Abstract

We present a workflow that iteratively combines *ab-initio* calculations with a machine-learning (ML) guided search for superconducting compounds with both dynamical stability and instability from imaginary phonon modes, the latter of which have been largely overlooked in previous studies. Electron-phonon coupling (EPC) properties and critical temperature (T_c) of 417 boron, carbon, and borocarbide compounds have been calculated with density functional perturbation theory (DFPT) and isotropic Eliashberg approximation. Our study addresses T_c convergence of Brillouin zone sampling with an ansatz test, stabilizing imaginary phonon modes for significant EPC contributions and comparing performance of two ML models especially when including compounds of dynamical instability. We predict a few promising superconducting compounds with formation energy just above the ground state convex hull, such as $\text{Ca}_5\text{B}_3\text{N}_6$ (35 K), TaNbC_2 (28.4 K), $\text{Nb}_3\text{B}_3\text{C}$ (16.4 K), $\text{Y}_2\text{B}_3\text{C}_2$ (4.0 K), Pd_3CaB (7.0 K), MoRuB_2 (15.6 K), RuVB_2 (15.0 K), RuSc_3C_4 (6.6 K) among others.

I. Introduction

The pursuit of high-temperature superconductivity (SC) is a challenging and active research area. The recent discovery of superconducting temperature (T_c) near 200 K in H_3S at the high pressure of 150 GPa[1] has re-energized the field to focus on phonon-mediated SC. However, at ambient pressure, increasing T_c even just higher than the 40 K of MgB_2 [2, 3, 5, 6, 11] has been difficult [7–19]. While the recent report of a $T_c=32$ K for MoB_2 under the pressure of 110 GPa is a promising development [20], the large temperature and pressure gaps between MgB_2 and H_3S still remain, which motivates intensive search for new phonon-mediated SC compounds. Despite the challenges faced in experiments, theoretical studies continue to provide valuable insights into potential SC materials and their properties, such as SC in FeB_4 [21, 22] was predicted and verified. Density functional perturbation theory (DFPT) [23, 24] is one of the most robust *ab-initio* methods [10] to compute the electron-phonon coupling (EPC) matrices over the full Brillouin zone (BZ). One can then employ either isotropic Eliashberg approximation or Green function-based anisotropic Migdal-Eliashberg equations to compute T_c [1, 26–28, 30–33]. Therefore, computational exploration of compounds containing atoms slightly heavier than H, such as B and C[34–39], with strong EPC is a promising venue to search for high-temperature SC at ambient pressure and also fill the large materials gap between MgB_2 and H_3S .

Machine learning (ML) and Artificial intelligence (AI) are increasingly taking important roles for predicting materials properties including SC. Previous studies performing ML predictions based on random forest [40], regression [41–44], classification [41], natural language processing (NLP) [45], and deep learning [46] models have trained on experimental data, mostly from SuperCon database [36]. Comparing to the more expensive and time consuming experiments to explore many new compounds to generate SC data for ML, the high throughput (HT) *ab-initio* first-principles approaches are valuable tools to obtain the data that can be trained to predict potential SC compounds. Several recent studies have utilized *ab-initio* computed data for training ML model and predicting SC. One approach involves performing BCS-inspired screening of materials to identify potential candidates based on certain key properties such as the Debye temperature and the density of states at the Fermi level ($N(E_F)$) [9]. A study similar to that described in Ref. [9] has been conducted on a vast range of materials, but restricting the size of the compounds to eight or fewer atoms, as reported in Ref. [49]. In a recent study [50], a ML approach was used to predict the maximum T_c and corresponding pressure of binary metal hydrides. The input layer consisted of atomic properties of the heavier metallic atom, while the output layer had two nodes representing T_c and pressure. The *ab-initio* data utilized in this study has been collected from literature. Recently, ML-driven search with experimental feedback was also performed to discover a novel superconductor in Zr-In-Ni systems [51].

Notably in these previous HT and ML studies, compounds of dynamical instability with imaginary phonon modes have been largely discarded. However, as shown by our recent EPC study [52] on Y_2C_3 with experimentally known $T_c=18$ K[18], imaginary phonon of C dimer wobbly motion once stabilized can carry significant EPC contributions, which explains well the observed sizable T_c . In recent model Hamiltonian studies, phonon softening and anharmonicity have also been found to enhance T_c [53, 54]. Here we present a workflow that iteratively combines *ab-initio* calculations with an ML-guided search across the dataset of compounds with both dynamical stability and instability from imaginary phonon modes by focusing on boron/carbon/borocarbide (B/C/B+C) compounds. *Ab-initio* calculations were performed to compute the EPC strength (λ), the logarithmic average phonon frequency (ω_{log}) and T_c of 417 compounds employing DFPT and isotropic Eliashberg approximation. Two major issues arise during DFPT calculations: choosing appropriate BZ sampling (\mathbf{k} and textbfq-mesh) for convergence and the problem of calculated dynamic instability. To address the convergence problem, we developed an ansatz test to check the convergence of EPC properties, particularly the T_c . For dynamically unstable compounds, we employed large electronic smearing, lattice distortion, and pressure to stabilize them. We then calculated their EPC properties, which were included in building the ML models. We evaluated ML models, specifically the crystal graph convolutional neural network (CGCNN) and the atomistic line graph neural network (ALIGNN), trained utilizing *ab initio* computed data to predict SC properties. Among the two models, especially when including the dynamically unstable compounds, ALIGNN consistently outperforms the CGCNN in predicting EPC properties. We predict a few promising SC compounds with formation energy just above the ground state convex hull. For dynamically stable systems, we predict $TaNbC_2$ (28.4 K), Nb_3B_3C (16.4 K), $Y_2B_3C_2$ (4.0 K) among others. For systems with dynamical instability and imaginary phonon, we predict $Ca_5B_3N_6$ with a T_c as high as 35-42.4 K, besides Pd_3CaB (7.0 K), and a few Ru compounds of $MoRuB_2$ (15.6 K), $RuVB_2$ (15.0 K), and $RuSc_3C_4$ (6.6 K).

II. Results

A. Machine learning guided workflow

A ML-guided search workflow is employed in this study. It can be divided into three parts: data extraction, DFPT calculations, and training ML models. We will discuss each part in the following three sections (A, B and C) before presenting the main results in the last three sections (D, E and F). As illustrated in Fig. 1 for obtaining the crystal structures of all the known B/C/B+C compounds, we utilized the Materials Project (MP) database [55–57], which offers a diverse range of compounds, including experimentally synthesized and theoretically predicted ones. We selected those B and C compounds in the MP database that meet certain criteria: being metallic with negative formation energy, excluding oxides, C_{60} and Lanthanides except for La. Approximately 1500 compounds fall within this category, out of which 400 exhibit magnetic moments, and these magnetic cases are not considered in the present study. Consequently, our focus narrows down to around 1100 nonmagnetic compounds, forming the pool for investigating phonon-mediated superconductivity. To manage computational cost, we set a further criterion that considers only systems with primitive cells containing 40 atoms or less and composed of up to four different elements ($N_{type} \leq 4$). This refinement narrows our selection to approximately 700 compounds. These 700 include 121 compounds with known T_c from experimental measurement as in SuperCon database (113 being dynamically stable and 8 dynamically unstable) and the other 579 compounds of unknown T_c . We will first discuss the 113 compounds with known T_c and also dynamical stability (no imaginary phonon modes), while the remaining 8 compounds with dynamical instability will be discussed later. Figure 2 provides a statistical description of the 113 B/C/B+C compounds with known

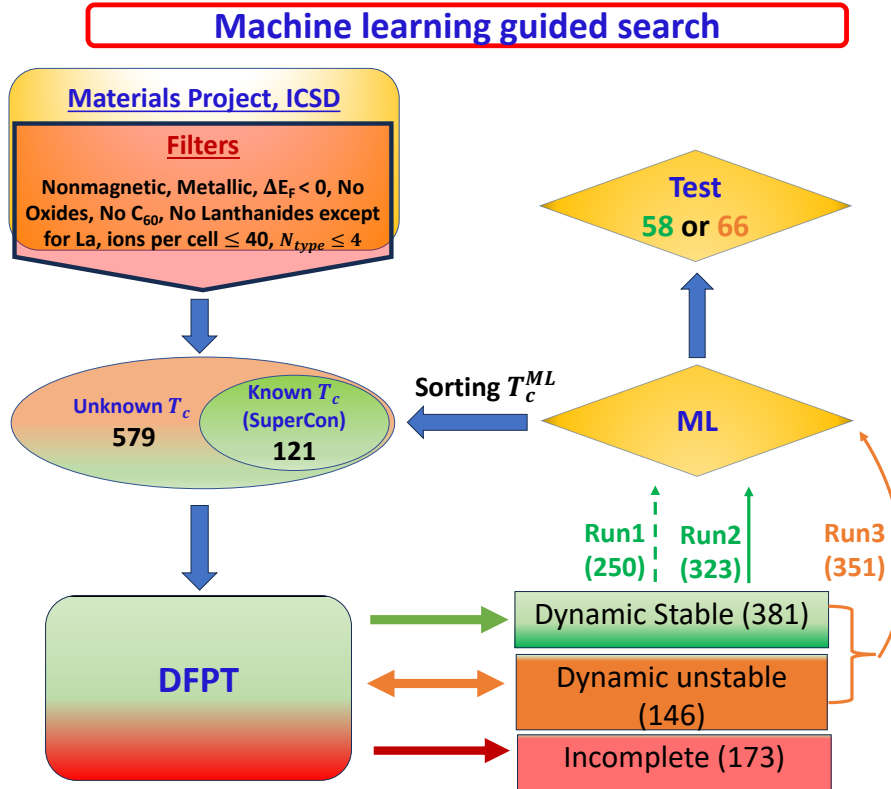

FIG. 1: Machine learning workflow. The numbers are the counts of compounds involved in each step. See main text for the detailed summary.

T_c and dynamic stability, which are 53 superconductors (SC) and 60 non-superconductors (NSC). We reviewed and corrected any inaccuracies or discrepancies found in the SuperCon database through an extensive literature review [2, 15, 19–21, 37, 41, 42, 44, 46, 58–89, 91–100, 102–107, 109–130, 132–142].

Figure 2 (a)-(c) illustrate the distribution of different elements in these systems, allocation of B/C/B+C compounds and thermodynamic stability, respectively. The thermodynamic stability of these compounds, indicated by the energy above the ground state convex hull (ΔE_h), are obtained from the MP database[55]. Approximately 71% of the compounds are on the ground state convex hull with $\Delta E_h \sim 0$. Around 18% of the cases have an ΔE_h within 0.05

eV/atom, while the remaining 11% have ΔE_h larger than 0.05 eV/atom. Figure 2(d) shows the distributions of these compounds based on their space groups (SGs). In Fig. 2(a) and (d), each bar is partitioned into two segments with the red segment representing the number of SC, while blue segment for NSC. From Fig. 2(a), many known SC compounds are associated with transition metals (TM) such as Y, La, Ni, Rh, Mo, Nb and others. Figure 2(e)-(m) depict the crystal structures of the representative SC compounds in the top 6 SGs among the experimentally known SC. In these structures, B and C atoms form various structural motifs: honeycomb lattice of B in MgB_2 (Fig. 2(e)); monomers in NbC (Fig. 2(f)), MgCNi_3 (Fig. 2(h)) and Mo_2GaC (Fig. 2(i)); dimers in YC_2 (Fig. 2(k)); graphene sheets in SrC_6 (Fig. 2(j)); chains of lighter elements in Mo_2BC (Fig. 2(g)) and $\text{LaPt}_2\text{B}_2\text{C}$ (Fig. 2(m)); octahedral cage structures in YB_6 (Fig. 2(l)). In terms of the lattice types of these known SC compounds, highly symmetric structures with hexagonal, tetragonal and cubic SGs have the most compounds, as shown in Fig. 2(d). Similarly, statistical description for the SC compounds with predicted T_c that have not been measured, akin to Fig. 2, is illustrated in Supplementary Materials (SM) Fig.S1.

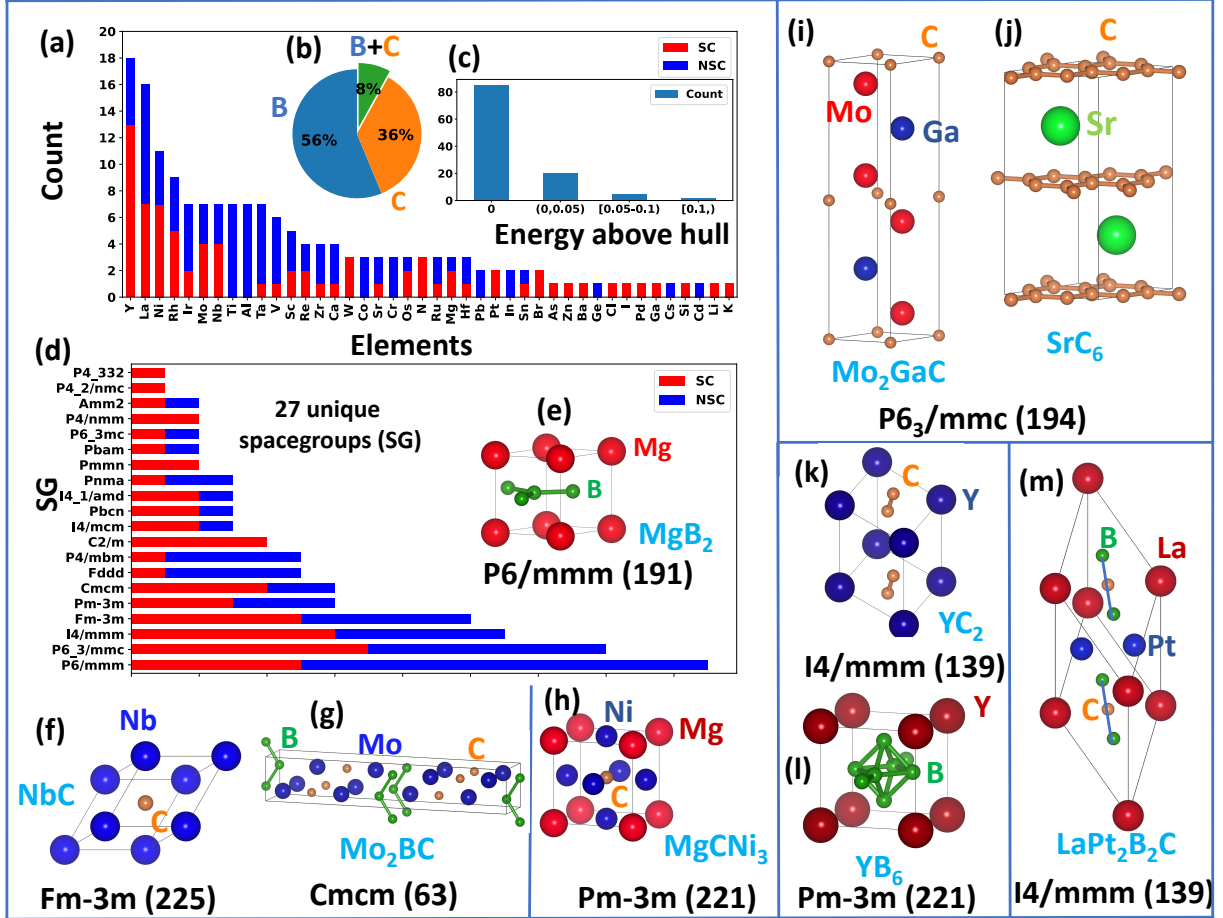

FIG. 2: Statistical description of dynamically stable 113 compounds, whose (non-) superconductivity have been experimentally measured. (a) Number of compounds according to elements, each bar is partitioned into two color segments, with red representing the number of superconductors (SC), while blue denote non-superconductors (NSC).; (b) Proportion of boron and carbon compounds (c) Histogram for energy above the convex hull in (eV/atom), (d) Distribution according to space group, (e) Crystal structure of MgB_2 . (f)-(m): Crystal structures of known superconductors. (f) NbC (10.03 K)[60], (g) Mo_2BC (7.5 K) [114], (h) MgCNi_3 (8 K)[144], (i) Mo_2GaC (3.9 K)[145], (j) SrC_6 (1.65 K)[146], (k) YC_2 (3.89K)[111], (l) YB_6 (7.2 K)[94], and (m) $\text{LaPt}_2\text{B}_2\text{C}$ (10 K)[72].

