LETTER TO THE EDITOR

Giant exoplanet composition:

Why do the hydrogen-helium equation of state and interior structure matter?

S. Howard¹, R. Helled¹, and S. Müller¹

Institut für Astrophysik, Universität Zürich, Winterthurerstr. 190, CH8057 Zurich, Switzerland, e-mail: saburo.howard@uzh.ch

ABSTRACT

Context. Revealing the internal composition and structure of giant planets is fundamental for understanding planetary formation. However, the bulk composition can only be inferred through interior models. As a result, advancements in modelling aspects are essential to better characterise the interiors of giant planets.

Aims. We investigate the effects of model assumptions such as the interior structure and the hydrogen-helium (H-He) equation of state (EOS) on the inferred interiors of giant exoplanets.

Methods. We first assess these effects on a few test cases and compare H-He EOSs. We then calculate evolution models and infer the planetary bulk metallicity of 45 warm exoplanets, ranging from 0.1 to 10 *M*^J .

Results. Planets with masses between about 0.2 and 0.6 M_J are most sensitive to the H-He EOS. Updating the H-He EOS reduces the inferred heavy-element mass, with an absolute difference in bulk metallicity of up to 13%. Concentrating heavy elements in a core, rather than distributing them uniformly (and scaling opacities with metallicity), reduces the inferred metallicity (up to 17%). The assumed internal structure, along with its effect on the envelope opacity, has the greatest effect on the inferred composition of massive planets $(M_p > 4 M_J)$. For $M_p > 0.6 M_J$, the observational uncertainties on radii and ages lead to uncertainties in the inferred metallicity (up to 31%) which are larger than the ones associated with the used H-He inferred metallicity (up to 31%) which are larger than the ones associated with the used H-He EOS and the assumed interior structure. However, for planets with $0.2 < M_p < 0.6 M_J$, the theoretical uncertainties are larger.
Conclusions, Advancements in equations of state and our understanding of giant pl

Conclusions. Advancements in equations of state and our understanding of giant planet interior structures combined with accurate measurements of the planetary radius and age are crucial for characterising giant exoplanets.

Key words. planets and satellites: gaseous planets – planets and satellites: interiors – planets and satellites: composition

1. Introduction

Determining the bulk composition and internal structure of giant planets is fundamental for understanding their origin (e.g., [Mordasini et al. 2016;](#page-4-0) [Turrini et al. 2018\)](#page-4-1). Observations of giant exoplanets have advanced significantly and nowadays, not only the planetary mass and radius are measured, but also the atmospheric composition (e.g., [Kreidberg et al. 2014;](#page-4-2) [Madhusudhan](#page-4-3) [et al. 2014;](#page-4-3) [Edwards et al. 2023\)](#page-4-4). However, the bulk composition of giant exoplanets is typically inferred through models, where the planetary structure is constrained by mass, radius and age measurements.

Accurate measurements of the gravitational fields and atmospheric composition of Jupiter and Saturn have led to the development of a more comprehensive theoretical framework for giant planet modelling. Interior models of both Jupiter and Saturn that fit Juno [\(Bolton et al. 2017\)](#page-4-5) and Cassini [\(Spilker 2019\)](#page-4-6) data suggest that the planets have dilute cores and complex interiors [\(Wahl et al. 2017;](#page-4-7) [Mankovich & Fuller 2021;](#page-4-8) [Miguel et al.](#page-4-9) [2022;](#page-4-9) [Howard et al. 2023a;](#page-4-10) [Helled & Stevenson 2024;](#page-4-11) [Howard](#page-4-12) [et al. 2023b;](#page-4-12) [Müller & Helled 2024\)](#page-4-13). In addition, giant planets models strongly depend on our understanding of the hydrogenhelium equation-of-state (H-He EOS) (e.g., [Militzer & Hubbard](#page-4-14) [2013;](#page-4-14) [Chabrier et al. 2019;](#page-4-15) [Howard & Guillot 2023\)](#page-4-16).

