Matching Design with Sufficiency and Applications to Child Welfare

Terence Highsmith II¹

Version: December 4, 2024

Abstract

In many local foster care systems across the United States, child welfare practitioners struggle to effectively match children in need of a home to foster families. We tackle this problem while navigating a key sensitivity in this domain: in foster care systems, individual caseworkers must assent to any proposed matching. We codify this constraint in one-sided matching markets as the problem of matching design with sufficiency. We design a mechanism that guarantees outcome sufficiency, a form of welfare-maximizing Pareto efficiency ensuring that no caseworker can ex-post gain from any child-family placement reassignment and that the foster care authority's objective preferences for child-family placements are maximally satisfied. Our work subsequently evaluates this mechanism's strategic properties. Finally, we plan to conduct a lab-in-the-field experiment to elicit real-world caseworkers' preferences and estimate the child welfare gains our algorithm produces. Current simulation-based results show dramatic improvements to welfare. Designing sufficient matching systems is an example of mechanism-reform because replacing existing systems without regard for existing agents' preferences and wishes has previously resulted in failure. 1 Introduction

In the United States, the foster care system is responsible for caring for children found to be victims of abuse or neglect at the hands of their parents. In 2022, there were 368,530 children in the foster care system (U.S. Children's Bureau 2024). Economists have evaluated numerous policy interventions to improve outcomes in foster care (Bald et al. 2022). However, one critical aspect of foster care has gone unnoticed: how should a child be matched to a temporary foster home?

Existing processes for matching children to foster home are highly varied across U.S. counties, burdened with inefficiencies, and leaves practitioners longing for better systems (Zeijlmans et al. 2016). Therefore, we cannot offer a uniform characterization of a child's journey from her home of origin to a foster home. Instead, we describe a broad generalization. Children that are suspected to be victims of abuse or neglect are often reported to the local child welfare agency by community members. The child welfare agency sends an investigator to the child's home, and, if the investigator substantiates the allegations, then the child is removed from her home. The agency assigns a caseworker to represent the child, and the child can be kept in custody of the county for up to several days before she is matched to a temporary foster home. The caseworker can use various means to search for a suitable match for the child, and this step in the process is the most heterogeneous step across counties. In most counties, caseworkers sequentially decide to match the child that the caseworker represents to the caseworker's most preferred available home, where the order is simply the first (or next) caseworker to initiate matching. We describe this time-ordered serial dictatorship as the "status quo".

One main goal in the matching process is placement stability (Carnochan, Moore, and Austin 2013). A child's placement in a foster home is stable if the child remains in the home until the child is reunified with their home of origin, the foster home permanently adopts the child, or the child ages out of the foster care system. We refer to this as persistence to avoid confusion with the matching theory concept of stability. Persistence is not common¹, and there are widespread efforts to improve persistence for children as more placements are strongly associated with trauma and worse outcomes for youth in foster care. In this paper, we develop matching mechanisms that are appropriate for this child welfare domain, and we do so while navigating a key sensitivity—caseworker approval. Caseworkers representing children have preferences over the homes that a child can be matched to. Often, these preferences can legitimately be in the best interests of the child and encode important, qualitative information that cannot be easily subsumed into algorithms that predict a child's persistence in a home. On the contrary, some caseworkers might have erroneous judgment or bias causing them to systemically choose homes where children will not persist. Nevertheless, the human element in the matching process is essential, and most counties are unwilling—justifiably so—to fully replace caseworkers with algorithms that decide placements. Our largest contribution is to design matching mechanisms that maintain caseworker approval—the status quo—in that every matching that our mechanism produces is the outcome of some serial dictatorship applied to the matching problem. Simultaneously, our mechanism ensures that no child could potentially improve her persistence without harming another child's persistence or some caseworker's preferences.

We model this problem as a standard one-sided matching market where children are strategic agents allocated to homes. Children have ordinal preferences over homes that

¹The average number of placements for a child was 2.56 in 2015; see Robinson-Cortés (2021).

can involve indifference as there can be substantial horizontal differentiation that precludes constructing strict rankings in foster care². We restrict the preference domain to most-least preferences with, at most, three strict classes (most preferred homes, less preferred homes, and unacceptable homes) which is necessary for tractability and applicable for our setting. We also allow the matchmaker to have strict ordinal preferences over homes that a given child can be placed in and call these preferred outcomes. We require a familiar efficiency standard from our mechanism: weak Pareto efficiency, where in any allocation μ' that weakly Pareto dominates μ , it must be that every child with a different home between the two matchings strictly prefers μ' . This suffices to describe the efficiency of placements under the status quo. Furthermore, we impose a constrained welfare maximizing property that our mechanism must satisfy called outcome sufficiency. A matching μ is outcome dominated if there is another matching μ' where some subset of children improve their outcomes without making any other children worse off. A matching μ is outcome sufficient if it is weakly Pareto efficient and not outcome dominated by any μ' that it does not Pareto dominate.

We prove that our main mechanism, Linear Exchange, is outcome sufficient (Theorem 1). Any matching that outcome dominates a matching that it produces must infringe on some caseworker's preferences, and any matching that Pareto dominates it must worsen some child's outcome. Turning to strategic incentives, we show that no outcome sufficient mechanism can be strategy proof (Theorem 2). This important result generalizes to any setting with Pareto-efficient constrained welfare maximization since outcome sufficiency is a weaker property than, for example, maximizing a sum of match valuations. However, this implies that Linear Exchange is manipulable (Proposition 3). Furthermore, the manipulations are often simple truncation strategies. Nevertheless, we restore some positive results regarding the strategic incentives of Linear Exchange. We prove that it is non-obviously manipulable (Theorem 3) defined as in Troyan and Morrill (2019). Any child that successfully manipulates Linear Exchange needs both information that is not revealed to her and a favorable realization of uncertainty.

In our work in the future, we plan to conduct a lab-in-the-field experiment with real caseworkers in partnership with one of the largest child welfare organizations in the United States facilitating interdisciplinary research that improves practice. Our experiment will illicit caseworker preferences in a simulated market. Using a predicted persistence measure constructed from and validated on youth in foster care in a real United States county, we will compute the counterfactual matching and improvements in persistence in the simulated market over the status quo. This step to evaluate our mechanism in a plausible field environment is important to establish the existence (or non-existence) of misalignment in caseworker preferences and predicted persistence. Currently, we use fully simulated data and preferences to show the potential improvements in persistence.