B. Overview of DFPT calculations

After the crystal structures of B and C compounds have been collected, the next step as shown in Fig.1 is to do HT calculations with DFPT on EPC properties for compounds with both known and unknown T_c using our

recently developed high-throughput electronic structure package (HTESP) [147]. We performed DFPT calculations and computed EPC properties using the isotropic Eliashberg approximation. The accuracy of the EPC data is crucial for building reliable ML models. We have encountered two major challenges in the HT calculations with DFPT. One is the convergence with respect to BZ sampling and the other is dynamic instability. The first obstacle involved determining appropriate BZ samplings (**k**- and **q**- meshes) to compute the EPC properties, as these calculations become computationally expensive with dense meshes. To reduce the computational cost, we initiated an efficient screening by using a **k**-point mesh that accurately describes the ground-state structures and energetics. EPC quantities are then interpolated to fine **k**-mesh only twice the size of the coarse **k**-mesh. But we noticed that calculations with such grid combination can lead to inaccurate predictions, with discrepancies as high as approximately 10% of the total compounds with known T_c , giving NSC for known SC and vice versa. To address this problem, we developed an ansatz test to assess the convergence of T_c with respect to the **k**-point mesh. This approach leverages the decaying behavior of T_c with respect to Gaussian broadening width (σ), which is used in the double-delta integration. Initially, we acquired results using the DFPT method with the **k**-point mesh size from the MP database. Subsequently, we assessed the convergence of these results based on the convergence ansatz test. To ensure convergence, we repeated calculations with denser **k**-mesh for the cases where results did not pass this test. We applied this technique to the 113 dynamically stable compounds, and obtained reasonable accuracy for the calculated T_c with a mean absolute error (MAE) of 2.21 K compared to experimental data. Further details regarding the convergence with respect to the **k**- and **q**-point meshes are discussed in the Method section and SM. In addition to the 113 dynamically stable compounds with known T_c , we also computed the EPC properties of 268 compounds of unknown T_c with dynamical stability, resulting from the ML-guided search as summarized in Fig.1.

The second obstacle encountered in EPC calculations was the presence of imaginary phonon modes and dynamical instability in almost 146 compounds. Among them, the imaginary phonon modes in 36 compounds show large EPC contribution. Stabilizing these imaginary modes is crucial for calculating EPC properties in such systems. These imaginary modes can be stabilized through lattice distortion, pressure, and electronic smearing, with the later method being particularly effective in HT screening[52]. A comprehensive analysis of dynamical instability and its implications for superconductivity will be presented in the ‘‘Imaginary phonon modes and superconductivity’’ section. In addition to these instances, there are cases up to 173 compounds, where EPC calculations are not complete due to either numerical problems or too large size of unit cells. For now, we will set these cases aside and will revisit them in the future.

C. Training and testing ML models

Besides the data extraction and DFPT calculations, training and testing ML models also play crucial roles in the ML-guided search workflow in Fig.1. We utilized two different ML models: CGCNN[148] and ALIGNN[149]. CGCNN maps 3D crystal structures to 2D graphs by using chemical element information and neighbor bonding distance to encode them into local chemical environments through convolution operations and updating the node features based on these descriptors. The updated node features are then aggregated to represent the entire crystal, which is connected to the output via a neural network. ALIGNN includes extra local chemical information, such as bonding angles, in addition to the crystal graphs in CGCNN with another auxiliary graph of bonding distances and angles. The parameters, including weights and biases, of the neural network connections are learned through training with available DFPT data.

As shown in Fig. 1, we trained the initial ML models in Run 1 using a dataset of 250 dynamically stable compounds with 109 SC (calculated $T_c > 1$ K) and 141 NSC (calculated $T_c < 1$ K) including those 113 from SuperCon database that were already measured in experiments. This dataset encompasses 45 distinct SGs. For the purpose of evaluation, a separate collection of 58 stable compounds (18 SC and 40 NSC), belonging to 27 unique SGs (6 of which are not part of the training 45), was reserved exclusively for independent testing and was not involved in the ML training process. Moving from Run1 to Run2, we use the ML model from Run1 to predict T_c for the remaining dataset of B and C compounds. We then sort the predictions and select the top candidates of both SC and NSC for more DFPT calculations to close the ML-guided loop. In Run2, the original 250 stable systems were augmented with an additional 73 dynamically stable systems to refine the ML models. In the concluding stage of Run 3, we incorporated the results derived from the compounds with dynamic instability. Notably, this stage included results from 2 new SGs. Among the 36 results in this category, we incorporated 28 into the training set and added 8 compounds into the independent test set. In the overall count of 417 compounds with converged EPC properties, 181 were classified as SCs, whereas 236 were categorized as NSCs. The progress from Run 1 to Run 3 constitutes a loop, as illustrated in Fig. 1. In summary, our methodology has a series of iterations involving training and testing ML models with increasingly comprehensive datasets from dynamically stable to unstable compounds.

D. Comparison of ML models

Next, we will present the main results of the ML models and guided search, highlight the notable compounds, including cases of dynamical stability and instability. Figures 3(a-d) depict the ML-predicted vs. DFPT-calculated λ , ω_{log} , T_c , and T'_c using the dynamically stable systems in Run 1, respectively. Here, T_c represents the critical temperature computed using DFPT-computed λ and ω_{log} or predicted directly from ML models, while T'_c is calculated from the ML-predicted λ^{ML} and ω_{log}^{ML} using Eq. 1 in a postprocessing manner.

$$T'_c = \frac{\omega_{log}^{ML}}{1.2} \exp \left[-\frac{1.04(1 + \lambda^{ML})}{\lambda^{ML} - \mu_c^*(1 + 0.62\lambda^{ML})} \right], \quad (1)$$

Here, It is important to note that the data first used do not include dynamically unstable cases. For Run 1, we trained ML models using 250 compounds, divided into training, validation, and testing sets in a ratio of 0.8:0.1:0.1. The mean absolute errors (MAEs) for the 10% test set in each training iteration are documented in SM Table-S6. An additional independent test set of 58 compounds was used to assess the predictability of the ML models and their MAE and predictions are plotted in Fig. 3. The training process consisted of 3000 epochs using default settings provided by the ML packages, which have been thoroughly investigated in the original work [148, 149]. In both CGCNN and ALIGNN, training and validation procedures are employed. Checkpoints are established at regular intervals to store crucial parameters such as model weights and architecture. The ML packages operate automatically to retain and update the model exhibiting the best performance, determined by the lowest validation error. This iterative process also acts to mitigate overfitting concerns. The performance of the models was evaluated by computing the MAE between the predicted and target quantities for the independent test set. The MAEs for CGCNN-predicted λ and ω_{log} stand at 0.23 and 105 K, respectively, while the corresponding numbers for ALIGNN are slightly higher at 0.28 and 113 K (Figs. 3(a) and (b)). In terms of predicting T_c , the CGCNN and ALIGNN models yield MAEs of 2.4 K and 3.8 K, respectively. Despite the relatively small magnitude of MAEs, the ML outcomes exhibit distinct clustering patterns, as shown in Fig. 3(c). Specifically, for the CGCNN model, the results tend to cluster closely along the ‘‘DFPT’’ axis (red arrow in Fig. 3(c)), whereas for ALIGNN, the clustering is pronounced along the ‘‘ML prediction’’ axis (blue arrow in Fig. 3(c)). An alternative approach, rather than directly training and predicting T_c , is to utilize ML-predicted values, specifically λ^{ML} and ω_{log}^{ML} , to estimate T'_c using Eq. 1. This modification not only enhances predictive performance for both models but also slightly ameliorates the issue of clustering [Fig. 3(d)]. A comparable approach has been employed in a recent study [150], wherein λ and ω_{log} can be directly acquired from first principles calculations.

Then we use the predicted T'_c to rank the remaining compounds to pick the ones with high and low T'_c for additional DFPT calculations. In this next stage, we utilized ML-guided search to expand the dataset to 323 systems characterized by 54 distinct SGs, the ML models underwent further training. Subsequently, the improved ML models were subjected to the same independent testing, employing the same set of 58 system test cases. The outcomes of the Run 2 are presented in Figs. 3(e)-(h). The results demonstrate a notable improvement in addressing the issue of prediction clustering with the expansion of the training dataset, all while maintaining reasonable accuracy. ALIGNN improves the prediction of λ and ω_{log} with MAEs of 0.24 and 93K, respectively, compared to CGCNN’s MAEs of 0.26 and 97K. However, T'_c calculated from ML-predicted λ^{ML} and ω_{log}^{ML} shows a significant improvement for ALIGNN, with an MAE of 2.7K. Notably, ω_{log} is more accurately predicted than λ and then T_c , because the former is directly related to the overall bonding strength and cohesive energy, while the later depends on the details of the Fermi surface and the EPC matrix elements.

As mentioned above, from the ML-guided search, we find quite some number of compounds with imaginary phonon and dynamical instability. In all the previous high throughput phonon-mediated SC studies, these dynamically unstable compounds are simply discarded, but as shown by our recent study [52] on Y_2C_3 , some imaginary phonon modes once stabilized can carry a large EPC and give rise to a large T_c . Thus, specifically here we also include dynamically unstable compounds in ML. As far as we know, this is the first ML trained with both dynamically stable and unstable compounds for phonon-mediated SC. We carried out a distinct training and testing phase for ML models, incorporating dynamically unstable cases after stabilization, denoted as Run 3. These results predominantly included nonzero T_c . Among these, 28 results were added to the training dataset, while the remaining 8 were added for independent testing. In total, the independent test set now consists of the original 58 dynamically stable and additional 8 stabilized compounds with imaginary phonon modes. Both the training and test datasets were balanced across various SGs. The outcomes of Run 3 are illustrated in Fig. 4(a)-(d). In Run 3, the ALIGNN model consistently outperforms the CGCNN model across different superconducting properties. The ALIGNN model achieves MAEs of 0.27 for λ , 86 K for ω_{log} , 4.3 K for T_c , and 3.5 K for T'_c . In contrast, the CGCNN model records MAEs of 0.34, 104 K, 4.5 K, and 5.3 K for the respective properties. The reason is that ALIGNN includes the bonding angles as part of training parameters, which better describe the dynamically unstable compounds, because imaginary phonon

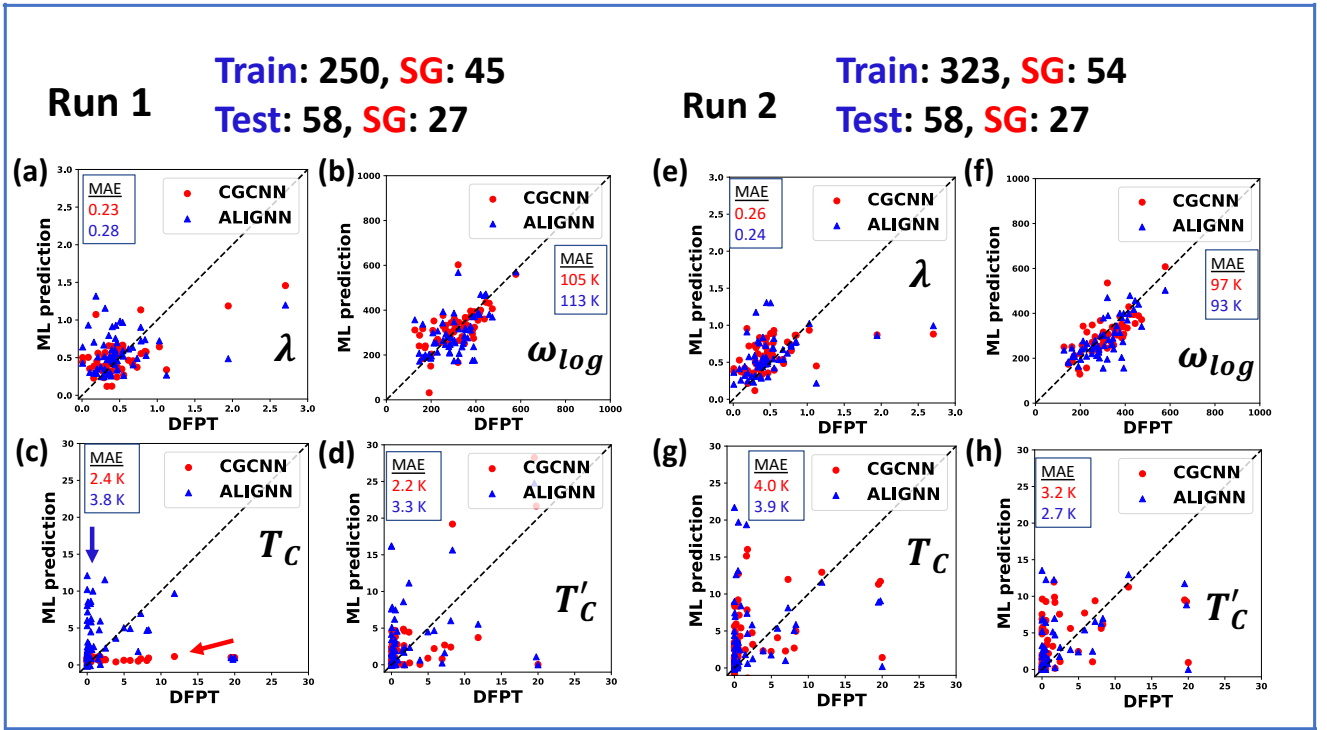

FIG. 3: Predicting λ , ω_{log} , T_c , and T'_c using CGCNN (red circles) and ALIGNN (blue upper triangle) models for the independent test set in comparison to the DFPT-calculated results in Run 1 (left panel) and Run 2 (right panel). Sizes of training and testing data, Number of distinct spacegroups (SGs) are shown. Mean absolute error (MAE) are presented in inset. Red and blue arrows show the clustering pattern, discussed in the main text.

modes often involves lower-energy bond rotation with changing angle than higher-energy bond stretching vibration. Based on the information presented in Figs. 3 and 4, it is apparent that the ML model performs better in learning the parameters ω_{log} than λ and then T_c . As a result, it is justifiable to utilize Eq. 1 to estimate the ML-predicted critical temperature T'_c rather than relying solely on the directly predicted T_c values.