As observational uncertainties are progressively being reduced, thanks to ground-based observations (e.g., HARPS [\(Mayor et al. 2003\)](#page-4-17), NIRPS [\(Bouchy et al. 2017\)](#page-4-18), ESPRESSO

[\(Pepe et al. 2021\)](#page-4-19)) and space missions (e.g., Kepler [\(Borucki](#page-4-20) [et al. 2010\)](#page-4-20), TESS [\(Ricker et al. 2015\)](#page-4-21), JWST [\(Gardner et al.](#page-4-22) [2006\)](#page-4-22) and in the future PLATO [\(Rauer et al. 2014\)](#page-4-23), Ariel [\(Tinetti](#page-4-24) [et al. 2018\)](#page-4-24)), it is clear that more advanced models should be used for the characterisation of giant exoplanets. In addition, it is important to identify the theoretical uncertainties and compare them to the observational ones.

Several previous studies have explored the importance of model assumptions such as the interior structure and the EOS on the inferred planetary bulk composition (Baraff[e et al. 2008;](#page-4-25) [Müller et al. 2020;](#page-4-26) [Bloot et al. 2023\)](#page-4-27). In addition, the large sample of observed giant exoplanets with measured radius, mass and age, together with theoretical models allows inferring the relationship between the planetary mass and its metallicity [\(Thorn](#page-4-28)[gren et al. 2016;](#page-4-28) [Müller & Helled 2023\)](#page-4-29). The goal of this work is to further investigate the effects of model assumptions on the inferred internal structures of giant exoplanets. Our models use the most up-to-date H-He EOS, allow for Core+envelope and Fully-mixed interiors, and the opacity scales with the metallicity. We improve upon previous work by systematically studying how the H-He EOS and the distribution of heavy elements affect the inferred bulk composition and mass-metallicity relations.

Our paper is organised as follows. Section [2](#page-1-0) describes our methods. In Sec. [3](#page-1-1) we analyse the effects of the assumed interior structure and hydrogen-helium (H-He) EOS on a few test cases. Section [4](#page-2-0) focuses on a sample of observed exoplanets. Our conclusions are presented in Sec. [5.](#page-3-0)

2. Methods

We used CEPAM [\(Guillot & Morel 1995;](#page-4-30) [Howard et al. 2024\)](#page-4-31) to run planetary evolution models and assess the effects of both the H-He equation-of-state (EOS) and the assumed interior structure (i.e., the distribution of heavy elements). We compared calculations using the SCvH95 [\(Saumon et al. 1995\)](#page-4-32) and the CMS19+HG23 EOSs[\(Chabrier et al. 2019;](#page-4-15) [Howard & Guillot](#page-4-16) [2023\)](#page-4-16). More details about the differences between these EOSs are presented in Sec. [3.](#page-1-1) We also compared models assuming either a "Core+envelope" or "Fully-mixed" structure. In the first structure, all the heavy elements were concentrated in a central core. We used the analytical EOS of [Hubbard & Marley](#page-4-33) [\(1989\)](#page-4-33) to calculate the pressure-dependent density in the isothermal core, which was assumed to be made of 50% ices and 50% rocks. In the second structure, the heavy elements were uniformly distributed within the planet. We also assumed an ice-torock ratio of unity and used the SESAME water EOS for ices and the SESAME drysand EOS for rocks [\(Lyon & Johnson 1992\)](#page-4-34). The hydrogen-to-helium ratio in the envelope was protosolar: $Y/(X + Y) = 0.27$ [\(Asplund et al. 2021\)](#page-4-35). Our models used a nongray atmosphere [\(Parmentier et al. 2015\)](#page-4-36) and the method from [Valencia et al.](#page-4-37) [\(2013\)](#page-4-37) to account for the opacity enhancement due to the heavy elements.

3. Proof of concept: metallicities of synthetic giant planets

We first calculated models of synthetic planets, with masses of 0.3 , 1 and 3 M_J . We focused on planets that are not highly irradiated and hence not inflated (e.g., [Thorngren & Fortney](#page-4-38) [2018;](#page-4-38) [Fortney et al. 2021\)](#page-4-39), with an equilibrium temperature T_{eq} of 500 K. For each planetary mass, we ran models with both H-He EOSs (SCvH95, CMS19+HG23) and internal structures (Core+envelope, Fully-mixed). We assumed different bulk metallicities *Z*, from 0 to 0.5 (*Z* = M_Z/M_p where M_Z and M_p are the total heavy-element mass and the planet's mass, respectively).