Literature Contribution—This paper intersects results on Pareto-constrained welfare maximization in computer science literature and standard matching theory. The work closest to ours is Biró and Gudmundsson (2020). They study the computational complexity of finding a Pareto efficient matching of highest welfare, where welfare in their case is a sum of match valuations and, in a large part of their work, where the match valuation depends only on one side. They find that this problem is NP-hard in general and prove stringent conditions under which it is computationally feasible. Following this, they define a general linear programming solution that may require permuting all matchings to

²One can think of caseworkers analogously as the parents in school choice. Parents, or caseworkers, actually have preferences over the objects, but we primarily refer to the students or children in exposition.

identify the constrained welfare maximizing matching. They also analyze some conditions where positive strategy proofness results can be proven. We contribute through proving that, in general, there does not exist a constrained welfare maximizing and strategy proof mechanism. Additionally, we allow for indifference in preference rankings and constructively demonstrate that an analytically tractable and computationally feasible mechanism satisfying outcome sufficiency (Linear Exchange) exists. Our work also always allows for the match valuation to depend on the specific child-home match. Other works by Cechlárová, Fleiner, and Schlotter (2017) and Saban and Sethuraman (2015) explore the computational tractability of problems inherent in computing an outcome sufficient matching and motivate some of our restrictions on the problem (Assumption 1).

In the economics literature, Abdulkadiroglu, Dur, and Grigoryan (2021) and Bodoh-Creed (2020) focus on finding welfare maximizing matchings in the context of school choice. School choice involves matching students to schools in a two-sided market where both sides are strategic and have preferences over the other side. The former work finds stability-constrained welfare maximizing matchings using a network-flow approach, and the latter work uses fractional approximation techniques from optimization to find welfare maximizing matchings that satisfy a modified definition of stability. Our contribution defines constrained welfare maximization in one-sided matching markets where the constraint is weak Pareto efficiency rather than stability, and our maximization requirement is more general than maximizing a sum of valuations. This is key in the context of child welfare as mechanisms that maximize sums can unfairly give weight to changing placements for children with large cardinal improvements in persistence. Ashlagi and Shi (2016) and Shi (2021) aim for similar goals of welfare maximizing matchings in generally two-sided markets, but they treat the constraint of stability more flexibly than the aforementioned two papers.

Lastly, a few select papers intersecting matching theory and child welfare loosely relate to our work. Slaugh et al. (2016) analyze the matching recommendation system that had previously been abandoned by the Pennsylvania child welfare system and take an operations approach to reform it. They show tangible benefits in increasing the number of placements. Robinson-Cortés (2021) estimates caseworker preferences and counterfactual persistence for children under various different policies using an empirical matching framework. Some policies that focus on increasing market thickness, like matching across larger geographic regions, can significantly boost persistence. Notably, Baron et al. (2024) study the problem of reassigning child investigations to investigators while maintaining a sort of status quo. They coin the term "mechanism reform"—changing the status quo mechanism while maintaining at least the same level of welfare for all agents—which we similarly apply to our problem. For a more comprehensive overview of the overlap between market design and child welfare systems, we refer the reader to this paper's sister Highsmith (2024). This work develops matching mechanisms for expedient adoptions from foster care where dynamic incentives play a far greater role than in matching children to temporary foster homes.

Linear Exchange in Practice—Foster care in the United States is an interesting application of matching theory because, at present, there are no counties that we are aware of that utilize any formal matching mechanism to assign children to homes. One simple reason why this could be the case is that the status-quo, as we have described it, is equivalent to a weakly Pareto efficient matching mechanism. Therefore, all mechanisms developed in matching theory, save those that we described in our literature review,

would have nearly or exactly the same efficiency as the status-quo³. Furthermore, two-sided matching mechanisms are not well-fit for foster care. This is because the set of children to be matched is fluid and constantly changing; the preferences that homes report, then, must similarly constantly update. One could construct preferences based on child observable characteristics which homes report once-and-for-all, but this would require additional theoretical developments to reach the same desirable properties as in the standard case. Additionally, as we will highlight as we present our model, evaluating a home is a costly task for caseworkers. Constructing long preferences lists is arduous on both sides of the market. Whether or not homes have preference ranking in foster care is also dubious; it is more likely that they have dichotomous preferences which allows the two-sided problem to be transformed into a one-sided problem. In contrast, Linear Exchange, an outcome sufficient mechanism, has the benefit that it maintains the status quo and improves persistence for all children.

In working on this and related projects, we have conducted interviews with practitioners to understand the matching process in foster care. Our interviews indicate that individual caseworkers face a relatively easy problem: choose the best perceived home for a child. However, when practitioners aggregate this decision-making rule to the entire market, they find that many children end up unplaced when there is a reallocation that could guarantee more placements, and they find that persistence falls short of their goals. Both observations are consistent with the status quo which fails outcome sufficiency. One final concern with the implementation of a formal mechanism is that children often need to be matched quickly and frequently (for example, daily). In any static problem, only a handful of children might be involved in the mechanism, resulting in low market thickness. Outcome sufficiency reduces to weak Pareto efficiency when caseworkers' top choices for children are heterogeneous (which is more likely with low market thickness). Therefore, frequent matching might preclude gains from outcome sufficiency. We note that this would only be true in environments with frequent matching and few children in the foster care system. In large markets, there would still be a gain to outcome sufficiency. Furthermore, children within foster care, as noted, are often reassigned to new homes. Including these children within the mechanism increases market thickness and suggests that better outcome might follow. Finally, utilizing Linear Exchange could provide rationale for aggregating matching decisions on coarser time scales such as weekly.

Paper Organization—In Section 2, we detail our model preliminaries and mechanism properties. In Section 3, we give theoretical results on Linear Exchange, its non-strategic properties, and its strategic properties. We also present existence proofs for other mechanisms satisfying our properties. In Section 4, we detail our simulations and empirical results. Last, we conclude in Section 5 with practical considerations.