E. Dynamically stable systems

In Table I, we present the results of our ML-guided search for dynamically stable compounds with DFPT-calculated T_c exceeding 10 K, while the complete list of EPC properties of the 381 dynamically stable compounds are presented in SM from Table S7 to S13. It is worth noting that the compounds with high T_c tend to be thermodynamically metastable, as indicated by their formation energy significantly above the convex hull. B_2CN in different phases, with ΔE_h up to 0.35 eV/atom, has been predicted to exhibit SC, consistent with earlier theoretical findings [151]. TaC and NbC, both have sizable T_c in the metastable hexagonal structure, while their more stable cubic structures in $Fm-3m$ have already been observed with SC [152, 153]. In Table I, the first compound close to the ground state convex hull ($\Delta E_h \sim 0.02$ eV/atom) is TaNbC₂, whose crystal structure and EPC properties are plotted in Fig. 5(a)-(c). It crystallizes in the trigonal structure of $R-3m$. The calculated EPC properties are $\lambda = 1.4$, $\omega_{log} = 326$ K, and $T_c = 28.4$ K, with the majority of the contribution coming from phonons within the 3-6 THz range (Fig. 5(b) and (c)), as well as a significant contribution from the 16-20 THz range of C-dominated modes. Other compounds close to the ground state convex hull with $\Delta E_h \leq 0.02$ is TaB₂. The presence of SC in TaB₂ remains a subject of debate as discussed in the previous studies [85].

Moreover, we predict other ternary superconductors, such as Nb₃B₃C (ΔE_h of 0.018 eV/atom [55]), with T_c of 16.4 K (Figs. 5 (d), (f), (h) and (j)). Comparison between the calculated and experimental T_c are also plotted (blue circles) for the Nb-B-C superconductors with known T_c . These ternary metallic borocarbides were all experimentally synthesized [154], however, some of their SC (red circles) have not been reported yet, with Nb₃B₃C has a predicted T_c as high as 16.4 K. The crystal structure of Nb₃B₃C exhibits a novel layer-like arrangement as in Fig. 5(f), where B atoms form strips of honeycomb lattice, while C being monomers. The λ -projected phonon dispersion (Fig. 5(h))

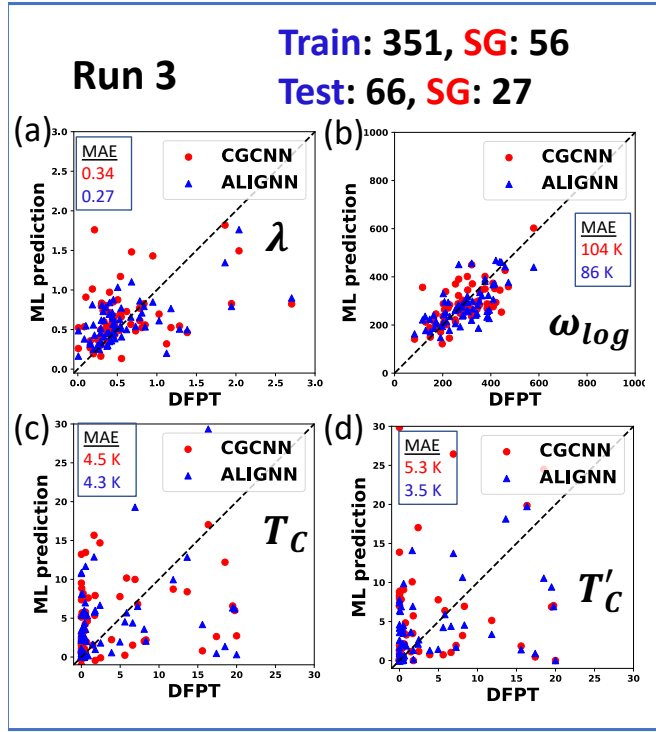

FIG. 4: Predicting λ , ω_{log} , T_c , and T'_c using CGCNN (red circles) and ALIGNN (blue upper triangle) models for the independent test set including both stable and dynamically unstable cases in comparison to the DFPT-calculated results in Run3. Sizes of training and testing data, Number of distinct SGs are shown. MAEs are presented in inset.

analysis indicates that the SC is attributed to the presence of low-frequency soft phonon modes in the vicinity of the Z and T points of the BZ. For ternary Nb-B-C systems, EPC calculations with isotropic approximation tend to overestimate T_c , while for Y-B-C systems, EPC calculations have also notable underestimations as plotted in Fig. 5(e). Therefore, we also show the EPC properties of $Y_2B_3C_2$ with a predicted T_c of 4 K, but having $\Delta E_h \sim 0$ [55], along with other experimentally measured Y-B-C systems in Fig. 5(e). Unlike Nb_3B_3C , the crystal structure of $Y_2B_3C_2$ shows a layer of mixed B and C network sandwiching the Y layer (Fig. 5(g)). The λ -projected phonon dispersion shows that the EPC properties are mostly contributed by phonon within the 4-10 THz energy range around the Γ and Z points (Figs. 5 (i) and (k)). Other compounds with calculated $T_c < 10$ K and their EPC properties are listed in SM.

F. Imaginary phonon modes and superconductivity

In this section, we address the issue of dynamical instability observed in the DFPT-computed phonon dispersion (146 out of 700 compounds). Out of these 146 dynamical unstable compounds, 34 exhibit large EPC in their imaginary phonon modes. Figure 6 (a) and (b) provide the breakdown of these 34 compounds based on their constituent elements, while (c) and (d) show the distribution of systems in terms of formation energy and SG, respectively. As expected, a considerable portion of these compounds with imaginary phonon have formation energies above the convex hull. Superconductivity in Sc_2C_3 , shown in Fig. 6 (d), are very likely because SC has been observed in the same structure with larger cations of the same group as in Y_2C_3 [155] and La_2C_3 [156], which are closer to the convex hull. We have categorized these compounds into two groups based on whether the imaginary phonon modes occur at the Γ -point or elsewhere. The instabilities at Γ -point are represented by Sc_2C_3 , Ta_2B , and La_3InB (Fig.6(e-g)) which constitutes 11 cases, whereas the other 23 compounds including MoB_2 represents the case of dynamic instability outside of Γ -point, as illustrated in Figs. 6(h) for MoB_2 . The unstable phonon modes possess a large mode-resolved λ in the vicinity of instability, $\lambda_{\mathbf{q}\nu} = \frac{\gamma_{\mathbf{q}\nu}}{\pi N(E_F)\omega_{\mathbf{q}\nu}^2}$, where $\gamma_{\mathbf{q}\nu}$ is the change in phonon linewidth due to EPC (See Fig. 6). The systems with dynamical instability at Γ -point can be stabilized by obtaining a low-symmetry ground state structure through lattice distortion along the direction of the imaginary eigenmodes at Γ and performing a full ionic relaxation. The analysis presented here is expanded from our earlier work on Y_2C_3 [52]. The application of smearing to stabilize imaginary

phonon modes has been explored in other systems, including β -phase Ni_xAl_(1-x) [157], NiTi [158] and EuAl₄[159]. In these cases, instead of optical modes, the instability arises from acoustic modes. It was proposed that the dynamic instability observed in these materials is the result of strong EPC between nested electronic states near the Fermi level [157–159]. Previously as exemplified with Y₂C₃ [52] these imaginary phonon modes can significantly contribute to λ after stabilization. Although these cases represent only a small fraction of the compounds, disregarding them would exclude potential SC compounds with a sizable T_c .

Performing EPC calculations on low-symmetry structures can be computationally expensive, especially when the system contains a large number of atoms like Sc₂C₃. Hence, it is recommended to first try stabilization using pressure and smearing. The former option of stabilizing through pressure can give interesting pressure-dependent properties, whereas the latter with increasing electronic smearing can be beneficial for HT computations. To stabilize the dynamically unstable systems, we applied pressure (ranging from 5 to 60 GPa) or used a larger electronic smearing (0.05, 0.06, 0.08, 0.1 Ry). In each case, we fully relaxed the structures. We computed the EPC properties for the stabilized systems around Γ -point and presented the results in Table II together with their SG and ΔE_h . Most of these compounds crystallize in high-symmetry structures such as cubic, hexagonal and tetragonal lattices. The relative ground state energy of relaxed low-symmetry structures compared to the original high-symmetry ones are listed as Distorted GS. We utilize pressure and the electronic smearing to stabilize the imaginary phonons in Y₂C₃, La₂C₃ and Sc₂C₃. However, for Ta₂B and La₃InB systems, pressure and smearing were insufficient for stabilization, so lattice distortion was employed. The calculated T_c using DFPT for the stabilized systems agrees well with experimental data. For example, Al₂Mo₃C exhibits an instability at Γ akin to that observed in Sc₂C₃. After stabilization with electronic smearing, the calculated T_c is 12.05 K, which is comparable to the experimental T_c of 9.2 K [160]. We predict the EPC properties for Sc₂C₃, YBC, and MoB₄ with a sizable T_c of 27.9 K, 10.15 K and 7.58 K under ambient or moderate pressure. These compounds have formation energy higher (0.11, 0.42, and 0.26 eV/atom respectively)

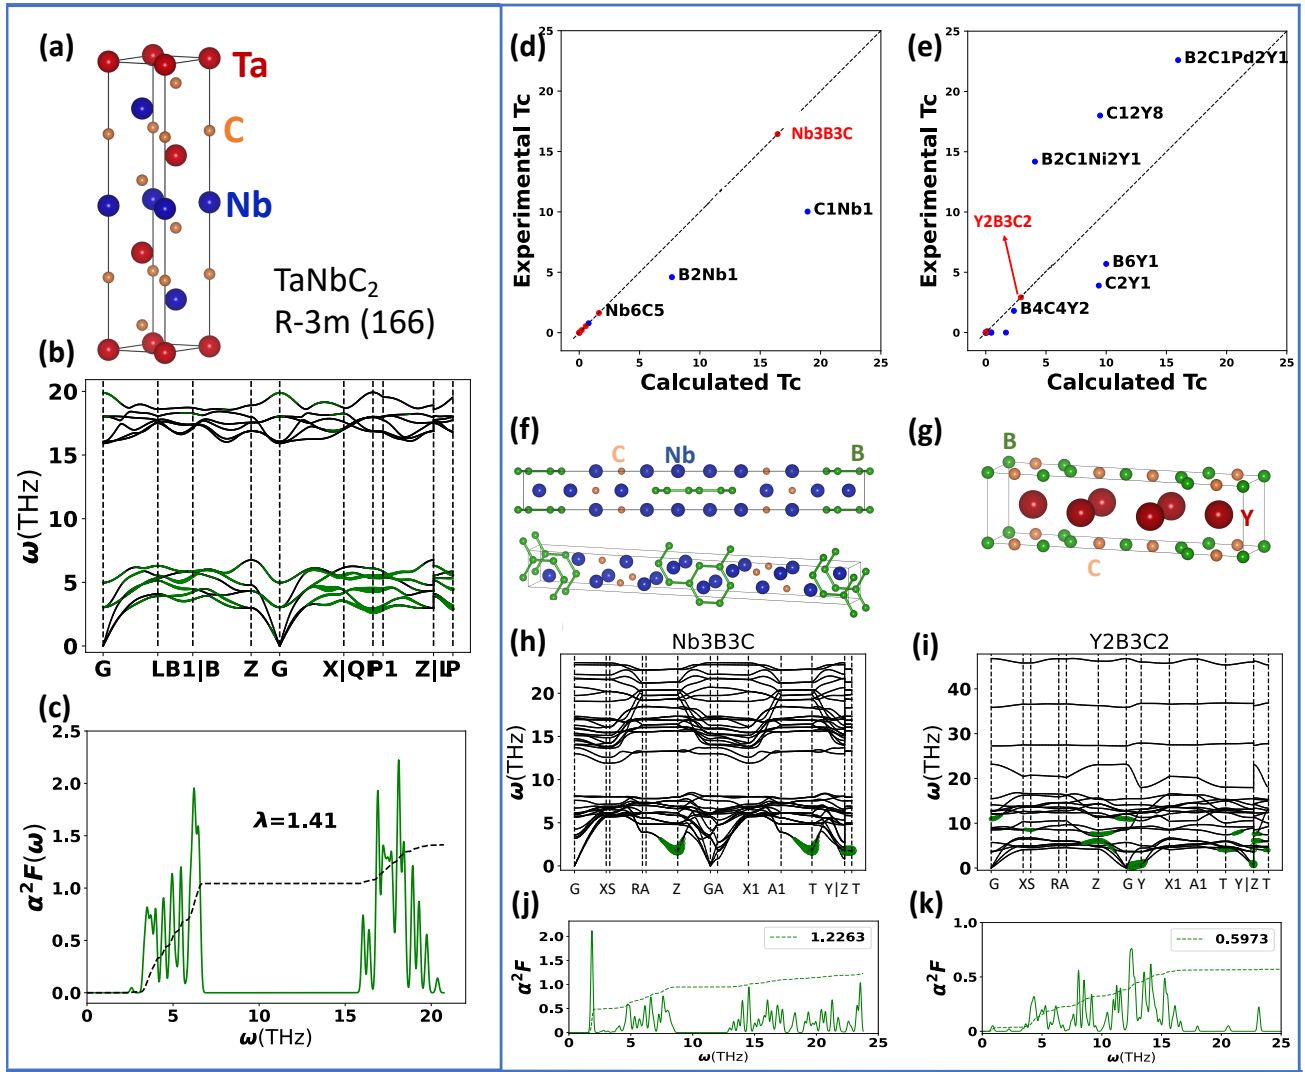

FIG. 5: X-B-C compounds (X=Nb,Y): Comparison between DFPT computed T_c values with experiments for (a) Nb-B-C, and (b) Y-B-C systems. Experimentally known results are represented by blue circle, while red circles are not reported ones shown along the $y=x$ dashed line. (c),(d) Crystal structures respectively for Nb₃B₃C, and Y₂B₃C₂. Atoms are highlighted by the colored symbols. (e),(f) Phonon dispersion projected with mode-resolved λ (green open circles) for Nb₃B₃C, and Y₂B₃C₂ respectively. (g),(h) Eliashberg spectral functions for Nb₃B₃C, and Y₂B₃C₂ respectively. (i) Crystal structure of TaNbC₂ in R-3m spacegroup (j) EPC projected phonon dispersion and (k) isotropic Eliashberg's spectral function of TaNbC₂.

than the ground state convex hull, indicating they are metastable.