Figure [1](#page-1-2) shows the planetary radius vs. time for the different cases. For the Core+envelope structure, CMS19+HG23 always yields smaller radii than SCvH95, by up to 10 % [\(Müller](#page-4-26) [et al.](#page-4-26) [\(2020\)](#page-4-26) found that CMS19 also yields smaller radii). We also find that higher metallicities lead to smaller radii. The range of radii spanned by models with different metallicities is larger for lower-mass planets. For $M_p = 0.3$ M_J , the radius decreases
by about a factor of two when changing Z from 0 to 0.25 while by about a factor of two when changing *Z* from 0 to 0.25, while for $M_{\rm p}$ = 3 $M_{\rm J}$, changing *Z* from 0 to 0.5 changes the radius by only 15%. In the Core+envelope case, for a given measured radius and its associated uncertainty, the range of inferred metallicity is narrower for a 0.3 *M*^J planet compared to a 3 *M*^J planet. In addition, for a given measured radius and its uncertainty, the Core+envelope structure leads to a narrower range of inferred metallicity for a $0.3 M_I$ planet, compared to a Fully-mixed structure. However, the opposite behaviour is expected for a $3 M_{\rm I}$ planet. The comparison between both structures depends on the planetary mass and metallicity.

In the Fully-mixed case, higher metallicities do not always lead to smaller radii. This is because of two opposite effects due to enriching the envelope with heavy elements: it increases both the mean molecular weight and the opacities [\(Guillot 2005\)](#page-4-40). At early times, the opacity effect seems to dominate and delays the cooling and contraction of the planet; but at late times, the mean molecular weight effect wins. [Müller et al.](#page-4-26) [\(2020\)](#page-4-26) also found that the radius is not monotonically decreasing with *Z* if the effect of the heavy elements on the opacity is accounted for. For $M_{\rm p}$ = 0.3 M_J , we find that CMS19+HG23 always yields smaller radii than SCvH95. However, this is not the case for $M_{\odot} = 1$ and than SCvH95. However, this is not the case for $M_p = 1$ and 3 *M*^J . For these two planetary masses, especially at early times, CMS19+HG23 yields larger radii than SCvH95 for *^Z* > 0.

Fig. 1. Radius vs. time for planets with masses of 0.3, 1 and 3 M_J (top, middle, and bottom panels, respectively). Left (right) panels correspond to models assuming a Core+envelope (Fully-mixed) structure. Results with different H-He EOSs are shown with dashed and solid lines. The colors correspond to different assumed metallicities. The middle and bottom panels have similar limits on the y-axis, but not the top panels.

Understanding these results requires investigating the differences between the SCvH95 and CMS19+HG23 EOSs. SCvH95 is based on the so-called chemical picture (see [Saumon et al.](#page-4-32) [1995,](#page-4-32) for a detailed description). It models the interactions between molecules or atoms by using pair-potentials. The Helmholtz free energy is determined through the free-energy minimisation technique and pressure, entropy, or internal energy can then be calculated [\(Hummer & Mihalas 1988\)](#page-4-41). However, at densities corresponding to dissociation and pressure ionisation, pair-potentials fail at correctly describing describing the behaviour of matter. Using the additive volume law, one can obtain the properties (density and entropy at given pressures and temperatures) of a H-He mixture. On the other hand, CMS19+HG23 also applies the additive volume law to combine pure H and He tables from [Chabrier et al.](#page-4-15) [\(2019\)](#page-4-15), while additionally accounting for non-ideal mixing effects as described by [Howard & Guillot](#page-4-16) [\(2023\)](#page-4-16). It accounts for different EOS sources for different regions of the H-He phase diagram using in particular the data from [Militzer & Hubbard](#page-4-14) [\(2013\)](#page-4-14). Based on the physical picture, these *ab initio* calculations focus on electrons and nuclei and model their interactions by Coulomb potentials. [Militzer &](#page-4-14)

[Hubbard](#page-4-14) [\(2013\)](#page-4-14) considered a H-He mixture (in proportions close to protosolar) and provided a more realistic description of the regime of dissociation and ionisation.

Figure [2](#page-2-1) shows the relative difference in density between CMS19+HG23 and SCvH95. We include the *T*-*P* profiles of some models from Fig. [1,](#page-1-2) at 0.1 and 10 Gyr. We calculate the differences assuming a H-He mixture of protosolar composition (He mass fraction of $Y = 0.27$), and interpolate the density from CMS19+HG23 at the pressure and temperature points corresponding to SCvH95. In the region where *ab initio* calculations from [Militzer & Hubbard](#page-4-14) [\(2013\)](#page-4-14) have been performed (dotted black square), the *T*-*P* profiles of our models can go through regions where CMS19+HG23 is denser than SCvH95 (shown in blue) or less dense (shown in red). We note that entropy influences a planet's position on the *T*-*P* diagram by affecting the calculation of the adiabatic gradient. The density differences between the EOSs under these *T*-*P* conditions then explain the differences in inferred planetary radii.