2 Preliminaries

We model a one-sided matching market. Let A be a set with an arbitrary, finite number of agents. C is the set of all children and H is the set of all prospective homes for children, thus $A = C \cup H$. The matchmaker's task is to assign each generic child $c \in C$ to a generic home $h \in H$. Formally, the matching market is an undirected, bipartite graph with labels M = (C, H, E) where E is the edge set representing feasible assignments. Let $\gamma : E \to \{\{c, h\} : c \in C, h \in H\}$ represent the incidence function for M and

 $^{^3}$ Serial Dictatorship appropriately modified for indifference could improve weak Pareto efficiency to Pareto efficiency.

 $E_h(\mu) = \{d \in \mu : h \in \gamma(d)\}$ where $\mu \subseteq E$. A feasible matching or assignment is some $\mu \subseteq E$ that is one-to-one⁴.

We say that child c is assigned to or placed with home h under μ if $\{c, h\} \in \mu$. For convenience, we use the shorthand notation with μ as a function where $\mu : A \to A \cup \emptyset$ such that $\mu(c) = h \iff c \in \mu(h) \iff \{c, h\} \in \mu$. We say that c is unassigned or unplaced if $c \notin \gamma(d)$ for any $d \in \mu$ and write $\mu(c) = \emptyset$.

P is the set of preference orderings over $H \cup \varnothing$. Each child c has a ranking $\succ_c \in P$ over prospective homes. There are no externalities. Each child only cares about her own assignments. We write $h \succ_c h'$ if and only if c ranks h higher than h'. If $\varnothing \succ_c h$, we say that h is unacceptable to c. We write that $h \sim_c h'$ if c is indifferent between h and h' and $h \succsim_c h'$ if c weakly prefers h over h'. In the foster care setting, it is important to note that children do not represent themselves in the matching process. Instead, caseworkers typically decide the best home for a child. Nevertheless, we will primarily refer to children as holding preferences and making decisions in our theoretical work for exposition's sake. When we highlight our applications, it will be an important fact that caseworkers are the real decision-makers. We also make the following restrictive assumption:

Assumption 1. (Most-Least Preferences) For any c, for any $h, h' \in T(c)$ or $B(c), h \sim_c h'$ where $T(c), B(c) \subseteq H$ and $T(c) \cap B(c) = \emptyset$. If $h \in T(c)$ and $h' \in B(c)$, then $h \succ_c h'$.

We discuss the warrant for Assumption 1 below. We then refer to child c's most preferred options as T(c) and her set of least preferred options as B(c). We write that c's true preferences are $\succ_c = (T(c), B(c))$.

In addition to these preferences, the matchmaker has preferred outcomes for a child c which is a ranking $>_c \in P(h)$ over prospective homes for that child. We assume that these outcome preferences are strict. While outcomes will play a similar role to priorities, for example, in the school choice literature, they are not the same⁵. We write $m^*(c|H')$ to denote the matchmaker's most preferred outcome for c in H' that c considers acceptable.

The vector of preferences for all children is $\succ_C = (\succ_c)_{c \in C}$ and for all matchmaker outcomes is $> = (\gt_c)_{c \in C}$. A preference double is a combination of these two: $\succ = (\succ_C, \gt)$. Fixing the market M, a mechanism $\phi : \succ \to \mu$ maps a preference double to a feasible matching μ on M. From hereon, we omit "feasible" when referring to matchings and consider it implicit.

A matching μ is Pareto dominated by μ' if, for all $c \in C$, $\mu'(c) \succsim_c \mu(c)$ and, for some $c' \in C$, $\mu'(c') \succ_{c'} \mu(c')$. μ is weakly Pareto dominated by μ' if, for all $c \in C$ such that $\mu'(c) \neq \mu(c)$, $\mu'(c) \succ_c \mu(c)$. A matching μ is (weakly) Pareto efficient if there does not exist another matching μ' that (weakly) Pareto dominates it. Similarly, μ is outcome dominated by μ' if, for all $c \in C$ such that $\mu'(c) \neq \mu(c)$, $\mu'(c) \gt_c \mu(c)$. We write $\mu \operatorname{PD} \mu'$, $\mu \operatorname{wPD} \mu'$, and $\mu \operatorname{OD} \mu'$ to say that μ is dominated by μ' in the respective senses. A matching μ is outcome sufficient if there does not exist a weakly Pareto efficient μ' that (1) outcome dominates μ and (2) is not Pareto dominated by μ . We say that the sufficiency is exclusive if μ is Pareto efficient and there does not exist a Pareto efficient μ' that outcome dominates μ .

⁴It is easy to extend the model to consider capacities, and all theorems hold. The issue of sibling groups in foster care is salient, but matchmakers often break up sibling groups and, when not, may prefer to match these outside of the formal mechanism.

⁵They differ in an important aspect. The matchmaker's outcome need not be comparable across children even if it is comparable within a single child. Hence, it might not be possible to translate outcomes into priorities that homes have over children.

A mechanism ϕ , considering the set of children and homes fixed, inputs a preference report and outputs a matching μ . Let \succ'_c be a preference report for child c. ϕ is strategy proof if no child can benefit by misreporting her most or least preferred options irrespective of other children's reports. Denote \succ_{-c} as the preference report vector for all $c' \neq c$. Formally, ϕ is a strategy proof mechanism if, for all c, given any preference tuple $\succ' = (\succ'_c, \succ'_{-c}, \gt)$, we have that $\phi(\succ_c, \succ'_{-c}, \gt) \succsim_c \phi(\succ')$ where $\succ'_c = (T'(c), B'(c))$ such that either $T'(c) \neq T(c)$ or $B'(c) \neq B(c)$.

Most-Least Preferences—As mentioned, we have several strong reasons for Assumption 1. First, there have been several significant results in the computer science literature demonstrating that certain algorithmic steps necessary to compute outcome sufficient matchings are computationally intractable (Cechlárová, Fleiner, and Schlotter 2017 and Saban and Sethuraman 2015) without restrictions on the preference space. The preference space that we consider is restrictive but more general than most considerations in this literature. Explicitly, we build on Cechlárová, Fleiner, and Schlotter (2017) which restricts preference lists to those that are strict and at most length two. The class of most-least preferences also generalizes well-known classes such as dichotomous preferences (where $B(c) = \emptyset$ for all c). It also satisfies single-peakedness (Bade 2018) when preferences are top-single and complete, though we do not require this for our main results.

