given by $B_3 = 2.86 \times 10^9 M_p^{-2}$, $\mathcal{D}_1 = 2.58 \times 10^{-5} M_p$ and $\mathcal{D}_2 = 3.15 \times 10^{-4} M_p$. The blue curve is obtained for the special value of $\theta = 10^9 M_p^{-2}$, in which $B_3 = 2.24 \times 10^{10} M_p^{-2}$, $\mathcal{D}_1 = 2.25 \times 10^{-5} M_p$ and $\mathcal{D}_2 = 1.18 \times 10^{-4} M_p$. Finally, the green curve is built with the values; $\theta = 10^{10} M_p^{-2}$, $B_3 = 2.17 \times 10^{11} M_p^{-2}$, $\mathcal{D}_1 = 2.09 \times 10^{-5} M_p$ and $\mathcal{D}_2 = 1.94 \times 10^{-5} M_p$, respectively. In relation to the left panel of this figure, we note that the reconstructed Hubble parameter in terms of the scalar field presents an approximately quasi de Sitter behavior (flat region) for large- ϕ ($\phi > 10M_p$). In addition, from the right panel, we note that the reconstructed effective potential in terms of the scalar field $V = V(\phi)$ shows a maximum value given by a flat region for values of $\phi > 10M_p$, in which the scalar field begins to roll towards values of the scalar field $\phi \sim 0$ in which the inflationary epoch ends.

FIG. 7: The figure shows the reconstructions of the Hubble parameter (left panel) and the effective potential (right panel) versus the scalar field, for different values of the parameter θ . In both panels we have considered that the tensor to scalar ratio $r_k = 0.039$ and the number of e−folds $N_k = 60$.

On the other hand, to analyze the reheating epoch in our modified Friedmann equation $\mathcal{F}(H) = H^2 + \theta H^4$, we will proceed as in the previous examples. To determine the energy density at the end of the inflationary scenario, we need to calculate the second term of the $Eq.(31)$ $Eq.(31)$. In this way, we have that this term becomes

$$
\frac{1}{2\kappa} \left(\frac{d\mathcal{F}}{d\ln H} \right) \bigg|_{\text{end}} = \frac{1}{\kappa} H^2 \left(1 + 2\theta H^2 \right) \bigg|_{\text{end}}.
$$
\n(93)

Introducing this expression into the $Eq.(31)$ $Eq.(31)$, we find that the energy density at the end of the inflationary stage results

$$
\rho_{\rm end} = \frac{3}{\kappa \theta} \left(1 + \kappa \theta V_{\rm end} \pm \sqrt{1 + \kappa \theta V_{\rm end}} \right). \tag{94}
$$

Here we note that in order to obtain the standard result from Eq.[\(94\)](#page-19-1) in which $\rho_{end} = (3/2)V_{end}$, when $\theta \to 0$, it is necessary to consider the negative sign of this equation. In the following, we will use the negative sign of the expression given by Eq.[\(94\)](#page-19-1).

To study the reheating epoch, as before, we need to determine the functional form of the reheating parameters T_{reh} and N_{reh} in terms of the scalar spectral index n_s for our $\mathcal{F}(H)$ -model. In this context, using Eqs.[\(34\)](#page-7-3), [\(35\)](#page-7-4) and [\(36\)](#page-7-2) and now replacing the new expressions given by [\(92\)](#page-18-3) and [\(94\)](#page-19-1), we find that the temperature and the number of e−folds as a function of the n_s during the reheating epoch result

$$
T_{\rm reh}(n_s) = \exp\left[-\frac{3}{4}(1+\omega_{\rm reh})N_{\rm reh}(n_s)\right] \left[\frac{90\left(1+\kappa\theta V_{\rm end} - \sqrt{1+\kappa\theta V_{\rm end}}\,\right)}{\kappa\theta\pi^2 g_{\star,\rm reh}}\right]^{1/4}, \text{ and } (95)
$$

$$
N_{\rm reh} = \frac{4}{1 - 3\omega_{\rm reh}} \left[\frac{2}{n_s - 1} - \ln\left(\frac{k}{a_0 T_0}\right) - \frac{1}{3} \ln\left(\frac{11 g_{\rm s,reh}}{43}\right) - \frac{1}{4} \ln\left(\frac{90\kappa \left(1 + \kappa \theta V_{\rm end} - \sqrt{1 + \kappa \theta V_{\rm end}}\right)}{\theta \pi^2 g_{\star, \rm reh}}\right) + \tilde{r}_3 \right], \quad (96)
$$

with the EoS parameter $\omega_{\text{reh}}\neq 1/3$ and the function $\tilde{r}_3 = \tilde{r}_3(n_s)$ defined as

$$
\tilde{r}_3(n_s) = \ln\left\{\kappa^{1/2}\left[\mathcal{D}_1 - \frac{(1-n_s)}{2}\mathcal{D}_2\right]\right\}.
$$
\n(97)