We find that 1 M_J with $Z = 0.25$ and a Core+envelope structure (solid magenta line) mostly covers the region where CMS19+HG23 is denser than SCvH95 (around 1 Mbar). Interestingly, we find that the *T*-*P* profiles of models assuming the Core+envelope structure are rather similar even the planetary mass or metallicity are changed. This explains why we always found that CMS19+HG23 yielded smaller radii compared to SCvH95 in the Core+envelope case (see left panels of Fig. [1\)](#page-1-2). However, *T*-*P* profiles of Fully-mixed models are more affected by changing the mass and metallicity. These models have a much hotter interior because enhancing the opacities due to heavy-element enrichment in the envelope delays the planetary cooling. The 0.³ *^M*^J model shown in Fig. [2](#page-2-1) (dashed red line) is still in a *T*-*P* regime where CMS19+HG23 is denser than SCvH95, explaining why CMS19+HG23 yielded smaller radii than SCvH95 for $M_p = 0.3$ M_J in the Fully-mixed case (see
top right panel of Fig. 1) The 1 M_J model with $Z = 0.25$ (dashed top right panel of Fig. [1\)](#page-1-2). The 1 M_J model with $Z = 0.25$ (dashed magenta line) goes through the less dense region at 0.1 Gyr but is then mostly affected by the denser region at 10 Gyr. This explains why CMS19+HG23 yielded larger radii at early times and smaller radii at late times (middle right panel of Fig. [1\)](#page-1-2). Overall, the differences in radii between CMS19+HG23 and SCvH95 seen in Fig. [1,](#page-1-2) depend on the position of the planet within the temperature-pressure-density space during its evolution. As CMS19+HG23 models the regime of dissociation and ionisation more accurately, this H-He EOS should be used for exoplanet characterisation.

4. Inferred metallicities of observed giant exoplanets

In this section we characterised a sample of observed giant exoplanets. We used the PlanetS catalog [\(Otegi et al. 2020;](#page-4-42) [Parc](#page-4-43) [et al. 2024\)](#page-4-43) and selected planets with masses from 0.1 to 10 *M*^J with relative measurement uncertainties smaller than 10 and 8% for the mass and radius, respectively. We selected planets with T_{eq} < 1000 K and with an age estimate. We ended up with a sample of 45 exoplanets that allowed a reliable determination of the internal composition. The planets in our sample are listed in Appendix [A.](#page-5-0)

For each exoplanet, we inferred the heavy-element mass (M_Z) by calculating two evolution models which fit the upper and lower bounds of the radius and age measurements $(R_{obs}^{min}, age_{obs}^{min}$ and $R_{obs}^{max}, age_{obs}^{max}$, listed in Table [A.1\)](#page-6-0). This pro-
vided the possible range of the inferred bulk metallicity $(Z_{-}$ vided the possible range of the inferred bulk metallicity (Z_p =

Fig. 2. Relative difference in density between the CMS19+HG23 [\(Chabrier et al. 2019;](#page-4-15) [Howard & Guillot 2023\)](#page-4-16) and SCvH95 [\(Saumon](#page-4-32) [et al. 1995\)](#page-4-32) EOSs. Blue regions on the *T*-*P* diagram indicate where CMS19+HG23 is denser than SCvH95, while red regions highlight less dense areas. The coloured solid and dashed lines show *T*-*P* profiles of some models (using CMS19+HG23) from Fig. [1,](#page-1-2) at 0.1 or 10 Gyr. The dotted square indicates the region of the *ab initio* presented by [Militzer](#page-4-14) [& Hubbard](#page-4-14) [\(2013\)](#page-4-14). The CMS19+HG23 EOS is more accurate in this region. The hashed area corresponds to the region where hydrogen becomes solid (see e.g., [Chabrier et al. 2019\)](#page-4-15).

 M_Z/M_p). The inferred heavy-element mass for our sample of exoplanets is shown in Fig. [3](#page-3-1) (top panels). We also show the absolute difference in the inferred heavy-element mass (ΔM_Z) between both EOSs (middle panels) as well as the absolute difference in the bulk metallicity ($\Delta Z_p = \Delta M_Z/M_p$) (bottom panels).