Second, this preference space is flexible enough to accommodate caseworker preferences. Caseworkers already have a difficult task in managing caseloads for multiple children. Anecdotally, it is demanding to request that a caseworker should evaluate and rank more than one potential home for a child if it is not necessary. Instead, they may use simple criteria classifying homes into more-preferred and less-preferred, for example, it is common for caseworkers to place children in family homes whenever possible rather than institutional homes (orphanages). Within their class of most or least preferred homes for a child, there is wide horizontal differentiation which problematizes assigning a strict order.

Third, the aforementioned literature intersecting computer science and Pareto-efficiency constrained welfare maximization in discrete allocation problems demonstrates that there is little hope to achieve reasonable algorithms that can simultaneously compute sufficient assignments and ensure strategy-proofness (Biró and Gudmundsson 2020 and Theorem 2). Strategic incentives are very important in our setting as manipulating constrained welfare maximizing mechanisms can be a trivial task. Our preference restriction forfeits some generality but allows us to design a mechanism that is analytically tractable, computationally tractable, and non-obviously manipulable.

Outcomes and Sufficiency in Child Welfare—In many practitioners' views, some features of foster care render it unamenable to algorithmic decision-making. Caseworkers routinely use qualitative information that is not easily encoded into usable data to make matching decisions. Our formulation would still allow caseworkers to declare preferences that utilize these qualitative datum, whereas previous work in this area has been abandoned because the algorithms in use frequently produced nonsensical and unusable results due to ignoring factors that caseworkers see as relevant. As it stands, to reap the boundless improvements from algorithmic decision-making seen in traditional matching theory applications like school choice, hospital-doctor matching, and kidney exchange, practitioners must agree to utilizing the methods invented in matching theory. Ensuring that they do not suffer more than the status quo is a binding constraint.

Outcome sufficient matching guarantees this while allowing practitioners to implement tools from matching theory and predictive analytics. Concretely, a local matchmaker

could use predicted placement stability as its outcome for children. Predicted placement stability is the probability that, if c is placed at h, the placement would persist until c permanently exits foster care. We will refer to this as persistence to avoid confusion with the matching theory term stability. Note that this outcome can only form a ranking over homes for a given child c. It cannot allow priority comparisons as is common in matching literature. To fix ideas, suppose that there are two families: h and h' as well as two children: c and c'. c has persistence $Y_c(h) = 0.89$ at h and $Y_c(h') = 0.9$ at h'. c' has $Y_{c'}(h) = 0.8$ and $Y_{c'}(h') = 0.1$. A rudimentary solution to translate outcomes into priorities would be to assign priority at h by ranking children's persistence at h. This would establish a priority order that disadvantages c' at both homes, even though is seems intuitive that the matchmaker should assign c to h' and c to h whenever possible.

Caseworkers in almost all counties in the United States effectively follow a decentralized approach where the earliest caseworker to find a suitable home for a child can contact that home to begin the match. This is equivalent to a serial dictatorship ordered by time; in the context of indifferences, this process will always yield a weakly Pareto efficient matching. We call this the status quo. Our work in this paper devises mechanisms that would select assignments that leave no room for improvement in persistence without compromising the status quo for caseworkers as weakly outcome sufficient mechanisms only yield assignments that are weakly Pareto efficient relative to their preferences. As we will detail in our empirical section, this simple strategy could greatly improve persistence in foster care and substantially benefit the tens of thousands of children entering foster care every year in the United States.

Finally, implementing algorithmic matching could constitute a partial solution to the major labor supply issues seen in child welfare. Caseworkers are notoriously overwhelmed with large caseloads, and a simple system that uses an objective metric to place children with the best possible home could simplify caseworkers' decisions and decrease the amount of manual labor involved. Importantly, the algorithms we devise cannot *replace* caseworkers; we do not desire this. Instead, caseworkers would be an important checkand-balance against an algorithm that may have systemic prediction errors that could harm children's persistence. Thus, outcome sufficient matching would achieve the best of both worlds: maximum utilization of qualitative data present in caseworker preferences and automated optimization of child outcomes using predictive analytics.

Illustrative Example

Before continuing to our main results, we provide an example of outcome sufficiency that we will continue to use throughout this paper. Suppose that the market participants are $C = \{a, b, c, d, e\}$ and $H = \{1, 2, 3, 4, 5\}$. The preferences and outcomes are as follows:

$$d$$
 e $\succ_{d}: [5], [3] $\succ_{e}: [5], [3]$ $\gt_{e}: 3, 5$ $\gt_{e}: 3, 5$$

The first bracketed home in the list of preference indicates a child's most preferred set, and the second bracketed homes indicate a child's least preferred set.

Let (i, j, k, x, y) indicate the matching where $\mu(a) = i$, $\mu(b) = j$, $\mu(c) = k$, $\mu(d) = x$, and $\mu(e) = y$. Suppose that we naively use a serial dictatorship with an alphabetic order of dictators while allowing subsequent dictators to choose from previous dictators' indifferent alternatives. This would produce:

$$\mu = (1, 2, 3, 5, \emptyset)$$

This matching is Pareto efficient since neither b nor e can Pareto improve without making another child worse off, therefore it is also weakly Pareto efficient. However, it plainly fails outcome sufficiency. To see this, consider the matching:

$$\mu' = (2, 4, 1, 5, 3)$$

d cannot Pareto improve, so e cannot Pareto improve without making d worse off. This also implies that c cannot Pareto improve without making d worse off. The only two Pareto improving cycles involve c swapping with either a or b to strictly improve either and weakly improve herself. Yet, this implies that c changes matches but does not strictly improve. Therefore, there is no alternative matching where every child that changes homes strictly improves, implying that μ' is weakly Pareto efficient.

Under μ' , every child except d strictly improves. Therefore, μ OD μ' , and $\neg(\mu'$ PD $\mu)$ because $\mu'(e) \neq \emptyset$. One can verify that μ' is outcome sufficient.