The Fig[.8](#page-20-0) exhibits the number of e−folds (upper panel) and the temperature (lower panel) during the reheating epoch versus the spectral index for the modified Friedmann equation $\mathcal{F}(H) = H^2 + \theta H^4$. In these plots we have considered various values for the parameter θ , as well various values associated to the EoS parameters $\omega_{\rm reh}$ in each case. In the left panel, we have assumed two different values of the parameter θ for each EoS parameter $\omega_{\rm reh}$ with values of $\omega_{\rm reh} = \{-1/3, 0, 1, 2/3\}$. In the right panel we have utilized the specific case in which the parameter $\theta = 10^{10} M_p^{-2}$, also for various values of the EoS parameter $\omega_{\rm reh}$.

In this context, for each barotropic index $\omega_{\text{reh}} = \{-1/3, 0, 1, 2/3\}$ three sets of curves have been drawn considering different values of θ . In the left panel, the purple curve has been obtained by using the following set of parameters; for $\theta = 10^8 M_p^{-2}$, we have found that the constants B_3 , \mathcal{D}_1 and \mathcal{D}_2 together with the number of e-folds at the end of the inflationary era are given by $B_3 = 2.86 \times 10^9 M_p^{-2}$, $\mathcal{D}_1 = 2.58 \times 10^{-5} M_p$, $\mathcal{D}_2 = 3.15 \times 10^{-4} M_p$ and $N_{\text{end}} = 13.1$, respectively. The blue curve corresponds to the value $\theta = 10^9 M_p^{-2}$, in which $B_3 = 2.24 \times 10^{10} M_p^{-2}$, $\mathcal{D}_1 = 2.25 \times 10^{-5} M_p$, $\mathcal{D}_2 = 1.18 \times 10^{-4} M_p$ and $N_{\text{end}} = 6.08$. In the right panel, the green curve corresponds to the values of $\theta = 10^{10} M_p^{-2}$, $B_3 = 2.17 \times 10^{11} M_p^{-2}$, $\mathcal{D}_1 = 2.09 \times 10^{-5} M_p$, $\mathcal{D}_2 = 1.94 \times 10^{-5} M_p$ and $N_{end} = 1.53$, respectively.

FIG. 8: In both plots; the upper panel shows the number of e−folds and the lower panel exhibits the temperature during the reheating stage versus the scalar spectral index, for different values of the parameter θ , as well as various values of the EoS parameter $\omega_{\text{reh.}}$ In the left panel, we show two different values of θ ; $\theta = 10^8 M_p^{-2}$ and $\theta = 10^9 M_p^{-2}$, while the right panel shows the situation in which $\theta = 10^{10} M_p^{-2}$. In these panels the different curves and shaded regions are as the Fig.[\(3\)](#page-12-0). Beside, in these plots, we have fixed the tensor to scalar ratio $r_k = 0.039$ together with $N_k = 60$.

FIG. 9: Three-dimensional plot for the reheating temperature T_{reh} (logarithmic scale) in terms of the scalar spectral index n_s and the EoS parameter $\omega_{\rm reh}$. Here we have used that the tensor to scalar ratio corresponds to the upper bound $r_k = 0.039$ and the parameter $\theta = 10^8 M_p^{-2}$.

As before, we observe that the instantaneous reheating takes place when $N_{\text{reh}} \sim 0$ and reheating temperature presents a maximum valor. Besides, we notice that any temperature between the BBN bound and the instantaneous temperature is allowed inside the observational bound, independently of the value of $\omega_{\rm reh}$. In relation to the two plots, we note that from the left panel, the purple and blue curves are more centered around the value within the Planck's 1 σ , in relation to the right panel, in which we have considered the value of the parameter $\theta = 10^{10} M_p^{-2}$. Also, we observe from the right panel that increases the value of the parameter θ , the model predicts a large number of e−folds during the reheating epoch $(N_{\text{reh}} < 40)$, for the different reheating temperatures.

In Fig[.9](#page-20-1) we show the three-dimensional plot for the reheating temperature T_{reh} (logarithmic scale) in terms of the EoS parameter and the scalar spectral index. From this figure, we note that the maximum value of the reheating temperature or instantaneous reheating takes place for all values of the EoS parameter $\omega_{\rm reh}$ within the Planck's 1σ limit. Also, we note that for positive values of the EoS parameter the reheating temperature can achieve lower values of the reheating temperature within Planck data 1σ limit, in comparison when we consider negative values of the EoS parameter in which the reheating temperatures are higher than $T_{\text{reh}} > 10^7$ GeV, (see also Fig.[\(8\)](#page-20-0)).