For the Core+envelope case, we find that: (i) CMS19+HG23 yields a lower heavy-element mass than SCvH95 for all planets. (ii) ΔM_Z increases with M_p in the range from $M_p = 0.1$ M_J to $M_a = 1$ M_u after which it reaches a plateau at $\Delta M_z \sim 15$ M_a $M_{\rm p}$ = 1 $M_{\rm J}$, after which it reaches a plateau at $\Delta M_{\rm Z} \sim 15 M_{\oplus}$ for planets with masses larger than 1 M_J . (iii) ΔZ_p peaks at $M_p = 0.3 M_J$, with a value of ~11%. In the Fully-mixed case, we find that: (i) CMS19+HG23 also vields a lower heavy-element find that: (i) CMS19+HG23 also yields a lower heavy-element mass than SCvH95 except for six planets. This includes the two most massive planets from our sample, as expected (see Sec. [3\)](#page-1-1). (ii) The variation of ΔM_Z is similar to the Core+envelope case. However, there is greater scatter from $M_p > 1 M_J$. (iii) ΔZ_p peaks at $M_p = 0.4 M_t$, with a maximum value of about 13% at $M_p = 0.4$ M_J , with a maximum value of about 13%.
We find that the inferred bulk metallicity of pla

We find that the inferred bulk metallicity of planets with masses between 0.2 and 0.6 M_J is most affected by the H-He EOS update. This holds for both interior structures and the abso-EOS update. This holds for both interior structures and the absolute difference in bulk metallicity can go up to 13%. This is due to how the planets lie in the temperature-pressure-density space (Fig. [2\)](#page-2-1). Planets with $M_p < 0.2$ M_J are less affected by changing the H-He EOS as they only have a small amount of H-He. We also note that CMS19+HG23 leads to eight additional planets (compared to SCvH95) for which the lower limit of the inferred heavy element mass is zero (in Table [A.1,](#page-6-0) planets with a single dagger). For these planets, the radius inferred from a pure H-He model cannot match the upper bound of the measured radius suggesting that these planets may be inflated.

We next compare the heavy-element content obtained with the Core+envelope and Fully-mixed structures, using CMS19+HG23 since it is the better EOS for modelling planets. This time, we show the mass-metallicity relation by calculating the ratio of the planet metallicity Z_{planet} to that of the par-

Fig. 3. Inferred heavy-element mass vs. planetary mass. *Top panels*: comparison of the results obtained with CMS19+HG23 and SCvH95, for both Core+envelope and Fully-mixed structures. The circles represent the midpoint between the upper and lower bounds of the errorbars. *Middle panels*: absolute difference in heavy-element mass due to the H-He EOS update. *Bottom panels*: absolute difference in bulk metallicity. Empty circles correspond to planets for which CMS19+HG23 leads to a higher metallicity than SCvH95. The black dotted line shows the 1/*M*^p curve.

ent star *Z*_{star}. We follow [Müller & Helled](#page-4-29) [\(2023\)](#page-4-29) and perform a Bayesian linear regression. The parameters α and β of the powerlaw $Z_{\text{planet}}/Z_{\text{star}} = \beta \times M[M_J]^{\alpha}$ are estimated using a Markov
chain Monte Carlo (MCMC) method and their posterior districhain Monte Carlo (MCMC) method and their posterior distributions are shown in Appendix [B.](#page-7-0) Figure [4](#page-4-44) (top panel) shows for both structures the best fit as well as the 1σ error contour.