This example highlights the pitfalls of using serial dictatorships with first-come ordering to select homes for children in foster care. In this example, reallocation according to outcome sufficiency guarantees an additional child a home *and* improves hypothetical persistence for all children.

In general, outcome sufficient matchings all satisfy an attractive property. Suppose that μ is outcome sufficient. If there is another weakly Pareto efficient matching μ' such that μ PD μ' , then $\neg(\mu$ OD μ'), i.e., if there is a coalition of children that can Pareto improve without making other children Pareto worse-off, then some child's outcome must deteriorate. Conversely, if μ OD μ' , then $\neg(\mu$ PD μ'), and the same explanation vice-versa follows.

3 Results

In this section, we detail our mechanism for computing outcome sufficient matchings and give important results on its properties.

The Linear Exchange Mechanism

The mechanism we present here represents a new class of mechanisms which we call exchanges. The first distinct feature of an exchange is that a child may not be permanently matched after choosing in any given round, and her match may be subject to unilateral dissolution if another child is permitted to exchange for her home. The second distinct feature is the mirror of the first: once a child exits the exchange based on some rule, that child's match is permanent. The most important step is choosing a rule that guarantees weak Pareto efficiency without compromising weak outcome sufficiency.

A (strict) Pareto improving cycle on μ is a cycle $(c_1, c_2, ..., c_n)$ where $\mu(c_{j+1}) \succ_{c_j} \mu(c_j)$ for all $j \neq n$ and $\mu(c_1) \succ_{c_n} \mu(c_n)$. A well-known result is that, under strict preferences,

a matching is Pareto efficient if and only if there are no Pareto improving cycles and there does not exist a h with $\mu(h) = \emptyset$ such that $h \succ_c \mu(c)$ for some c. We call the second condition a Pareto improving chain and prove the following lemma in addition for completeness:

Lemma 1. μ is weakly Pareto efficient if and only if there are no Pareto improving cycles and no Pareto improving chains.

Proof. (\Longrightarrow) We prove the following claim: if μ has a Pareto improving cycle or chain, then μ is not weakly Pareto efficient. The contrapositive is that if μ is weakly Pareto efficient, then it cannot contain a Pareto improving cycle or chain. The claim is immediate as if μ has a Pareto improving cycle or chain, we can indicate μ' as the matching with the proposed trades executed. Every c with $\mu(c) \neq \mu'(c)$ strictly prefers μ' to μ , therefore μ is weakly Pareto dominated.

(\Leftarrow) We prove that if μ is not weakly Pareto efficient, then it has a Pareto improving cycle or chain. The contrapositive is that if μ has no Pareto improving cycle or chain, then it is weakly Pareto efficient. If μ is not weakly Pareto efficient, then there is some μ' such that for every c with $\mu'(c) \neq \mu(c)$, $\mu'(c) \succ_c \mu(c)$. If $\mu(\mu'(c)) = \emptyset$ for any such c, then the claim follows. If not, then we can construct a finite (by the finiteness of C) sequence $(c_1, c_2, ..., c_n)$ where c_j satisfies $\mu(c_j) = \mu'(c_{j-1})$ for all $j \neq 1$ and $\mu(c_1) = \mu'(c_n)$. This will be a Pareto improving cycle.

With this proven, we can describe our mechanism for finding outcome sufficient matchings: Linear Exchange.

Algorithm 1. Linear Exchange

Initialize the following: the matching μ^1 such that $\mu^1(c) = \emptyset$ for all c. The set of children initially in the exchange is $C^1 = C$ and $H^n = \{h : \mu^n(h) = \emptyset \text{ or } \mu^n(h) \in C^n\}$. The most preferred set restricted to available, unmatched homes is $T^n(c) = \{h : h \in T(c) \text{ and } \mu^n(h) = \emptyset\}$.

Round $n \ge 1$:

According to an arbitrary order, select the next $c \in C^n$ with $\mu^n(c) = \emptyset$. Let $h^* = m^*(c|H^n)$.

- $h^* \in T(c)$: then set $\mu^{n+1}(\mu^n(h^*)) = \emptyset$, $\mu^{n+1}(c) = h^*$, and $C^{n+1} = C^n c$.
- $h^* \notin T(c)$: Suppose that $T^n(c) = \varnothing$. $h \in H^n$ is a no-trade home for c if $h \in H^n$ and there is no strictly Pareto improving cycle among children not in the exchange when c matches to h. The set of no-trade homes for c is $NT^n(c)$. If $h^{NT} = m^*(c|NT^n(c))$ is defined, then set $\mu^{n+1}(\mu^n(h^{NT})) = \varnothing$ and $\mu^{n+1}(c) = h^{NT}$. Set $C^{n+1} = C^n c$. If $T^n(c) \neq \varnothing$, then set $\mu^{n+1}(c) = m^*(c|T^n(c))$ and $C^{n+1} = C^n$.

If C^{n+1} or H^{n+1} are empty or the end of the exchange is reached, terminate and return μ^{n+1} . Otherwise, continue to round n+1.

Theorem 1. Linear Exchange is outcome sufficient.

Proof. In the Appendix.

Note that the algorithm terminates. In every round, either a child is matched or a child is unmatched while another is matched and permanently removed from the exchange. ϕ_{LE} will terminate since it does so when all children are matched, there are no children left in the exchange, or there are no homes left in the exchange.

The structure of an exchange mechanism is similar to dictatorial mechanisms in that an arbitrary ordering determines a series of children that will, in turn, select their most preferable option from all available options. However, it differs in the key feature that children with potential to improve their outcomes remain in the exchange, and children that would Pareto- and outcome-improve their matching by replacing a children within the exchange can do so. The surprise of the Linear Exchange mechanism is that, when the replacement rule is carefully designed not to generate strict Pareto cycles among children outside of the exchange, replacements will not generate beneficial trades among any children nor will they leave potential outcome improvement cycles unrealized. The sole exception to the latter point is that there might exist a matching that reallocates children remaining in the exchange at termination and outcome dominates ϕ_{LE} . However, since these children never exited the exchange, they must all be matched to their most preferred homes. Any matching that outcome dominates through reallocating these children must assign at least one to a least preferred option to improve that child's outcome. Thus, this reallocation will cause the matching to be Pareto dominated by ϕ_{LE} .