Figure 6(j)-(m) displays the λ -projected phonon dispersion for four different stabilized compounds: Sc₂C₃ (P-30), Ta₂B (D), La₃InB (D), and MoB₂ (S-0.1), utilizing pressure of 30 GPa, distortion (D), distortion (D), and smearing of 0.1 Ry, respectively. By comparing these plots with Figs. 6(e)-(h), we can see that the soft optical phonon modes are stabilized and contribute significantly to λ near the Γ -point, represented by green open circles. Despite the slight lifting of phonon band degeneracy caused by distortion, the large contribution to EPC remains, which give rise to SC. The discovery of such systems is interesting as it presents opportunities for stabilization through pressure and alloying, leading to potentially high T_c metastable compounds that may be synthesizable in experiment.

For the compounds with imaginary phonon modes away from the Γ point, i.e. MoB₂-type, we also stabilized these dynamically unstable compounds with larger electronic smearing of 0.1 Ry and tabulated the results in Table. III. For example, compounds like MoB₂ in the MgB₂ structure have shown experimentally measured T_c of 32 K under high pressure around 110 GPa [20]. Another notable example in Table III is Ca₅B₃N₆ with ΔE_h of 0.03 eV/atom, which exhibits dynamical instability at the H point and displayed a significant mode-resolved λ near its unstable phonon

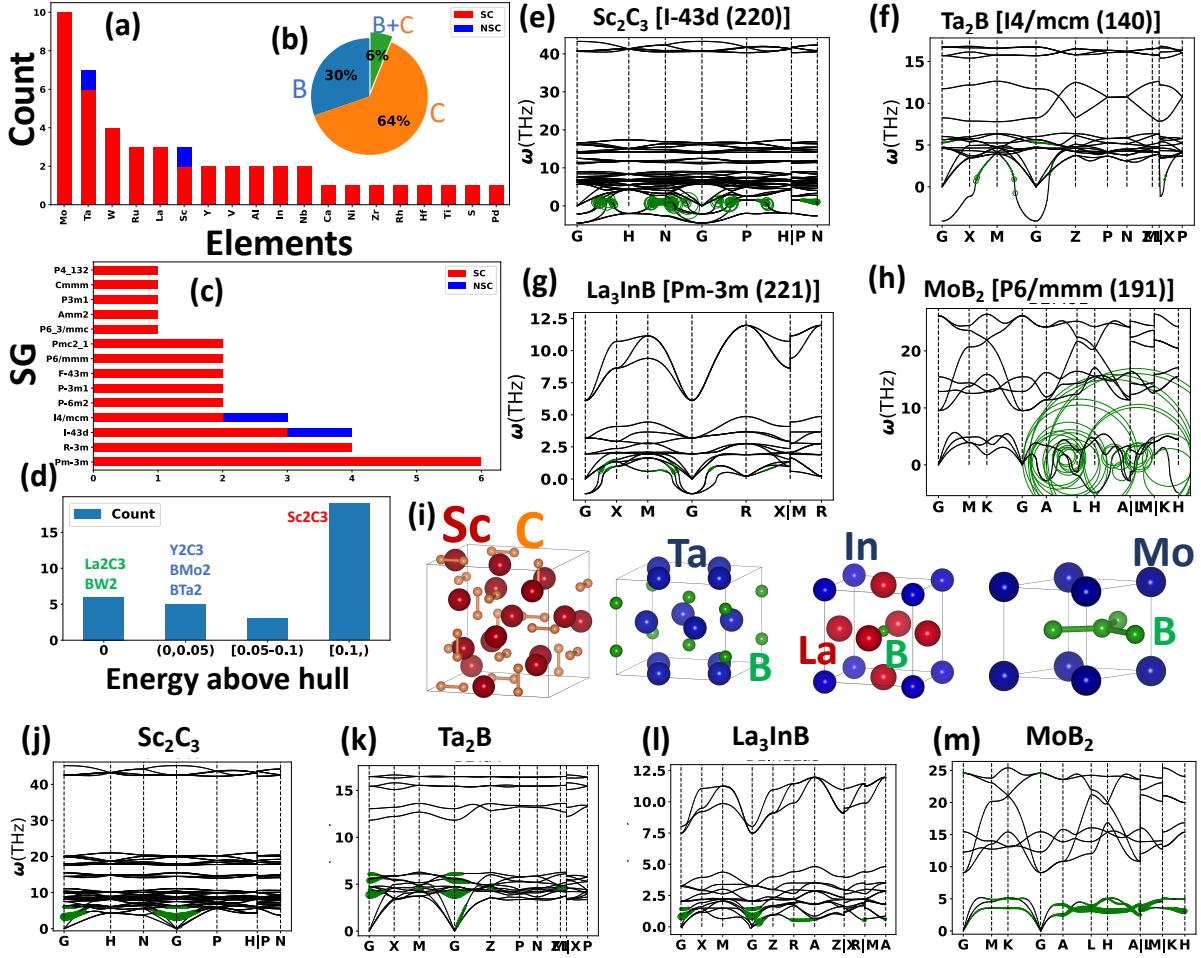

FIG. 6: Imaginary frequency modes with large EPC on the soft modes. Fig. (a) and (b) represent the count of different elements and allocation of B/C/B+C compounds in dynamically unstable systems respectively. Statistics according to spacegroup(c) and (d) energy above the convex hull. (e)-(h) Phonon dispersion plots of dynamically unstable systems corresponding to Sc_2C_3 , Ta_2B , La_3InB , and MoB_2 , respectively. First 3 plots represent the instability of soft phonon modes at Γ -point, while the last one corresponds to the instability outside of Γ . (i) Crystal structures of systems representing plots (d)-(g). (j)-(m): EPC results for compounds with stabilized imaginary phonon modes. EPC projected (highlighted by green circles) phonon band dispersions for Sc_2C_3 (P-30), Ta_2B (D), La_3InB (D), and MoB_2 (S-0.1) respectively.

modes, as depicted in Fig. 7 (d)-(e). After stabilizing the system with electronic smearing of 0.06 Ry, $\text{Ca}_5\text{B}_3\text{N}_6$ exhibits a λ of 1.5. The ω_{log} is found to be 372 K. Moreover, when computing λ (with broadening parameter $\sigma = 0.01$ Ry), the T_c is determined to be 35 K with Coulomb potential $\mu_c^* = 0.16$ and 42.4 K with $\mu_c^* = 0.10$, much larger than that of MgB_2 (16-20 K) computed from isotropic approximation. It should be noted that $\text{Ca}_5\text{B}_3\text{N}_6$ has been synthesized in cubic structure and $\text{Im}\bar{3}'m$ (229) SG with partial occupancy in the 8c site of Ca [162]. The crystal structure of this boronitride (Fig. 7(a)-(c)) has a cage-like structure, similar to XB_3C_3 borocarbides ($X = \text{Ca}, \text{Ba}, \text{Sr}, \text{Y}, \text{La}$). For the stoichiometric $\text{Ca}_5\text{B}_3\text{N}_6$, Fig. 7(f) and (g) present the isotropic Eliashberg spectral function and electronic band structure, respectively. It shows an electron-doped band structure that connects to strong EPC as also found in other predicted SC compounds and studies. As listed in Table III, interestingly some of the trigonal compounds of NbMoC_2 are in the same structure as the stable TaNbC_2 in Table I. This shows that in this particular structure, with the substitution of neighboring group of early TMs, although bringing dynamical instability, the phonons once stabilized can still provide a large EPC contribution for a sizable T_c . As also listed in Table III, other compounds with sizable predicted T_c after stabilization that also near GS hull are some notable ternary Ru compounds, MoRuB_2 at 15.6 K, RuVB_2 at 15.0 K, Pd_3CaB at 7.0 K and RuSc_3C_4 at 6.6 K.

TABLE II: Stabilization of imaginary phonon modes (around Γ) utilizing Distortion (D), Pressure (P), and Smearing (S). The values of pressure and smearing are presented as P-value (GPa) and S-value (Ry) respectively. Crystal is distorted along the direction represented by eigenmode at Γ and relaxed to obtain low-symmetry ground-state structures. Distorted GS is the difference between ground-state total energy of an undistorted and distorted structures at equilibrium. SG is spacegroup and ΔE_h represents the energy above the ground state hull.

III. Discussion

In this work, we have employed the machine learning (ML) models that utilize the data generated from *ab-initio* calculations using the DFPT and the isotropic Eliashberg approximation to iteratively guide the search for new phonon-mediated superconductors among B and C compounds. Our study also focuses on addressing the challenges encountered during DFPT calculations, such as convergence of Brillouin zone (BZ) sampling and the problem of calculated dynamic instability. To address the convergence issue, we developed an ansatz test to verify the convergence of superconductivity (SC) critical temperature T_c . This test uses the variation of T_c with respect to Gaussian broadening to compute the double delta summation. For dynamically unstable compounds, we applied large electronic smearing, lattice distortion, and pressure to stabilize imaginary phonon modes. We then calculated their EPC properties and incorporated these into the ML models. Between the two ML models, ALIGNN consistently outperforms CGCNN in predicting EPC properties especially after including the stabilized compounds with imaginary phonon and dynamical instability. Our ML-guided search demonstrates promising predictability for T_c values. For example, we predict SC in compounds with calculated dynamically stability such as TaNbC₂ (28.4 K), Nb₃B₃C (16.4 K), Y₂B₃C₂ (4.0 K), among others. In addition to studying dynamically stable compounds, we also focus on compounds with calculated dynamic instability, an area that, to our knowledge, has not been systematically explored before. We predicted SC in compounds showing dynamic instability such as Ca₅B₃N₆ (35 K), Pd₃CaB (7.0 K), some ternary Ru compounds, MoRuB₂ (15.6 K), RuVB₂ (15.0 K), Pd₃CaB (7.0 K) and RuSc₃C₄ (6.6 K) with ΔE_h mostly below 0.1 eV/atom. With further refinement and larger dataset, our workflow can be improved in accurately predicting more SC compounds. In this regard, identifying metastable compounds with calculated dynamic instability, where soft phonon exhibit significant EPC contribution, plays a crucial role.

IV. METHODS

A. Convergence with respect to Brillouin zone sampling (k-point mesh)

To identify cases of convergence failure (i.e., incorrect prediction of SC/NSC) related to Brillouin zone sampling, we analyzed the variation of T_c with respect to Gaussian broadening (σ) in the double delta integration and developed a simple ansatz based on the converged results of MgB₂, as described in the "Convergence ansatz" section of the Supplemental Material (SM). This ansatz involves extracting T_c , similar to MgB₂, and estimating the decay parameter (A) in the exponential variation of T_c with σ ,

$$T_c = \exp(-A\sigma^{1/3} + B) \quad (2)$$

TABLE III: DFPT calculated EPC results for MoB₂-type instability (outside of Γ), stabilized with electronic smearing of 0.10 Ry; SG is spacegroup, and ΔE_h is ΔE_h taken from MP database. Experimental results for some high-pressure T_c are also reported.

^a Stabilized with electronic smearing of 0.06 Ry

where A is the variable that quantifies the rate of exponential decay, and B is the constant associated with Debye temperature. Unconverged results show larger values of A, which decrease with denser \mathbf{k} -meshes. With larger \mathbf{k} - or \mathbf{q} - grids, the T_c vs σ curve becomes less steep. Our convergence analysis of MgB₂ suggests that $A_{MgB_2} = 12-13$ can be used as a threshold for this study: calculations are considered as unconverged for $A > A_{MgB_2}$, requiring a denser \mathbf{k} -mesh, while those with $A < A_{MgB_2}$ can be regarded as converged for accurate prediction.

B. Computational details

Data extraction from the MP database, as well as input preparation for ground state calculations, calculation submission, result extraction and input preparation for ML studies, and plotting, were performed using the high-throughput electronic structure package (HTESP) [147]. A script, ‘fitting_elph_smearing.py’, is included in the HTESP package to compute the decay parameter from T_c vs. broadening σ data. Ground-state DFT and EPC calculations were performed using the QE code [163, 164]. Ultrasoft or norm-conserving pseudopotentials (PP) from the efficiency standard solid-state pseudopotentials (SSSP) dataset [165] were employed, with the replacement of projector-augmented wave (PAW) PPs by GBRV ultrasoft norm-conserving high-throughput PPs [166]. The exchange-correlation energy was approximated using the Perdew-Burke-Ehrnzerhof (PBE) generalized-gradient approximation (GGA) [167]. The Brillouin zone was sampled using a \mathbf{k} -point mesh from the MP database to compute the ground-state charge density for EPC calculations. The \mathbf{q} -point mesh required for EPC calculations was obtained

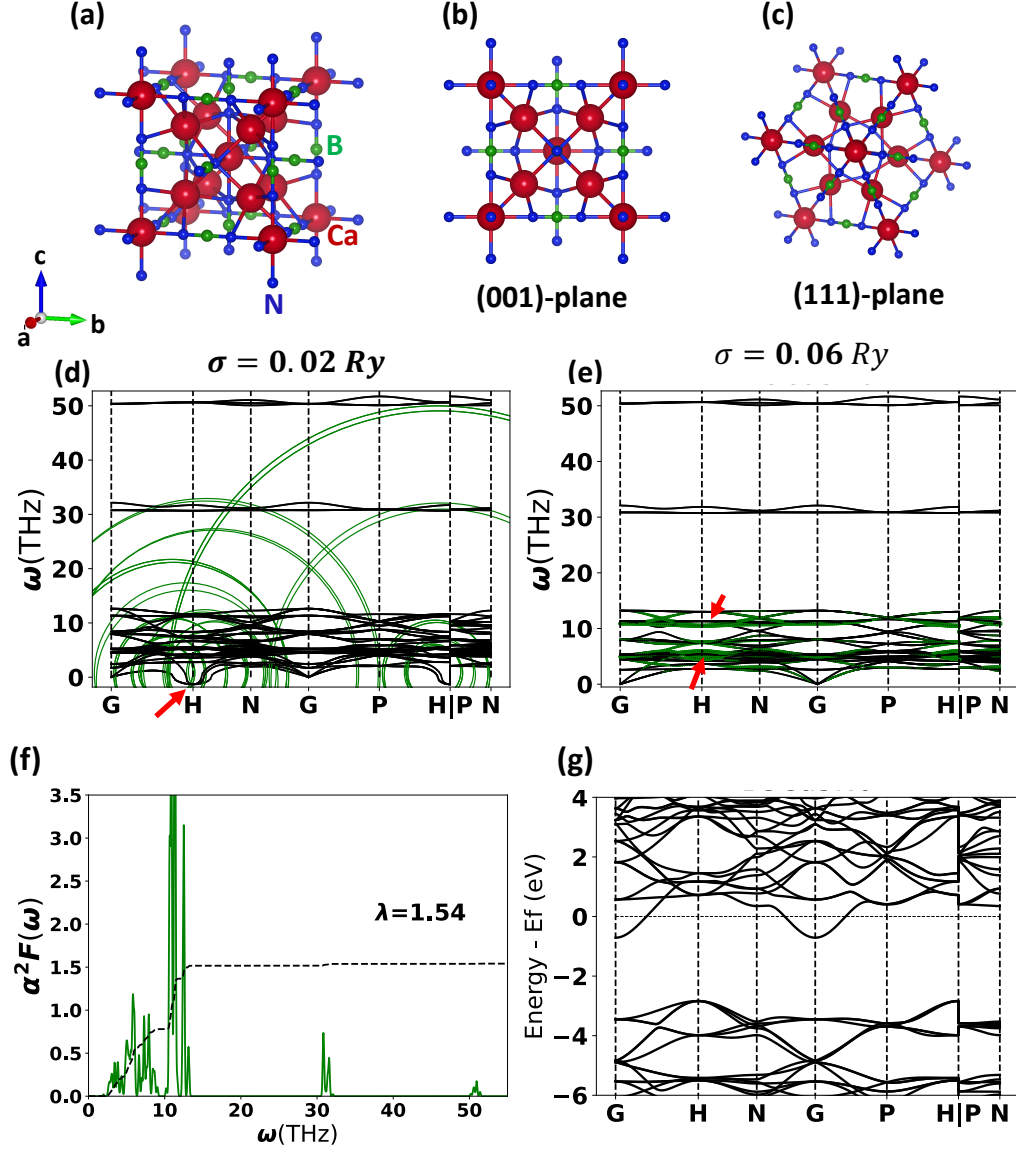

FIG. 7: (a)-(c): Crystal structures of $\text{Ca}_5\text{B}_3\text{N}_6$, viewed from different directions (d)-(e): EPC results for compounds with stabilized imaginary phonon modes for $\text{Ca}_5\text{B}_3\text{N}_6$. (d): EPC projected (highlighted by green circles) phonon band dispersions for dynamically unstable systems represented by small well at H-point (shown by red arrow), (e): Similar results for systems, stabilized with large electronic smearing of 0.06 Ry. (f) Eliashberg spectral function (g) Electronic band structure