In the Fully-mixed case, we find α = −0.37 ± 0.07 and $\beta = 8.61 \pm 0.88$. The mass-metallicity relation we obtain with the Fully-mixed structure is in line (within 1σ) with [Müller &](#page-4-29) [Helled](#page-4-29) [\(2023\)](#page-4-29) who found $\alpha = -0.37 \pm 0.14$ and $\beta = 7.85 \pm 1.49$, using CMS19. They considered opacity scaling with metallicity (with a different method than this work) and assumed a core with an enriched envelope for planets below 5 *M*^J , while adopting a Fully-mixed structure for those exceeding 5 M_J . The relation is also in rather good agreement with [Thorngren et al.](#page-4-28) [\(2016\)](#page-4-28) who found $\alpha = -0.45 \pm 0.09$ and $\beta = 9.70 \pm 1.28$, using SCvH95. They did not account for opacity enhancement and adopted a hybrid approach with a 10 M_{\oplus} core and the rest of the heavy elements in the envelope. However, the mass-metallicity relation we obtain with the Core+envelope structure is steeper. We find α = -0.57 ± 0.13 and β = 5.09 \pm 0.95. The Core+envelope structure yields lower metallicities for 36 out of 42 planets (blue squares, middle panel of Fig. [4\)](#page-4-44). For the six other planets, the Fully-mixed structure yields lower metallicities (orange squares), and especially for massive planets ($M_p > 4 M_J$). Fullymixed models require more heavy elements, as their contraction is delayed by the opacity enhancement resulting from the enriched envelope (see Sec. [3\)](#page-1-1). However, the lack of planets with high masses ($M_p > 5$ M_J) and the inability to find solutions for the two heaviest planets under the Core+envelope structure may impact the results and contribute to a steeper mass-metallicity relation. Furthermore, the Fully-mixed case is expected to be more representative of massive planets [\(Thorngren et al. 2016;](#page-4-28) [Müller](#page-4-45) [& Helled 2021\)](#page-4-45). Further discussion about the mass-metallicity relation is given in Appendix [C.](#page-8-0)

We next focus on the absolute difference in bulk metallicity ∆*Z*^p for different model assumptions. We find that ∆*Z*^p can go up to 17% due to the assumed interior structure and go up to 13% due to the H-He EOS update (middle panel of Fig. [4\)](#page-4-44). Overall, the interior structure and the H-He EOS seem to have comparable effects on the inferred planetary metallicity. Only for $M_p > 4$ M_J , the interior structure has a significantly larger
effect on the inferred metallicity than the H-He FOS. We then effect on the inferred metallicity than the H-He EOS. We then sum the effects of both the H-He EOS and the interior structure (pink dots, bottom panel) and compare it to the inferred range of metallicity (black triangles) that arises from the uncertainty in the measured radii and ages. This uncertainty range corresponds to the length of the errorbars shown on the top panel and is defined as $Z_p(R_{\text{obs}}^{\text{min}}, age_{\text{obs}}^{\text{min}}) - Z_p(R_{\text{obs}}^{\text{max}}, age_{\text{obs}}^{\text{max}})$. It can reach up to 31% Currently for most planets with $M_{\text{max}} > 0.6 M_t$, the un-31%. Currently, for most planets with $\overline{M}_{p} > 0.6$ $M_{\rm J}$, the uncertainties on radii and ages lead to uncertainties in the inferred certainties on radii and ages lead to uncertainties in the inferred metallicity larger than the ones associated with the used H-He EOS and the assumed interior structure. However, for planets with masses between 0.2 and 0.6 M_J the theoretical uncertainties are larger. As a result great caution should be taken when ties are larger. As a result, great caution should be taken when characterizing intermediate-mass giant planets. In addition, as future measurements are expected to have smaller uncertainties, the details of the theoretical modelling should be considered for all giant planets.

5. Conclusions

Using a sample of 45 warm giant exoplanets, ranging from 0.1 to 10 *M*^J , we investigated the effects of the used H-He EOS and assumed internal structure on the inferred planetary bulk composition. These assumptions are important because there is an interplay between the internal structure which defines the planet's *T*-*P* profile and its thermodynamical properties (e.g., density, entropy) that are calculated from the EOSs (Fig. [2\)](#page-2-1). Our main conclusions are:

- 1. Planets with $0.2 < M_{\rm p} < 0.6 M_{\rm J}$ are most sensitive to the H-He EOS. Using the CMS19+HG23 EOS rather than SCvH95 reduces the inferred planetary bulk metallicity. The corresponding absolute difference can reach up to 13%.
- 2. Assuming a Core+envelope rather than a Fully-mixed structure reduces the inferred bulk metallicity. The absolute difference can go up to 17%. For massive planets $(M_p > 4 M_J)$,