V. CONCLUDING REMARKS

In this article we have studied the reconstruction of the background variables during the early universe, in the framework of a generalized Friedmann equation given by the function $\mathcal{F}(H)$ associated to the Hubble parameter H. In this reconstruction we have utilized as cosmological parameter, the scalar spectral index $n_s = n_s(N)$, where N denotes the number of e−folds during the inflationary scenario.

Under the slow roll approximation, we have developed a new general formalism for reconstructing background variables. This involves a new methodology that rewrites the scalar spectral index as a function of the Hubble parameter and its derivatives. In this new analysis of this general formalism, we have determined from the attractor given by the scalar spectral index $n_s = n_s(N)$, an integral relation for a first order differential equation associated to the Hubble parameter in terms of the number of e−folds N, see Eq.[\(23\)](#page-5-4). Additionally, we have obtained a relation between the scalar field and the e -folds N , to reconstruct the background variables, such as, the Hubble parameter $H = H(\phi)$ and the effective potential $V = V(\phi)$, as functions of the scalar field ϕ .

To rebuild the background variables, we have considered the simplest parametrization (attractor) for the scalar spectral index $n_s = n_s(N)$ as a function of the number of e−folds N given by $n_s = 1-2/N$ for large-N. By assuming this parametrization for the scalar spectral index, we have applied our methodology for three different modified Friedmann equations associated with the various functions $\mathcal{F}(H)$. Thus, in the reconstruction of the background variables, we have considered the functions; $\mathcal{F}(H) \propto H^{\beta}$ as a first example, the function $\mathcal{F}(H) = H^2 - \gamma H^{-2}$, as a second application and finally the function $\mathcal{F}(H) = H^2 + \theta H^4$, as example III. In this sense, using the new methodology for reconstructing the background variables with different functions $\mathcal{F}(H)$, we have found that these reconstructed background variables depend on the sign of the integration constants that arise from the solutions of the differential equations, which are solved in terms of the number of e -folds N , for each of the chosen functions $\mathcal{F}(H)$. In addition, for the different $\mathcal{F}(H)$ –models analyzed, we have constrained these integration constants from the observational parameters, such as the power scalar spectrum and the tensor to scalar ratio, in the particular case in which the number of e−folds corresponds to $N = 60$. In Figs. [1,](#page-10-0) [4](#page-15-0) and [7,](#page-19-0) we show the evolution of the reconstructed effective potential in terms of the scalar field for the three different $\mathcal{F}(H)$ −models studied. In all cases analyzed, we have found that the scalar field begins to roll from the maximum value of the potential (approximately) towards values of the scalar field close to zero, where the number of e−folds at the end of inflationary epoch is $N_{\text{end}} \sim 0$, see e.g., the left panel of Fig[.1.](#page-10-0)

In relation to analyze of the reheating era for our different $\mathcal{F}(H)$ −models, we have obtained that it is possible to quantify this epoch in terms of the reheating parameters such as; the temperature, the number of e−folds and the EoS parameter during the reheating of the universe. From the reconstruction of the background variables found during the inflationary epoch from the attractor $n_s = n_s(N)$, we have been able to obtain these reheating parameters. In particular for the first function studied, we have found that the reheating temperature associated to the power $\beta = 1$ and $\beta = 2$ present a good compatibility with Planck's 1 σ bound on the scalar spectral index, for the different values of the EoS parameter $\omega_{\rm reh}$, excluding the negative value $\omega_{\rm reh} = -1/3$. For the second function $\mathcal{F}(H)$, we have found that the reheating temperature for the different values of the EoS parameter does not depend of the parameter $\gamma \ll 1$, since the reconstruction of the Hubble parameter and effective potential are not affected strongly for this parameter. In relation to the third function $\mathcal{F}(H)$, we have obtained that reheating temperature increases when we increase the parameter θ . In addition, we have found that the reheating temperature for positive values of the EoS parameter can achieve lower values in comparison with values of $\omega_{\rm reh} < 0$.

Regarding the number of e−folds during the reheating for these $\mathcal{F}(H)$ −models, we have observed that this number presents a high value when the EoS parameter $\omega_{\rm reh}$ is positive (the highest value corresponds to $\omega_{\rm reh} = 2/3$), see the respective figures associated to the reheating. In the different $\mathcal{F}(H)$ -models, we have found that the stage of instantaneous reheating is given when the number of e−folds at the end of inflation N_{reh} approaches zero. In the various panels associated to the reheating epoch, we have determined that this scenario corresponds to the point in which all lines converge to the value $N_{\text{reh}} \simeq 0$.

Finally in this article, we have not addressed the reconstruction of the background variables for another functions

 $\mathcal{F}(H)$ from the parametrization on $n_s = n_s(N)$, as well as the reheating study assuming an EoS parameter as a function of the time $\omega_{\rm reh} = \omega_{\rm reh}(t)$ in numerical form to obtain the reheating parameters; $T_{\rm reh}$ and $N_{\rm reh}$, respectively. In this sense, we hope to return to these points in the near future.