by halving the k-point mesh ($\mathbf{q} = \mathbf{k}/2$), with odd k-points changed to even by adding 1 to it. The structures were fully relaxed using Broyden–Fletcher–Goldfarb–Shanno (BFGS) minimization [168] until the total energy and forces for ionic minimization converged within 10^{-5} Ry and 10^{-4} Ry/Bohr, respectively. The self-consistent electronic energy and charge density were minimized with a convergence threshold of 10^{-12} Ry. Similarly, the SCF convergence for phonon calculations is achieved with an energy cutoff of 10^{-14} . Starting from the default α_{mix} value of 0.7, it is reduced to 0.3 if the EPC calculation does not converge. A fine k-point grid, twice the size of the k-point mesh used for charge density convergence, was used for interpolating EPC matrix elements to compute double-delta integration and the λ . Gaussian smearing of 0.02 Ry was applied for charge-density optimization. To compute λ for various σ values, we computed double-delta integration using 10 broadening (σ) values ranging from 0.005 to 0.05 Ry for the \mathbf{k} -mesh. For the \mathbf{q} -mesh integration, a fixed smearing of 0.5 meV was employed. The reported results were obtained for $\sigma = 0.01$ Ry with a Coulomb potential μ_c^* of 0.16.

V. Data availability

Data computed and utilized in this study are tabulated in STs ST7–ST13 in the SM, Tables. II and III. Raw data is available from the corresponding authors upon reasonable request.

VI. Acknowledgements

We thank Dr. Paul C. Canfield for the funding support, initiating the idea of searching for new phonon-mediated superconductors among boron and carbon compounds, and the helpful discussion throughout the project. This work was supported by Ames National Laboratory LDRD and U.S. Department of Energy, Office of Basic Energy Science, Division of Materials Sciences and Engineering. Ames National Laboratory is operated for the U.S. Department of Energy by Iowa State University under Contract No. DE-AC02-07CH11358.

VII. Author contributions

L.-L.W. conceived and supervised the work. N.K.N. and L.-L.W. designed and performed the high throughput calculations with the machine learning guided approach. N.K.N. developed the ansatz to test the convergence of T_c calculation. All authors discussed the results and contributed to the final manuscript.

VIII. Competing interests

The authors declare no competing interests.

Supplementary Materials for “Machine-learning Guided Search for Phonon-mediated Superconductivity in Boron and Carbon Compounds”

Statistics for compounds with unknown T_c

In Fig. S1, we present the descriptions of 268 dynamically stable compounds for which the experimental T_c is not known. Figure S1 (a)-(c) illustrate the distribution of different elements in these systems, the allocation of B/C/B+C compounds, and the deviation of their formation energy (ΔE_h) from stable structures, respectively. Most unknown compounds are associated with transition metals (TM) such as Nb, Ta, Mo, V, Y, and others. Approximately 80% of the structures are close to the ground state convex hull with $\Delta E_h \leq 0.05$ eV/atom, while the remaining 20% have ΔE_h greater than 0.05 eV/atom. Panel S1(d) showcases the distributions of these compounds based on their space groups. In Fig. S1(a) and (d), each bar is partitioned into segments, with the segments colored in red representing the number of SC, while the segments in blue denote the NSC. The overall description is similar to that of known compounds, as shown in Fig. 2 of the main text.

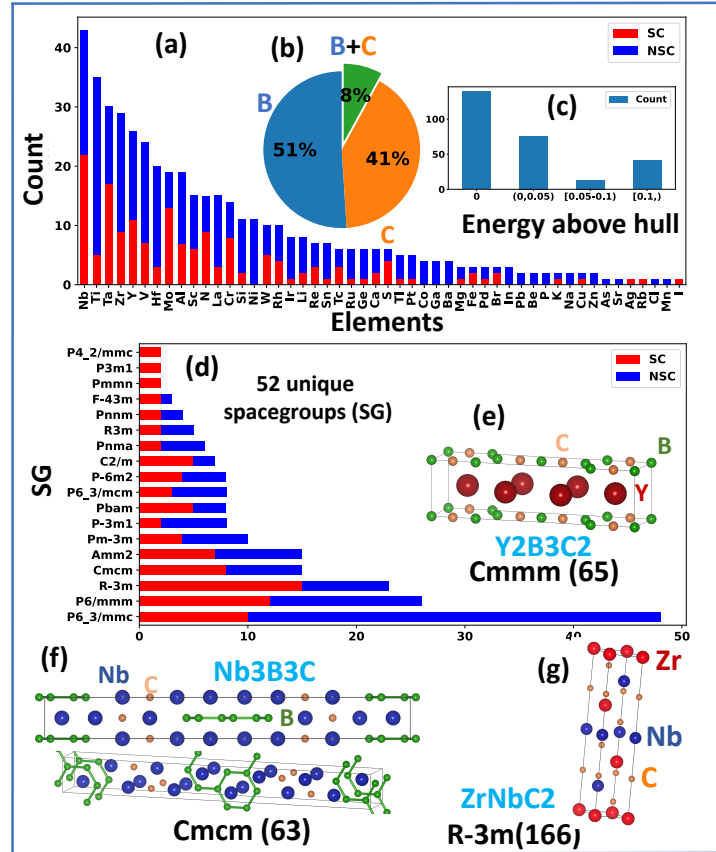

FIG. S1: Statistical description of dynamically stable materials, whose (non-) superconductivity hasn’t been experimentally measured. Each bar is partitioned into segments, with the segments colored in “red” representing the number of superconductors (SC), while segments in “blue” denote nonsuperconductors (NSC).; (a) Number of compounds according to elements, (b) Proportion of boron and carbon compounds (c) Statistics in terms of energy above the convex hull, (d) Distribution according to spacegroups, (e)-(g): Crystal structures of some potential superconductors with their respective spacegroups.

Theory of superconductivity: Isotropic Approximation

We have adopted the DFPT calculation with isotropic Eliashberg approximation to compute SC properties, which provides a harmony between accuracy and efficiency. The critical temperature can be calculated using the Allen-Dynes

formula [1],

$$T_c = \frac{\omega_{log}}{1.2} \exp \left[-\frac{1.04(1 + \lambda)}{\lambda - \mu_c^*(1 + 0.62\lambda)} \right], \quad (3)$$

where, $\lambda = 2 \int_0^\infty \frac{d\omega}{\omega} \alpha^2 F(\omega)$ is the EPC strength constant, $\omega_{log} = \exp \left[\frac{2}{\lambda} \int_0^\infty \frac{d\omega}{\omega} \alpha^2 F(\omega) \log \omega \right]$, $\alpha^2 F(\omega)$ is frequency (ω) resolved Eliashberg spectral function, and μ_c^* is the Coulomb potential. The spectral function $\alpha^2 F(\omega)$ is defined as,

$$\alpha^2 F(\omega) = \frac{1}{2} \sum_\nu \int_{BZ} \frac{d\mathbf{q}}{\Omega_{BZ}} \omega_{\mathbf{q}\nu} \lambda_{\mathbf{q}\nu} \delta(\omega - \omega_{\mathbf{q}\nu}). \quad (4)$$

Here, ω_{BZ} is the volume over the Brillouin zone $\int_{BZ} \frac{d\mathbf{q}}{\Omega_{BZ}} \rightarrow \frac{1}{N_{\mathbf{q}}} \sum_{\mathbf{q}}$, $\omega_{\mathbf{q}\nu}$ is the mode (ν) resolved phonon frequency, and $\lambda_{\mathbf{q}\nu}$ is the mode resolved EPC strength constant,

$$\lambda_{\mathbf{q}\nu} = \frac{1}{N(\epsilon_F) \omega_{\mathbf{q}\nu}} \sum_{mn} \int_{BZ} \frac{d\mathbf{k}}{\Omega_{BZ}} |g_{mn,\nu}(\mathbf{k}, \mathbf{q})|^2 \delta(\epsilon_{n\mathbf{k}} - \epsilon_F) \delta(\epsilon_{m\mathbf{k}+\mathbf{q}} - \epsilon_F). \quad (5)$$

$N(\epsilon_F)$ is the density of states at the Fermi level ϵ_F , and $g_{mn,\nu}(\mathbf{k}, \mathbf{q})$ is the EPC matrix element which quantifies the scattering process between Kohn-Sham states $m\mathbf{k}+\mathbf{q}$ and $n\mathbf{k}$. In Ref. [2], an effective approach to approximate double delta integration is explored, specifically tailored for situations where it is permissible to disregard the dependence on the momentum vector (\mathbf{q}). This method finds utility in scenarios such as the study of extensive molecular systems like alkali fullerenes, where momentum dependence can be safely overlooked. The net EPC strength constant is computed as

$$\lambda = \sum_{\mathbf{q}\nu} \lambda_{\mathbf{q}\nu} \quad (6)$$

For computational feasibility, these Dirac deltas can be approximated by Gaussian functions with a broadening parameter σ [3], and EPC strength is given by Eqs.5 and 6 can be redefined as

$$\lambda \approx \frac{1}{N(\epsilon_F) N_{\mathbf{q}} N_{\mathbf{k}}} \sum_{nm} \sum_{\mathbf{q}} \sum_{\mathbf{k}} \frac{|g_{mn,\nu}(\mathbf{k}, \mathbf{q})|^2}{\omega_{\mathbf{q}\nu}} \frac{1}{2\pi\sigma^2} \exp \left[-\frac{(\epsilon_{n\mathbf{k}} - \epsilon_F)^2 + (\epsilon_{m\mathbf{k}+\mathbf{q}} - \epsilon_F)^2}{\sigma^2} \right]. \quad (7)$$

Here, $N_{\mathbf{q}}$ and $N_{\mathbf{k}}$ respectively are the total number of \mathbf{q} and \mathbf{k} grid points, and σ is the smearing used to broaden states at the Fermi-level ϵ_F . With infinitely large \mathbf{k} -grids, and $\sigma \rightarrow 0$, the double summation changes back to double delta integration. Moreover, λ can also be obtained from frequency ω resolved Eliashberg spectral function as [4]

$$\lambda = 2 \int \frac{d\omega \alpha^2 F(\omega)}{\omega} = \frac{N(\epsilon_F) \langle g^2 \rangle}{M \langle \omega^2 \rangle}, \quad (8)$$

where, $\langle \omega^2 \rangle$ average of the square of the phonon frequency $\left(\frac{\int d\omega \omega \alpha^2 F(\omega)}{\int \frac{d\omega}{\omega} \alpha^2 F(\omega)} \right)$, $\langle g^2 \rangle$ is average over the Fermi surface of the square of electronic phonon coupling matrix element [4].

Convergence tests for MgB₂ and AlB₂

The ground-state total energy and phonon frequencies at Γ -point are well converged for MgB₂ with \mathbf{k} -grids of $8 \times 8 \times 6$, compared to the dense grid of $24 \times 24 \times 24$. \mathbf{k} -mesh grid in materials project database for MgB₂ is $8 \times 8 \times 7$. Since the superconducting properties of MgB₂ with \mathbf{k} -grid of $8 \times 8 \times 8$ doesn't follow the trend of converged result of denser \mathbf{k} -mesh with $\sigma \rightarrow 0$, we chose $8 \times 8 \times 6$ so that we can use sufficient \mathbf{q} -grids of $4 \times 4 \times 3$ instead of using $9 \times 9 \times 9$ \mathbf{k} -grid and $3 \times 3 \times 3$ \mathbf{q} -grid. We utilized $8 \times 8 \times 6$ \mathbf{k} -grid and its multiple to compute the decay parameter. In this work, we are taking $\lambda = 0.75$ obtained from solving anisotropic Migdal-Eliashberg equation using $\mu^* = 0.16$ as a reference [Comput. Phys. Commun. **209**, 116 (2016)]. One can obtain this converged λ with denser \mathbf{k} - and \mathbf{q} -grids and $\sigma \rightarrow 0$, as shown in Figs. S2 – S4. At last, we check whether the result is transferable to systems with larger unit cell where essentially smaller \mathbf{k} -grids provide converged ground-state properties and \mathbf{q} -grid, taken half of \mathbf{k} -grid, sometime shrinks only to include the Γ -point. To do that, we performed EPC calculations with $2 \times 2 \times 2$ supercell of MgB₂ which

has 24 atoms per cell, and present the results in Fig. S5 and S6. Results confirm that \mathbf{q} -grid as half as that of the \mathbf{k} -grid can provide converged results even for larger systems. Instead of increasing coarse \mathbf{k} - and \mathbf{q} - grids, one can also utilize extremely large \mathbf{k} - grid for interpolating EPC matrix element to achieve convergence, as shown in Figs. S4 and S7 respectively for MgB_2 and AlB_2 . However, it also increases computational complexity for larger systems.