Fig. 4. Mass-metallicity relation with both interior structures, using the CMS19+HG23 EOS. *Top panel*: errorbars show the inferred range of bulk metallicity with the Core+envelope (blue) or Fully-mixed (orange) structure, as in Fig. [3.](#page-3-1) Orange and blue solid lines show the best fit for both cases. The shaded areas show the 1σ error contour around the best fit. The metallicities of Jupiter and Saturn [\(Helled & Howard 2024\)](#page-4-46) are shown in black. The solid and dashed gray lines show the best fits from [Müller & Helled](#page-4-29) [\(2023\)](#page-4-29) and [Thorngren et al.](#page-4-28) [\(2016\)](#page-4-28), respectively. The star metallicities have been calculated using the solar value from [Asplund et al.](#page-4-35) [\(2021\)](#page-4-35). *Middle panel*: absolute difference in metallicity due to either the H-He EOS (gray dots, taken from Fig. [3\)](#page-3-1) or the interior structure (squares). Blue (orange) squares correspond to planets for which the Core+envelope case leads to a lower (higher) metallicity than the Fully-mixed case. *Bottom panel*: absolute difference in metallicity. Pink dots show the sum of the H-He EOS and the interior structure effects. Black triangles show the range of metallicity inferred from observational uncertainties (radius and age).

this choice of internal structure, along with its effect on the envelope opacity, has a greater effect than the H-He EOS.

- 3. For $M_p > 0.6 M_J$, the observational uncertainties on radii and ages lead to uncertainties in the inferred metallicity (up to ages lead to uncertainties in the inferred metallicity (up to 31%) which are larger than the ones associated with the used H-He EOS and the assumed interior structure. However, for planets with $0.2 < M_{\rm p} < 0.6 M_{\rm J}$, the theoretical uncertainties are larger are larger.
- 4. Using CMS19+HG23 and assuming a Core+envelope structure generally yield lower metallicities for most exoplanets. There are a few exceptions, especially when $M_p > 4 M_J$, for which a higher metallicity can be inferred (due to the planwhich a higher metallicity can be inferred (due to the planets' position within the temperature-pressure-density space during its evolution, Fig. [2\)](#page-2-1).

In this work, we modelled planets with either Core+envelope or Fully-mixed structures. However, in reality, the internal structures of giant planets may be more complex including fuzzy cores and composition gradients. As a result, our models should be viewed as the two limiting cases and future work should include more sophisticated internal structures. Interestingly, if giant exoplanets have non-homogeneous structures, the atmospheric composition does not represent the planetary bulk composition [\(Knierim & Helled 2024\)](#page-4-47). Indeed, [Swain et al.](#page-4-48) [\(2024\)](#page-4-48)

suggested that the discrepancy between the mass-metallicty relation based on atmospheric measurements and the one inferred from interior models may indicate the presence of composition gradients.

A better characterisation of giant exoplanets is expected from several fronts. First, improved experimental and theoretical research can refine the EOSs for H-He, heavy elements, and their mixtures as well as phase separations. Second, a deeper understanding of Jupiter and Saturn reveals information on the fundamental properties of gas giant planets. Third, upcoming space missions will provide accurate measurements of the planetary mass, radius and age (Plato) and determine the atmospheric compositions (Ariel) to further constrain the interiors of exoplanets. Overall, combining these different avenues will not only expand our understanding of distant gas giants but also enrich our comprehension of our own planetary system.

Appendix A: Sample of exoplanets

Table [A.1](#page-6-0) lists the sample of exoplanets studied in Sec. [4.](#page-2-0) We used the PlanetS catalog [\(Otegi et al. 2020;](#page-4-42) [Parc et al. 2024\)](#page-4-43) and selected planets with masses from 0.1 to 10 M_J which have relative measurement uncertainties on the mass and radius smaller than 10 and 8%, respectively. We selected planets with T_{eq} < 1000 K and with an age estimate. In Sec. [4,](#page-2-0) we mention that our sample includes 45 planets. We note that our sample initially included 4 additional planets (shown in bold in the table). However, the lower bound of their measured radius could not even be matched with a pure H-He model (for both EOSs). [Müller et al.](#page-4-26) [\(2020\)](#page-4-26) already reported 6 planets from the [Thorn](#page-4-28)[gren et al.](#page-4-28) [\(2016\)](#page-4-28) sample with a similar issue. This may warrant further investigation in the future.

Notes. $\dot{\bar{z}}$ indicates planets for which a model fully made of H-He cannot match the upper bound of the measured radius, for both EOSs. $\dot{\bar{z}}$ is similar but when only $CMS19+HG23$ does not match the upper bound. $_{\rm fm}$ indicates planets for which solutions have been found only with the Fully-mixed case. _{ce} indicates planets for which solutions have been found only with the core+envelope case. * indicates that the age was adapted so that the upper bound does not exceed the age of the galaxy. Planets shown in bold have not been considered in our analysis (see text in Appendix [A\)](#page-5-0).