This result is a significant step in finding more general conditions under which Pareto constrained welfare maximization in matching problems is computationally feasible. Our main assumptions may, in reality and in our setting, be reasonable. One can verify that ϕ_{LE} runs in polynomial time as the key step—checking for Pareto improvement cycles—can be done in linear time and is repeated, at most, |C|*|H| times. In contrast, Biró and Gudmundsson (2020) found that conditions wherein constrained welfare maximizing allocations could be identified in polynomial time that included problems with some combination of balanced number of agents on each side, common preferences, complete preferences, and object-based weights where welfare does not depend on any match-specific surplus.

We use the Illustrative Example to demonstrate how Linear Exchange operates. Recall the market:

$$d$$
 e $\succ_{d}: [5], [3] $\succ_{e}: [5], [3]$ $\gt_{e}: 3, 5$ $\gt_{e}: 3, 5$$

We also use the same alphabetic order as before: a, b, c, d, e. The rounds of Linear Exchange proceed as follows, where $i \to k$ implies that $\mu^{n+1}(i) = k$ and $i \downarrow$ implies $i \notin C^{n+1}$.

$$n=1$$
 $n=2$ $n=3$ $n=4$ $n=5$ $n=6$ $n=7$ $a \to 1$ $b \to 4$ $c \to 3$ $d \to 5$ $e \to 3$ $c \to 1$ $a \to 2$ $b \downarrow$ $c \downarrow$ $a \downarrow$

At n=2, the out-exchange set $C-C^n$ is empty, so $NT^2(b)=B(b)$ and b chooses the matchmaker's best outcome for her. Now, consider n=5. Since $c\in C^5$ and $3\in B(b)$, 3 is a no-trade home for e and the only remaining acceptable home for her, so e exits with 3. There is some nuance at n=6. Even though $1\in T(b)$, the only home that can be reallocated to c through a Pareto improving cycle in the out-exchange is 4. This cycle does not strictly improve c, therefore 1 is a no-trade home for c. Similar logic applies when a exits with 2. The final matching is $\mu=(2,4,1,5,3)$ which, as previously mentioned, is outcome sufficient. It also happens to be exclusively outcome sufficient, which raises the question if Theorem 1 can be strengthened further. Unfortunately, it cannot be.

Proposition 1. Linear Exchange is not exclusively nor strong exclusively outcome sufficient.

Proof. In the Appendix.

Linear Exchange failing strong exclusivity has already been demonstrated through the Illustrative Example. The matching that it produces is not Pareto efficient. Its failure of exclusive outcome sufficiency is more nuanced. In particular, there may exist knife-edge cases where children within the exchange at the termination of the algorithm may improve outcomes through a reordering of the exchange whereby some child's previously most preferred homes would be selected by earlier children that must all outcome improve. The later child has no option remaining other than to choose the matchmaker's best outcome for her that must be in her set of less preferred homes. Our present simulation results indicate that these cases are very rare and may not be a practical concern for Linear Exchange.

Proposition 2. Linear Exchange is exclusively outcome sufficient if preferences are top-single, and it is strong exclusively outcome sufficient if preferences are strict-single.

Proof. In the Appendix. \Box

Exclusive outcome sufficiency follows from the fact that top-single preferences rule out the exact knife-edge cases that we discussed, and strong exclusive outcome sufficiency follows under strict-single preferences because weak Pareto efficiency is equivalent to Pareto efficiency under strict preferences. In what circumstances would we expect top-single or strict-single preferences to adequately describe caseworker preferences? One example where top-singleness would hold is when caseworkers have a "favorite" home for a child but otherwise remain indifferent between remaining acceptable alternatives. This could represent counties managing few children that have highly specific needs. In this case, there might be a unique home for every child that would best care for them, but the caseworker might prefer that, in the circumstances that the home is occupied by another child, there might be some other homes that are "good enough". On the other hand, strict-single preferences would be a more restrictive case where, for example, caseworkers must evaluate a home rigorously before declaring that it is acceptable. Since evaluating a home is a costly, laborious process, caseworkers are hesitant to evaluate more than is

necessary—in this case, that might mean one ideal home and one backup home in case the ideal home has its capacity filled.

Strategic Properties

In this section, we prove several key results about the strategic properties of outcome sufficient matching mechanisms. Strikingly, we find that there is no outcome sufficient and strategy proof matching mechanism (Theorem 2). In addition, the manipulations that caseworkers could pursue are concerning to the healthy operation of any outcome sufficient matching mechanism. Subsequently, based on Troyan and Morrill (2019), we evaluate our mechanism's *obvious* manipulability, that is, whether or not an agent that has limited contingent reasoning can evaluate successful manipulations.

Proposition 3. Linear Exchange is manipulable.

Proof. We again use the Illustrative Example to demonstrate this. We assume that child a manipulates, setting $B'(a) = \emptyset$. The operation of Linear Exchange proceeds as follows:

n = 1	n=2	n = 3	n = 4	n = 5	n = 6
$a \rightarrow 1$	$b \to 4$	$c \to 3$	$d \to 5$	$e \rightarrow 3$	$c \rightarrow 2$
$a\downarrow$	$b\downarrow$			$e\downarrow$	$c\downarrow$

The final matching is (1, 4, 2, 5, 3), and a strictly improves over her truth-telling outcome.

a's optimal manipulation is simple: refuse to report less-preferred options when anticipating that she might be relegated to one of them. She can then exit the exchange earlier. The next natural question is: does an outcome sufficient and strategy-proof mechanism exist? The answer is no.

Theorem 2. An outcome sufficient and strategy proof mechanism does not exist.