TABLE ST1: Convergence of the ground-state total energy with respect to K-point mesh

K-mesh	Total Energy (eV/atom)
$6 \times 6 \times 4$	-615.178
$8 \times 8 \times 6$	-615.179

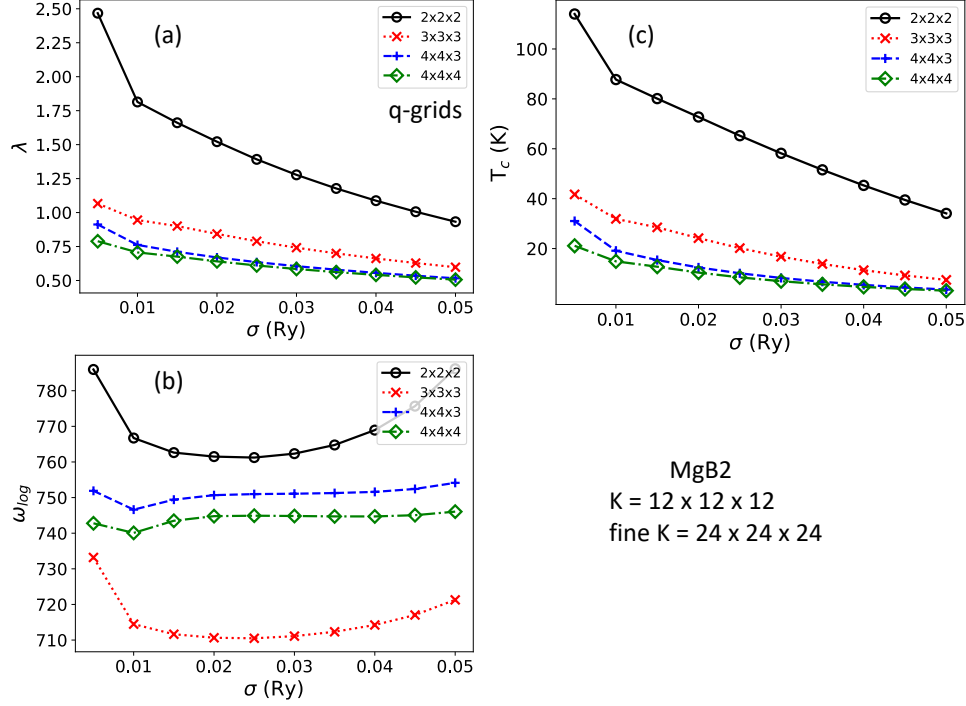

FIG. S2: Convergence test for MgB₂ results with respect to **q**-mesh. Unit of T_c and ω_{log} is Kelvin (K); As **q** becomes denser, convergence can be achieved across the $\sigma \rightarrow 0$, with less exponential decay. Fine **k**- grid is utilized for interpolation.

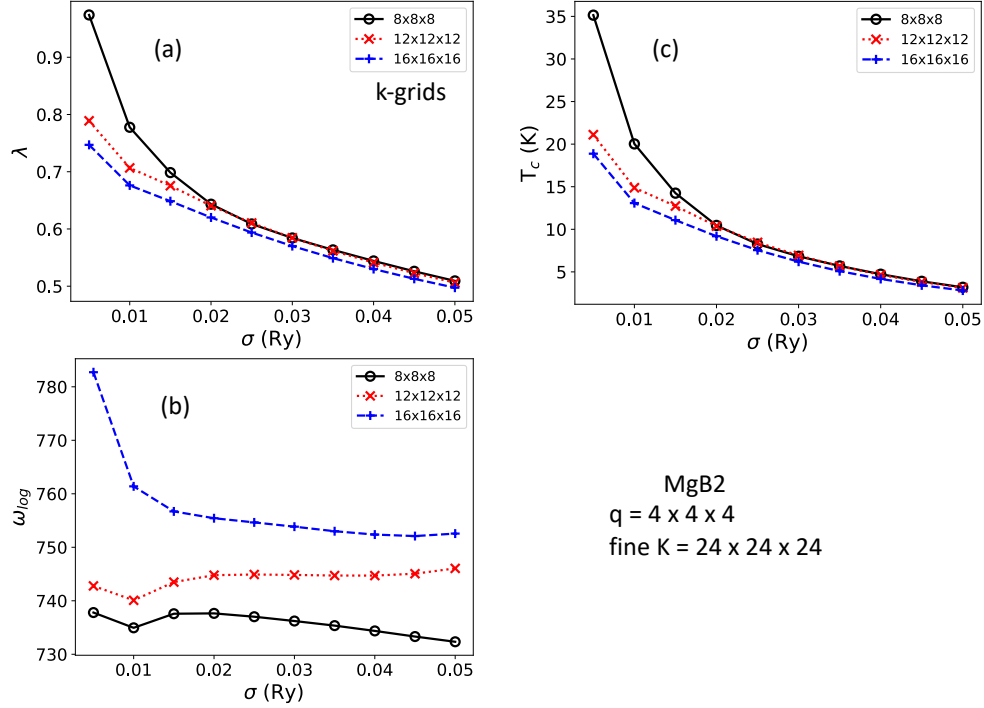

FIG. S3: Convergence test for MgB₂ results with respect to **k**-mesh. Unit of T_c and ω_{log} is Kelvin (K); As **k** becomes denser, convergence can be achieved across the $\sigma \rightarrow 0$, with less exponential decay. Fine **k**- grid is utilized for interpolation.

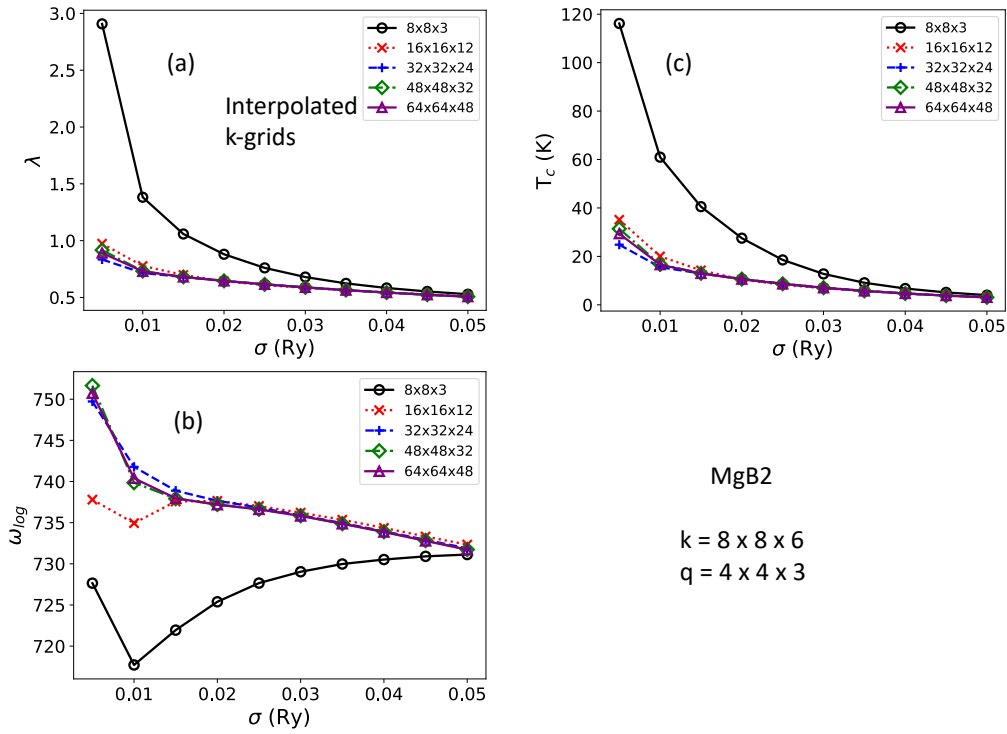

FIG. S4: Convergence test for MgB₂ results with respect to fine **k**-mesh used for interpolation. Unit of T_c and ω_{log} is Kelvin (K); As fine **k** becomes denser, convergence can be achieved across the $\sigma \rightarrow 0$, with less exponential decay.

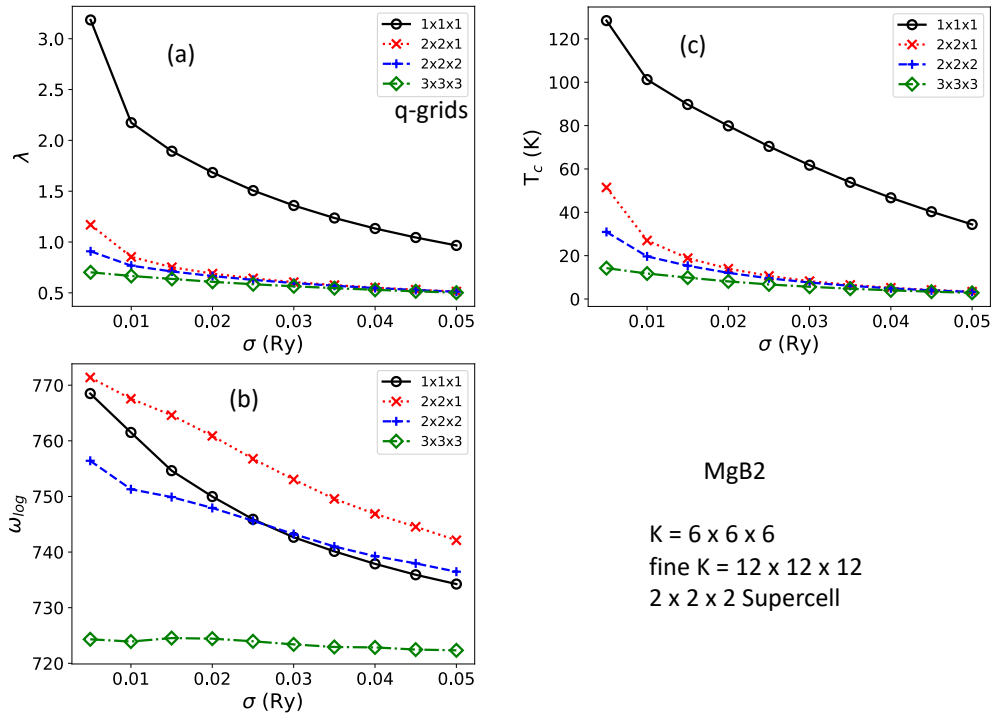

FIG. S5: Convergence test for 2x2x2 supercell of MgB₂ results with respect to **q**-mesh. Unit of T_c and ω_{log} is Kelvin (K); As **q** becomes denser, convergence can be achieved across the $\sigma \rightarrow 0$, with less exponential decay. Fine **k**-grid is utilized for interpolation.

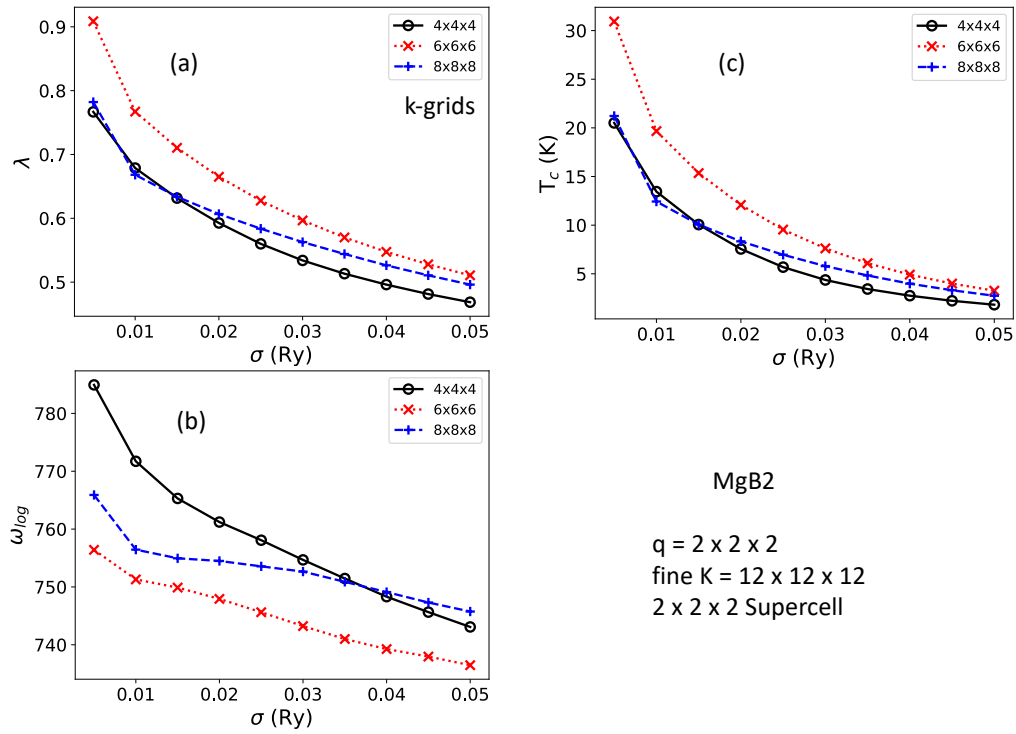

FIG. S6: Convergence test for $2 \times 2 \times 2$ supercell of MgB₂ results with respect to \mathbf{k} -mesh. Unit of T_c and ω_{log} is Kelvin (K); As \mathbf{k} becomes denser, convergence can be achieved across the $\sigma \rightarrow 0$, with less exponential decay. Fine \mathbf{k} - grid is utilized for interpolation.

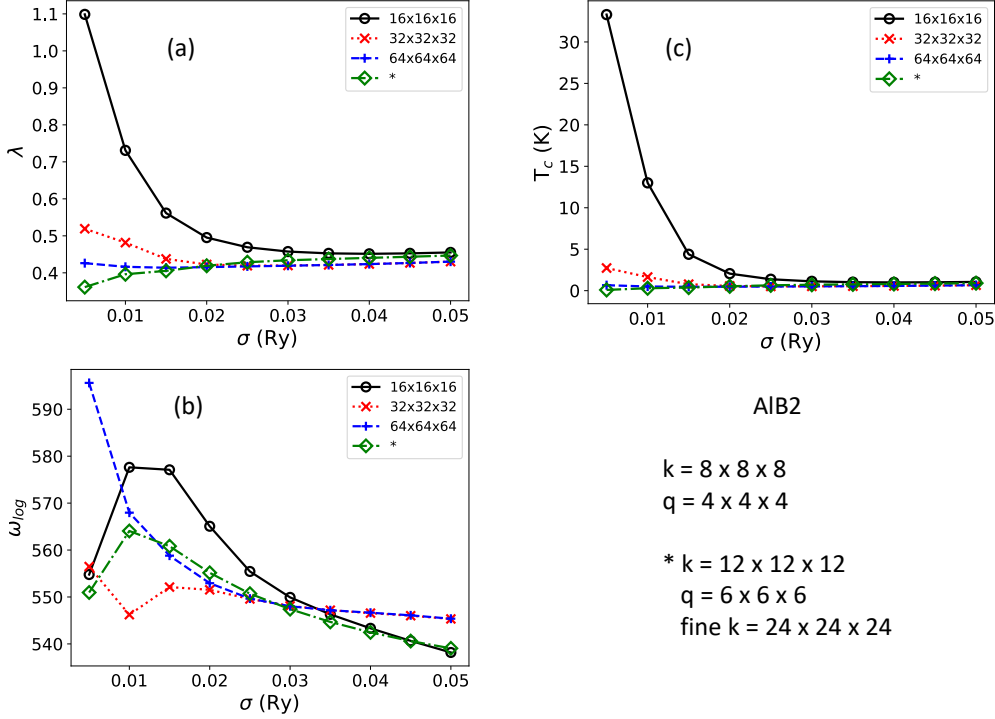

FIG. S7: Convergence test for AlB₂ results with respect to various \mathbf{k} - and \mathbf{q} -grids. Unit of T_c and ω_{log} is Kelvin (K); As grids becomes denser, convergence can be achieved across the $\sigma \rightarrow 0$, with less exponential decay. Separate results corresponding to \mathbf{k} - and \mathbf{q} - grids respectively of $12 \times 12 \times 12$ and $6 \times 6 \times 6$ is represented by “star (*)” symbol.