Appendix B: Sampling

Figures [B.1](#page-7-1) and [B.2](#page-7-2) show the posteriors distributions of the parameters α and β of the power-law $Z_{\text{planet}}/Z_{\text{star}} = \beta \times M[M_{\text{J}}]^{\alpha}$, derived in Sec. 4 derived in Sec. [4.](#page-2-0)

Fig. B.1. Posterior distributions of the parameters α and β in the Core+envelope case.

Fig. B.2. Posterior distributions of the parameters α and β in the Fullymixed case.

Appendix C: The mass-metallicity relation

Figure [C.1](#page-8-1) shows the mass-metallicity relations obtained when considering a different planetary mass range and well as a smaller sample with more accurate measurements. In Sec. [4,](#page-2-0) we presented the mass-metallicity relation obtained for the Core+envelope (CE) and Fully-mixed (FM) structures, using CMS19+HG23 and the full range of planetary masses (from 0.1 to 10 M_J). We found the following values for the parameters α and β of the power-law $Z_{\text{planet}}/Z_{\text{star}} = \beta \times M[M_{\text{J}}]^{\alpha}$:
 $\alpha = -0.37 + 0.07$ and $\beta = 8.61 + 0.88$ in the FM case and α = -0.37 ± 0.07 and β = 8.61 ± 0.88 in the FM case and $\alpha = -0.57 \pm 0.13$ and $\beta = 5.09 \pm 0.95$ in the CE case.

First we use a tighter range of planetary masses that correspond to the giant planet regime, with masses between 0.2 and 2 M_J [\(Helled 2023\)](#page-4-49). For this range we now find: $\alpha = -0.379 \pm 1.00$ 0.16 and $\beta = 7.81 \pm 1.28$ in the FM case and $\alpha = -0.48 \pm 0.24$ and $\beta = 4.72 \pm 1.21$ in the CE case. While the slope of the massmetallicity relation has not changed in the FM case, it has decreased in the CE case. Overall, with both internal structures, the inferred planetary bulk metallicities are lower than those inferred when considering the full range of planetary masses.

Second, we derived the mass-metallicity relation for the larger mass range as presented in the main text, but considering only planets with a relative error in their observed radius smaller than 3%. 24 planets from our sample meet this criterion. This time, we find: $\alpha = -0.39 \pm 0.11$ and $\beta = 7.15 \pm 1.18$ in the FM case and $\alpha = -0.60 \pm 0.23$ and $\beta = 4.12 \pm 1.24$ in the CE case. For both internal structures, the slope of these relations remained similar. However, the inferred bulk metallicities are lower than those obtained when considering also planets with larger measurement uncertainties in the planetary radius ($\sigma_R/R < 8\%$).

The analysis presented in this appendix demonstrates the importance of the chosen sample in inferring the mass-metallicity relation. As a result, caution should be taken when comparing relations inferred by different studies. In addition, it is also clear that having more planets with small measurement uncertainties

CNSI 91+HCC2 and The total range of planetary masses. (Form and product the internet of the planetary and the investigation of trends in exoplanetary data. The investigation of the planetary and $\sigma = 0.57 + 0.13$ and $\beta =$ Fig. C.1. *Top panel*: Mass-metallicity relation considering different planetary mass ranges. Orange and blue solid lines show the best fit for the Fully-mixed (FM) and Core+envelope (CE) cases when considering planets of masses between only 0.2 and 2 M_J . The shaded areas show the 1σ error contour around the best fit. The relations previously obtained (see Sec. [4\)](#page-2-0) when considering the full range of planetary masses (from 0.1 to 10 $M_{\rm J}$) are shown with dotted lines. The metallicities of Jupiter and Saturn [\(Helled & Howard 2024\)](#page-4-46) are shown in black. *Bottom panel*: Mass-metallicity relation considering different precision on observed radius. Orange and blue solid lines show the best fit for the Fully-mixed (FM) and Core+envelope (CE) cases when only considering planets with relative uncertainties on radii which are less than 3%. The previously obtained relations, shown with dotted lines, include planets with an uncertainty on radius of up to 8%.