Proof. We demonstrate Theorem 2 by counterexample. Let $C = \{a, c, d\}$, $H = \{1, 2, 3\}$, and $\kappa(1) = \kappa(2) = \kappa(3) = 1$. Children's and the matchmaker's preferences are as follows:

$$1 \succ_a 3$$
 and $3 >_a 1$
 $2 \succ_c 1$ and $1 >_c 2$
 $2 \succ_d 3$ and $3 >_d 2$

where omitted homes in the preference lists indicate that they are unacceptable. Let \succ' be the profile where c reports T(c)=2 and $B(c)=\varnothing$, and \succ'' is the profile where d reports T(d)=2 and $B(d)=\varnothing$. (x,y,z) denotes the matching where $\mu(a)=x, \mu(c)=y$, and $\mu(d)=z$. One can generate the full set of (weak) Pareto efficient matchings given these preferences using the Serial Dictatorship mechanism by permuting the order of dictators. They are as follows:

Under the true reports \succ : (1,2,3), $(1,\varnothing,2)$, (1,2,3), (1,2,3), $(1,\varnothing,2)$, and (3,1,2), where only (1,2,3) and (3,1,2) are not outcome dominated in the set of Pareto efficient matchings. Therefore, they are outcome sufficient matchings.

Under \succ' : (1,2,3), $(1,\varnothing,2)$, (1,2,3), (1,2,3), $(1,\varnothing,2)$, and $(1,\varnothing,2)$. Only (1,2,3) is outcome sufficient. However, this implies that any outcome sufficient and strategy proof

mechanism ϕ must select the matching (1,2,3) under the true reports \succ , otherwise c has an incentive to misreport.

Under \succ'' : $(1,2,\varnothing)$, $(1,\varnothing,2)$, $(1,2,\varnothing)$, $(1,2,\varnothing)$, $(1,\varnothing,2)$, and (3,1,2). Only (3,1,2) is outcome sufficient, implying that any outcome sufficient and strategy proof mechanism ϕ must select (3,1,2) under the true reports \succ , otherwise d has an incentive to misreport. This is a contradiction. Therefore, an outcome sufficient and strategy proof mechanism does not exist.

Note that weak Pareto efficiency is equivalent to Pareto efficiency when all preferences are strict as in this environment, so there does not exist an exclusive nor strict exclusive outcome sufficient and strategy proof mechanism. Unfortunately, this counterexample also demonstrates that any outcome sufficient mechanism is manipulable by truncations in such a way that a falsifying child can find a Pareto improvement while worsening her outcome. In worse case scenarios where all agents adopt truncation strategies, this could severely decrease the cardinality of the matchings generated by the algorithm.

The very structure of outcome sufficient matchings requires the matchmaker to use the reported preferences against the preferred interests of the children. In particular, when the matchmaker knows that children have acceptable homes that could improve their outcomes, the matchmaker is obligated to attempt to assign the children to these homes irregardless of whether they are in the children's most or least preferred sets. This proves to defeat strategy proofness altogether.

However, this all comes with one important caveat that has been an observation leading to a burgeoning literature of matching under incomplete information: it is unlikely that caseworkers know the preferences of other agents. In our setting—and in the case of outcome sufficient matching in general—the asymmetric information is more extreme, because caseworkers do not know the matchmaker's outcomes for all children⁶. How, then, should a caseworker evaluate manipulations under incomplete information? We adopt the notion of non-obvious manipulability as in Troyan and Morrill (2019). In short, a mechanism is non-obviously manipulable if there is no manipulation that makes a child strictly better off in the worst case or best case compared to truth-telling.

Defining Non-Obvious Manipulability— We assume that every child knows her own preferences and outcomes. Fix a mechanism ϕ , market M, and reported preferences \succ'_c for c. We say that \succ'_c is a worst-case manipulation if:

$$\min_{(\succ'_{-c}, >_{-c})} \phi(c|\succ'_{c}, \succ'_{-c}, >_{c}, >_{-c}) \succ_{c} \min_{(\succ'_{-c}, >_{-c})} \phi(c|\succ_{c}, \succ'_{-c}, >_{c}, >_{-c})$$

and \succ_c' is a best-case manipulation if:

$$\max_{(\succ'_{-c}, \gt_{-c})} \phi(c|\succ'_{c}, \succ'_{-c}, \gt_{c}, \gt_{-c}) \succ_{c} \max_{(\succ'_{-c}, \gt_{-c})} \phi(c|\succ_{c}, \succ'_{-c}, \gt_{c}, \gt_{-c})$$

where the minimizations and maximizations are taken to be with respect to c's preferences. A mechanism ϕ is non-obviously manipulable if no c has a worst-case nor best-case manipulation.

Next, we introduce a small modification to Linear Exchange. The Randomized Linear Exchange mechanism detailed below randomizes the order of children and then runs the Linear Exchange mechanism. This step renders the order ex-ante unknown and is an important step for the elimination of obvious strategic incentives.

⁶The outcomes for a given child might be reported to the caseworker that represents that child, but they need not be reported to caseworkers that do not represent the child.

Algorithm 2. Randomized Linear Exchange

Construct an ordering over C by uniformly randomly selecting a child to be next in the order. Run ϕ_{LE} given the randomized order.

Theorem 3. Randomized Linear Exchange is non-obviously manipulable.

Proof. In the Appendix.

The proof for the non-obvious manipulability of Randomized Linear Exchange is fairly straightforward. The best-case for truth-telling is always matching to a most preferred home. Therefore, the key step is to prove that the worst-case for truth-telling is never strictly worse than the worst-case under any misreport. This follows from one observation. Children that go later in the order of the exchange are at a disadvantage when children earlier in the exchange have preferences that align with the matchmaker's outcomes for them. Under such worst-case conjecture, manipulations can never help. We return to the Illustrative Example to show that manipulations can strictly harm a child when the order changes under some conjectures of others' preferences. Consider the same manipulation for a as in Proposition 3 where $B'(a) = \emptyset$, but we change the order to b, a, c, d, e while b also misreports $B'(b) = \emptyset$. The mechanisms operates as follows:

$$n=1$$
 $n=2$ $n=3$ $n=4$ $n=5$ $n=6$ $b \to 1$ $a \to \varnothing$ $c \to 3$ $d \to 5$ $e \to 3$ $c \to 2$ $b \downarrow$ $a \downarrow$

Changing a's spot in the order causes her misreport to result in her exiting with no match. One can verify that the final matching when a is truth-telling (but b continues to misreport) is $(2, 1, 3, 5, \emptyset)$.

While Randomized Linear Exchange is vulnerable to manipulations just as Linear Exchange is, these results and examples show that manipulating it, in practice, requires both information that agents are unlikely to have and realizations of uncertainty that play out in favor of the manipulator.