Convergence ansatz

Estimation of SC properties requires the computation of double-delta integration, which also defines the nesting function, around the Fermi level E_F over the entire Brillouin zone [Eq. 3]. However, it has a slow convergence with respect to \mathbf{k} - and \mathbf{q} - grids. In principle, it requires infinitely dense grids, which makes the computation exorbitantly expensive. Therefore, Gaussian broadening technique [Eq. 5] is employed to compute λ with finite \mathbf{k} -mesh. To compute T_c , we employed the DFPT calculation with the isotropic Eliashberg approximation. We used a coarse \mathbf{k} -grid obtained from the MP database, which provides reasonably accurate ground-state properties. The \mathbf{q} -grid was set to half the size of the \mathbf{k} -grid, and a broadening parameter (σ) of 0.01 Ry was utilized with the coarse MP grid, which accurately captures a converged electron-phonon coupling constant (λ) of MgB₂ computed using the anisotropic Migdal-Eliashberg equations [5]. However, in practice, $|g_{mn,\nu}(\mathbf{k}, \mathbf{q})|^2$ is computed for a reasonable coarse \mathbf{k} - and \mathbf{q} - grids and interpolated the matrix elements to fine \mathbf{k} - for any \mathbf{q} -point, from $32 \times 32 \times 32$ to as high as $60 \times 60 \times 60$, to achieve numerical convergence, as implemented in Quantum Espresso (QE) code[3]. Furthermore, an efficient interpolation scheme utilizing both dense \mathbf{k} - as well as \mathbf{q} -grids has been implemented in EPW package that uses wannier orbitals [5]. However, employing extremely fine grids for interpolation can increase the computational complexity, which is not suitable for highthroughput calculations. Therefore, we have restricted ourselves for choosing fine \mathbf{k} -grid only twice of corresponding coarse grid for highthroughput calculations.

Our investigation revealed that a reasonable number of calculations did not converge, leading to inaccurate predictions, while utilizing a coarse \mathbf{k} -grid from MP database and fine grid for interpolation only twice that of the \mathbf{k} -grid [Table ST3]. For example, AlB₂ was predicted to be a superconductor ($T_c \sim 11$ K) with the coarse grid [\mathbf{k} -grid: $8 \times 8 \times 8$, \mathbf{q} -grid: $4 \times 4 \times 4$, fine- \mathbf{k} -mesh: $16 \times 16 \times 16$] from MP database, whereas a denser grid twice the size of the coarse grid corrected this inaccuracy and predicted AlB₂ to be a nonsuperconductor, consistent with experimental observations [Fig. S7]. To identify such cases of convergence failure, we examined the variation of T_c with respect to σ and developed a simple ansatz based on the converged results of MgB₂, as depicted in Fig. S9. The ansatz involves extracting T_c with a fixed broadening value (as in the case of MgB₂) and estimating the decay parameter (A) in the exponential variation of T_c with σ as $T_c \sim \exp(-A\sigma^{1/3} + B)$. Unconverged results exhibit larger values of A , which decrease with a denser \mathbf{k} -mesh.

The detail theory of EPC calculations within DFPT formalism is presented in the section “Theory of superconductivity: isotropic approximation”. The variation of density of states at the Fermi level ($N(\epsilon_F)$) with respect to smearing σ , depends on Gaussian,

$$G(\Delta, \sigma) = \frac{1}{\sigma^2} \exp \left[-\frac{(\epsilon_{n\mathbf{k}} - \epsilon_F)^2 + (\epsilon_{m\mathbf{k}+\mathbf{q}} - \epsilon_F)^2}{\sigma^2} \right] \sim \frac{1}{\sigma^2} \exp \left[-\frac{\Delta^2}{\sigma^2} \right] \quad (9)$$

with $\Delta^2 \sim (\epsilon_{n\mathbf{k}} - \epsilon_F)^2 + (\epsilon_{m\mathbf{k}+\mathbf{q}} - \epsilon_F)^2$ also depends on σ . Despite of dependency of λ on EPC matrix ($\langle g^2 \rangle$) and phonon frequency ($\langle \omega^2 \rangle$) terms, the variation in λ is largely guided by the variation in $N(\epsilon_F)$ or the Gaussian term G . Fig. S8(a)(a) shows the variation of G with respect to smearing σ for different values of Δ , assuming Δ independent of σ . The effect of σ on G dictates the variation of λ and hence T_c , with Δ depends on the materials as well as on size of the grid to compute double delta integration. A larger Δ represents more states contributing towards the double delta summation within space around the Fermi-level spanned by σ . In other word, Δ will increase with σ if the density of states has local maximum close to the Fermi-level, and the variation of EPC properties will be similar to the Gaussian plots corresponding to $\Delta \geq 0.05$. For Niobium, the variation of EPC properties with respect to σ follows similar to blue-dashed curve corresponding to $\Delta = 0.01$ [3], whereas for MgB_2 , the variation follows the Gaussian corresponding to $\Delta < 0.01$. For $\sigma \rightarrow 0$ and $\Delta \rightarrow 0$, if $\frac{\Delta}{\sigma} \leq 1$ the Gaussian function recovers the delta function, while for $\frac{\Delta}{\sigma} \geq 1$ the Gaussian drops to zero similar to $\Delta \geq 0.01$ cases. Our primary focus is more on exponentially decaying cases.

The effect of smearing σ on ω_{log} is insignificant compared to $N(\epsilon_F)$ or λ [2]. According to the Bardeen–Cooper–Schrieffer (BCS) theory [6],

$$T_c \sim \Theta_D \exp(-1/\lambda) \sim \Theta_D \exp\left(-\frac{1}{N(\epsilon_F)U}\right) \quad (10)$$

where Θ_D is the Debye cutoff energy and U is electron-phonon coupling potential. One can established the relation between λ or T_c on σ as $\lambda \sim 1/\sigma^\alpha$ and $T_c \sim \Theta_D \exp(-1/\lambda) = \exp(-A\sigma^\alpha + B)$ with $\Theta_D \sim \exp(B) \times \text{constant}$. Here parameter α is a constant with a positive value if T_c decreases with increasing σ and becomes negative otherwise. Here A and B are constants to be determined with A denoting the coefficient of exponential increase (for negative A) or decrease (for positive A) of T_c with respect to σ . To determine the value of these constants, we perform linear-fit of $\log T_c$ vs σ^α for different \mathbf{k} - grids for MgB_2 , which is frequently studied both theoretically as well as experimentally and often challenging to obtain the converged SC properties [7–9]. Furthermore, one can capture the behavior of T_c vs σ for a wide range of T_c using MgB_2 , as shown in Fig. S8(a)(b). We utilize a smaller \mathbf{k} -mesh of $6 \times 6 \times 4$ and a slightly larger \mathbf{k}' -grid of $8 \times 8 \times 6$ for comparison [Fig. S8(a)(b) and (c)].

Fig. S8(a) (b) represents the variation of T_c with respect to σ , while Fig. S8(a) (c) presents $\log T_c$ vs σ^α plot. It exhibits nearly linear behavior up to $\sigma = 0.05$ Ry, i.e. $\sigma^{1/3} = 0.37$, after which it deviates from linearity. The linear-fit has optimal coefficient of determination score (R^2 -score) for $\alpha < 0.5$ on $\log T_c$ vs σ^α data for \mathbf{k} (charge density and EPC)- \mathbf{q} (Phonon and EPC)- $2\mathbf{k}$ (interpolating EPC matrix) grids (Fig. S8(a) (c)) [Table within the Fig. S8(a)(c)]. Therefore, we chose $\alpha = 1/3$ in this work with R^2 -score of 0.9987. Besides different choice of α leads to different values of A and B , it doesn't have a significant role. For coarse grid, the T_c has a larger dependency on σ and shows larger exponential decay, compared to more converged calculations on denser grids. The exponential decay parameter “ A ” decreases from 19 to 10 with grids changing from coarse to dense one. This analysis suggests that $A_{\text{MgB}_2} = 12\text{--}13$ can be used as a cutoff for this work, the calculations can be considered unconverged for $A > A_{\text{MgB}_2}$, while the calculations can be considered converged for $A < A_{\text{MgB}_2}$ for accurate predictions. Fig. S8(a)(d) shows the convergence of the T_c with respect to \mathbf{q} -point mesh, keeping \mathbf{k} -grid fixed at $12 \times 12 \times 12$. A \mathbf{q} -point grid as half as that of the ground-state \mathbf{k} -point grid is sufficient to provide the converged results for MgB_2 . Fig. S8(a) (e) represents the spectral functions for various grids with $\mathbf{k}=8 \times 8 \times 6$. Denser grid ($2\mathbf{k}$) slightly blue shifts the spectral function peaks at lower frequency range (15.5-16.5 THz), while peaks at higher frequency ranges (20-22.5 THz) remain unaffected. This results slight change in λ from 0.78 to 0.72 and T_c changing from 20 K to 15-16 K [Figs. S1-S5]. A λ of 0.78 agrees with previous theoretical value of ~ 0.75 from anisotropic Migdal-Eliashberg calculation using $\mu^* = 0.16$ [5], $\lambda = 0.71$ from fully anisotropic SCDFE [10], and $\lambda = 0.73$ from previous isotropic Eliashberg approximation [11] at slightly larger $\sigma = 0.015$ Ry. This indicates a \mathbf{k} -grid obtained from MP database with $\sigma = 0.01$ Ry already provide converged results in the case of MgB_2 . However, it is not always the case for other materials. Based on these results, parameters $\sigma = 0.01$ Ry with $\mu_c^* = 0.16$ seems to be reasonable choice for smearing with $8 \times 8 \times 6$ to $16 \times 16 \times 12$ \mathbf{k} -grids for MgB_2 , and for other systems for the sake of comparison. These parameters could also depend on pseudopotentials. In order to achieve converged results, it is necessary to use denser \mathbf{k} - and \mathbf{q} -grids. Subsequently, a double-delta integration should be performed, selecting the results that correspond to the limit of $\sigma \rightarrow 0$. Other details convergence tests of MgB_2 with respect to Brillouin-zone sampling are presented in Figs. S2-S7.

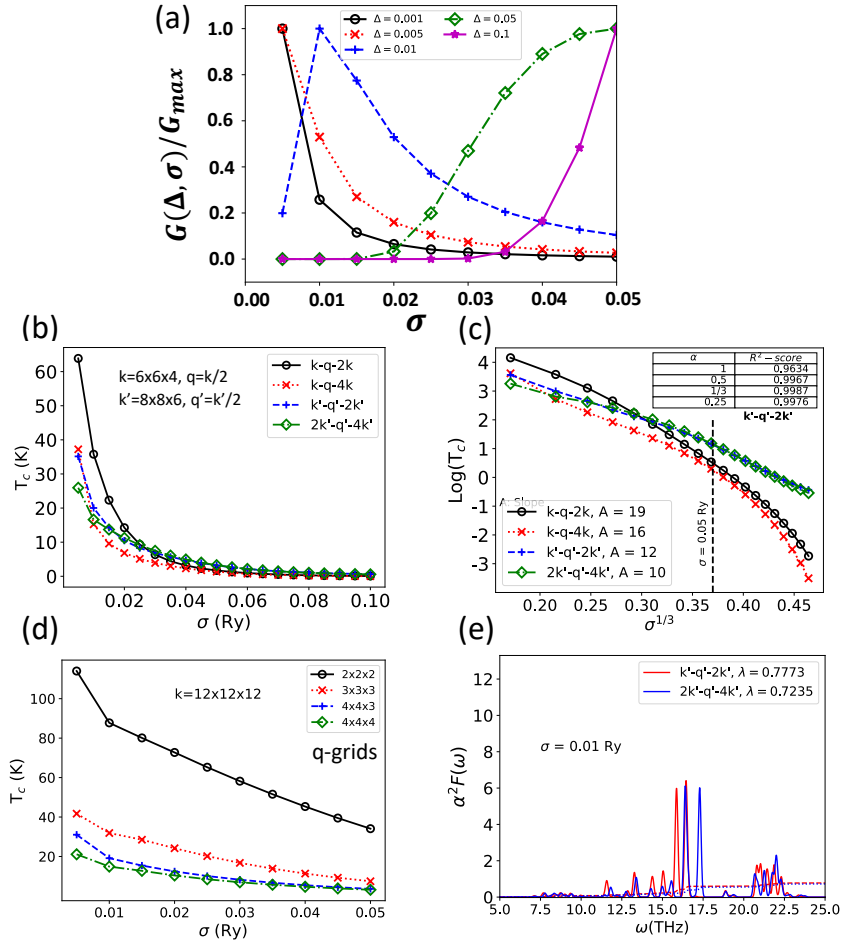

FIG. S8(a): (a) Variation of $\frac{G(\Delta, \sigma)}{G_{max}}$ with respect to σ for different values of Δ ; G_{max} being the maximum value of Gaussian for corresponding Δ within the value of σ from 0.005 Ry to 0.05 Ry. (b) T_c vs σ for various \mathbf{k} -grids for MgB₂. \mathbf{k} - \mathbf{q} - $2\mathbf{k}$ represents \mathbf{k} -mesh for self-consistent calculation for charge density and EPC, \mathbf{q} -mesh for phonon and EPC, and $2\mathbf{k}$ -mesh represents fine grid used for interpolating EPC matrix obtained from \mathbf{k} and \mathbf{q} -grids; \mathbf{k} and \mathbf{k}' respectively are $6 \times 6 \times 4$ and $8 \times 8 \times 6$. (c) $\log T_c$ vs $\sigma^{1/3}$ plot; Linear-fit is performed for data up to $\sigma = 0.05$ Rydberg (denoted by vertical dashed line), after which lines change slope; $\alpha = 1/3$ fits with an optimal coefficient of determination (R^2 -score) (Table inside plot); Fitting parameter “A” decreases from 19 to 10 as \mathbf{k} -grid change from coarse to dense; (d) T_c vs σ for various \mathbf{q} -grids keeping \mathbf{k} -grid fixed at $12 \times 12 \times 12$. (e) Spectral function $\alpha^2 F(\omega)$ vs ω plots with $\sigma = 0.01$ Ry with \mathbf{k} -grid of $8 \times 8 \times 6$.

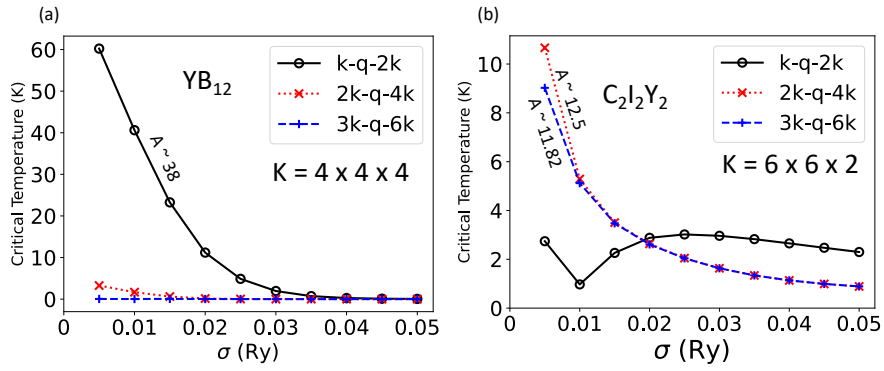

FIG. S8(b): T_c vs σ for various \mathbf{k} - grids; (a) for YB_{12} and (b) for $\text{C}_2\text{I}_2\text{Y}_2$.

In Fig. S8(b), we show two cases of YB_{12} and $\text{C}_2\text{I}_2\text{Y}_2$ in which the coarse \mathbf{k} - grids from Materials Project and fine \mathbf{k} - grid only twice of that result to qualitatively inaccurate results, unusually high T_c for the former while predicting negligible T_c for the latter. With coarse grids, the exponential decay parameter of YB_{12} is around 38, much larger than the critical value estimated for MgB_2 ($A_{\text{MgB}_2} \sim 12$). Increasing \mathbf{k} -mesh grids two times in each direction, T_c drops from 40.6 K to 1.67 K at $\sigma = 0.01$ Ry and drops to almost zero for $\sigma > 0.01$ Ry indicating non-superconductor, which is in good agreement with the experiment [12]. We found a couple of cases such as $\text{C}_2\text{I}_2\text{Y}_2$ when T_c first decreases and increases later with σ (we set $A = 0$ in Fig. S10). Such behavior hasn't been observed in $G(\Delta, \sigma)$ vs σ plots for a wide range of Δ (Fig. 8(a) of the main text). The coarse grids result to a very low T_c of 0.97 K for $\text{C}_2\text{I}_2\text{Y}_2$. However, the denser mesh corrects the behavior with an exponential decay parameter of 12.5 much closer to the reference value of MgB_2 . Also, the critical temperature T_c improves to 5.29 K agreeing much more strongly to the experiment [13]. Note that, this analysis only works for compounds with non-zero T_c for a wide range of σ . For $T_c < \sim 1$ K at $\sigma = 0.01$ Ry (computational details for choosing $\sigma = 0.01$ Ry), $T_c < 0.1$ K for $\sigma > 0.01$ Ry, and rapidly drops to zero for larger σ , we identify the compound to be non-superconducting with the value of A as zero ($A = 0 < A_{\text{MgB}_2}$, already converged). To summarize the ansatz, we present a simple schematics of the process shown as in Fig. S9.

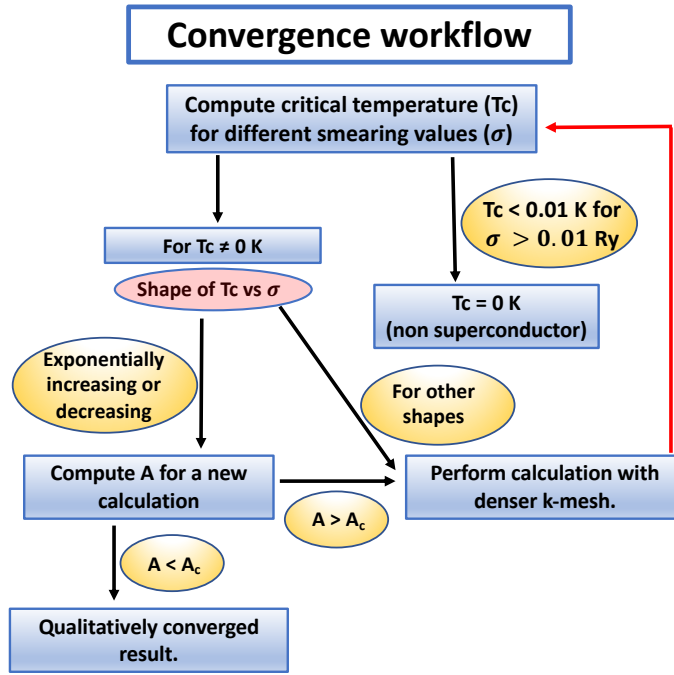

FIG. S9: Schematics of the convergence testing procedure explained in the main text. A_c is the value of the decay parameter computed for MgB_2 . First, we compute T_c for different values of σ . If the variation of T_c with σ decreases exponentially, we compute A . If $A < A_c$, then the results have converged. If the variation increases exponentially and $A < 0$, satisfying $A < A_c$, the results are also considered converged. If $A > A_c$ or if the variation follows a different pattern, the calculations are repeated with a denser k-mesh. If T_c decreases extremely rapidly with increasing σ , then the material is considered a non-superconductor.

TABLE ST3: Comparing results between coarse and fine grids for compounds with $A > A_{MgB_2}$; T_c^{eff} is the critical temperature calculated from efficient EPC calculations, using \mathbf{k} -point mesh grid from MP database; T_c^{Corr} is the critical temperature calculated using denser \mathbf{k} -point mesh and fine \mathbf{k} - mesh grids (2 times of MP database \mathbf{K} -point mesh), while \mathbf{q} -grid is kept fixed;

Compound	T_c^{eff} (K)	T_c^{Corr} (K)	T_c^{Expt} (K)

Next, we present results obtained from EPC calculations for 113 known boron and carbon superconducting ($N = 53$) and non-superconducting ($N = 60$) compounds from SuperCon database [36]. Fig. S10 represents the distribution of T_c with respect to exponential decay parameter A for efficient calculations for $\sigma = 0.01$ Ry with $\mu_c^* = 0.16$. Based on the convergence check ansatz, we found that around 15 % (NoConv) of the results are not fully converged, while 70 % of them are qualitatively inaccurate (NoConv-False), compared to available experimental results. Similarly, we have 12 % of cases that have $A < A_{MgB_2}$ with qualitatively inaccurate predictions (Conv-False), which could be attributed from either inaccuracy of approximations to compute T_c or inaccuracies within available experimental results. This work not only addresses the 15 % (NoConv) cases but also assists in validating true (Conv-True) results.

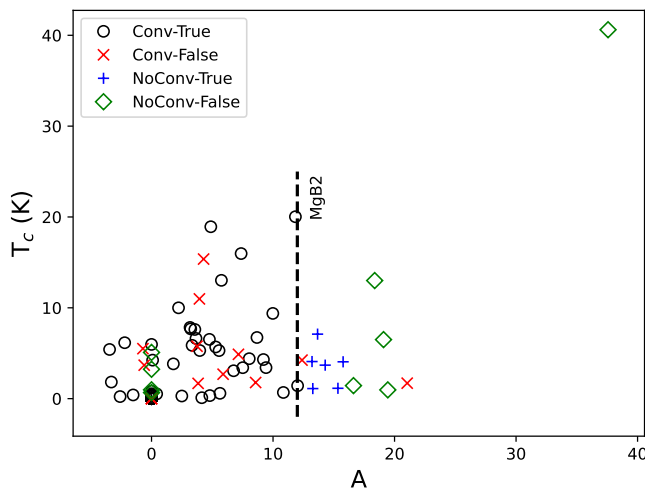

FIG. S10: Critical temperature T_c vs exponential decay parameter (A) plot; Black open circle and red cross symbols represent converged ($A < A_{MgB_2}$) true and false predictions respectively; Blue plus and green diamond symbols represent unconverged ($A > A_{MgB_2}$) true and false predictions respectively; A vertical dashed line at $A = 12$ represents the MgB_2 result; When T_c doesn't exponentially decay or increase with σ (parabolic in nature, first decrease and increase later), those results are simply identified as unconverged, and presented in the plot with $A = 0$; With denser grids, these results of parabolic T_c vs σ nature changes to exponential decay.

We present a few qualitatively inaccurate predictions with $A > A_{MgB_2}$ and improved results with a denser grid in Table ST3, while Table ST4 shows unaffected results (qualitatively) with denser grids for the cases with $A < A_{MgB_2}$. For example, AlB_2 is predicted to be superconductors with a coarse grid, while it changes to a non-superconductor with a denser grid, consistent with the experimental prediction. Similarly, T_c of superconductors such as $CaNiBN$, $C2I2Y2$, and $C2Cl2Y2$ change from below 1 K (non-superconductor) to a larger value, and show a better agreement with the experiment. On the contrary, the qualitative results remain unchanged for converged calculations represented by $A < A_{MgB_2}$, regardless of their agreement with the experimental references.

Application of convergence ansatz on known compounds of SuperCon

In this section, we compare the computed T_c with available experimental results, as shown in Fig. S11 for efficient EPC calculations with and without improved data for $A > A_{MgB_2}$ (left panel) and $A < A_{MgB_2}$ (right panel) cases respectively. We also highlight some significantly deviated results with red rectangles for efficient calculations. With improved data, computed critical temperatures T_c have much better agreement compared to the references, as indicated by the red rectangle enclosing more data points (right panel of Fig. S11), compared to the plot on the left. The results obtained from the *ab-initio* calculations demonstrate a notable level of accuracy with the mean absolute error (MAE) of 2.21 K for the critical temperature, compared to experiments, highlighting the reliability and robustness of this ansatz test. This is in comparison to the MAE of 3.18 K observed in efficient calculations. Please note that we have exclusively incorporated DFPT T_c results for systems that are dynamically stable. Despite the general agreement between DFPT and experimental findings, there exist notable discrepancies. Instances like $ZnNi_3C$ (Pm-3m), with a calculated T_c of 15 K, deviate enormously from the experimental values of 0 K [37]. A comparable investigation of $ZnNi_3C$ by Hoffmann *et al.*[38], utilizing different pseudopotentials from the PSEUDODOJO project[39], revealed phonon instabilities in these compounds. Notably, these unstable phonon modes were identified to possess significant mode-resolved EPC strength[40], a finding deserving attention, as we address these concerns in the ‘‘Imaginary Phonon Modes and Superconductivity’’ section. Similarly, Nb_2InC (P6₃/mmc) with a calculated T_c of 0.34 K, VC (Fm-3m) at 20 K, and WB (I4₁/amd) at 18.5 K, present a problematic cases. Experimental T_c measurements stand at 3.2 K [29], 4.3 K [41], and 7.5 K [42] for VC, WB, and Nb_2InC , respectively. These discrepancies can be ascribed to the constraints of both theoretical approaches and experimental procedures. For instance, older experimental investigations initially reported critical temperatures that were later rectified by more recent experiments or vice versa. For instance, in Ref [43], superconductivity below 4.7 K was claimed in certain YB_{12} samples, yet subsequent experiments, such as those in [44], failed to corroborate these findings. Furthermore, employing more sophisticated theoretical methodologies like solving the many-body anisotropic Migdal-Eliashberg equations or utilizing SCDFt to

estimate T_c can significantly enhance the accuracy of calculations compared to isotropic methods. As an illustration, when examining MgB_2 , T_c calculated using isotropic Eliashberg theory falls within the 15-20 K range. However, in Ref. [45], T_c values of 34-42 K were reported over a range of μ^* values, demonstrating the improvement achievable with these advanced techniques.

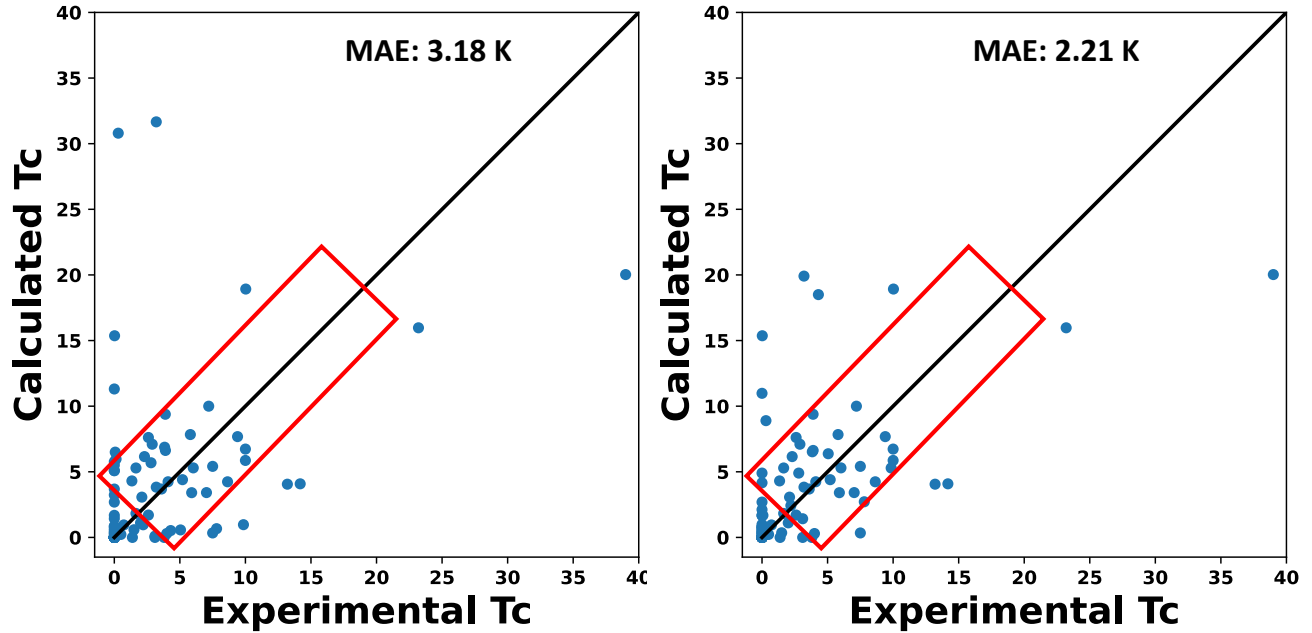

FIG. S11: (a) Comparing calculated and experimental critical temperature obtained from efficient calculations; Some largely deviated results are enclosed within red rectangular box. (b) Same plot with improved results with denser \mathbf{k} - grids for compounds with $A > A_{\text{MgB}_2}$. Red rectangular box on the right plot, enclosed more data points along the $y = x$ axis (dashed line), compared to plot on the left.

In Table ST5, we show some of the inaccurate results predicting nonsuperconductors with 2D \mathbf{q} - grids ($4 \times 4 \times 1$). Emergence of strong el-ph coupling and T_c with denser 3D \mathbf{q} - grid ($3 \times 3 \times 3$) is unlikely for such nonsuperconducting predictions with $T_c < 0.01$ K for $\sigma > 0.01$ Ry [Fig. S9].

TABLE ST5: Comparison of superconducting properties predicting nonsuperconductors that do not agree with the experiments. Denser \mathbf{k} - and \mathbf{q} - grids do not improve the results.