4 Empirical Performance

In this section, we provide the technical details for our simulations and show that Linear Exchange substantially increases welfare in the markets that we examine.

Simulation Data

For our simulations, we generate environments that we expect to mimic child assignment to homes. We split our simulations into a small market case with five to ten children and a large market case with twenty to fifty children. Both are representative of a typical foster care matching market in small and large counties, respectively⁷. The number of

⁷Robinson-Cortés (2021) documents that Los Angeles county had about forty placements per day between January and February 2011.

Table 1: Persistence, Uncorrelated vs. Correlated

Specification	Base	Corr
Average persistence, small market		
Linear Exchange	71.6%	75.2%
Serial Dictatorship	50%	49.8%
Average persistence, large market		
Linear Exchange	86.5%	89.8%
Serial Dictatorship	50%	49.9%

homes in a market is uniformly randomly distributed according to the same values⁸.

We simulate preferences and outcomes under five different specifications. The first specification is uncorrelated, unaligned preferences and outcomes. Concretely, for each child c, T(c) is a uniformly random subset of elements from H with |T(c)| = N(T(c)). N(T(c)) is a random variable uniformly distributed over integers in [1, |H|]. After the realization of T(c) is drawn, we draw B(c) which is a uniformly random subset of elements from H - T(c). Its size is a random variable N(B(c)) uniformly distributed over integers in [1, |H| - |T(c)|]. The preferred outcomes for c at a home b is determined by c's predicted persistence at b which is a random variable $C(b) \sim U[0, 1]$. $C(c) \sim U[0, 1]$.

Our second specification is child-correlated preferences and unaligned outcomes. In this specification, there is a random set of common most preferred homes T. We define T(c) as above then union this set with T to obtain "correlated" preferences. This procedure suffices to communicate our message that conflicting most preferred homes allows Linear Exchange to optimally reallocate homes while maintaining weak Pareto efficiency.

Our third, fourth, and fifth specifications involve uncorrelated preferences and aligned outcomes. In this model, $\alpha \in \{0.25, 0.5, 0.75\}$ measures the degree of alignment between child preferences and preferred outcomes. Every c has at least $\alpha * H$, rounded, of the matchmaker's top outcomes for her in T(c). We exclude $\alpha = 1$ because this trivializes the problem. Linear Exchange would always select the unconstrained welfare maximizing matching. We use these specifications to capture the fact that the wedge between the status-quo and outcome sufficiency may be smaller when, in some sense, children and the matchmaker agree on the most preferred home for a child.

In every specification, we run 1000 simulations and compare the status quo, Serial Dictatorship with randomly broken ties (see the Appendix for details), and Linear Exchange. We focus on the persistence rate averaged across children and simulations under the two mechanisms. In the future after we have our experimental results, we can follow a similar process using elicited preferences rather than simulated preferences.

Results

Small Markets—Despite our initial concerns about Linear Exchange lacking welfare improvements in small markets that we detailed in the Introduction, Linear Exchange performs very well. In the base case, Linear Exchange improves persistence by 21.6 pp.

⁸Systemic market imbalances do not affect our results. We can easily capture capacitated homes by cloning homes and carefully breaking ties in preferred outcomes; we leave this for future robustness checks.

When preferences are correlated across children, Linear Exchange improves by an additional 3.8 pp as it can exploit conflicts over most preferred homes to promote better outcomes. The same patterns hold under aligned preferences, where Linear Exchange continues to outpace the status quo by at least 20 pp in every specification.

Table 2: Persistence, Unaligned vs. Aligned

Specification	Base	0.25	0.5	0.75
Average persistence, small market				
Linear Exchange	71.6%	78.2%	78.5%	78.5%
Serial Dictatorship	50%	56.5%	56.5%	55%
Average persistence, large market				
Linear Exchange	86.5%	92.4%	92.5%	92.3%
Serial Dictatorship	50%	59.6%	58.7%	55.2%

Large Markets—On the baseline, Linear Exchange is more welfare enhancing—36.5 pp over the status quo—in large markets compared to small markets. The rationale behind this is exactly as we explained in the Introduction. Large markets have greater market thickness leading to better placement options for children on average and a larger space of weakly Pareto efficient matchings. Linear Exchange selects the outcome sufficient matching from this larger space which mechanically improves outcomes. Otherwise, the same patterns hold. Linear Exchange gains a marginal 3.4 pp under correlated preferences. In every specification with aligned preferences, its improvement is over 22 pp compared to the status quo.

In either small or large markets, increasing α beyond 0.25 does not substantially change persistence rates. This is most likely owing to the fact that there is not sufficient correlation in preferences to induce conflicts in most preferred homes among children. If the matchmaker's top preferred outcome aligns with a child's most preferred home, there may be no other child whom would want the first child's most preferred-outcome home. Therefore, the only relevant degree of alignment will be that the matchmaker's most preferred outcome should be one of the child's most preferred homes. Under Serial Dictatorship, increasing alignment fails to bridge the gap between it and Linear Exchange. This result flows from the fact that, when the rule to break indifference does not depend on the matchmaker's preferred outcomes (as is often the case in practice where search costs might imply that the first most preferred home that a caseworker finds is the one that she selects), increasing alignment is only helpful if the aligned homes are the *only* homes that the child has as her most preferred homes.

5 Conclusion

Before concluding, we highlight a number of salient future directions for our simulations. As mentioned in the Introduction, our tentative plan involves running a lab-in-the-field experiment with real caseworkers to evaluate their preferences and decision-making in a simulated market where children's predicted persistence is determined through a measure validated in a real U.S. county that we partner with. Combining these elements, we can estimate counterfactual matchings and persistence in the simulated market to provide plausible indications on the welfare improvements from using Linear Exchange in the

child welfare context. Furthermore, we can use different treatment arms to test how the availability of information—others' preferences and outcomes—affects strategic behavior. We also hypothesize that providing limited information about outcomes, for example, revealing or not revealing the outcome for a child that a caseworker represents, could function as an informational intervention that affects caseworkers' decisions.

Highsmith (2024) argues that child welfare systems have lacked the toolkit necessary to create organized and effective centralized assignments. Our work in this paper establishes a matching mechanism that is appropriate for foster care while also improving placements beyond the status quo (Serial Dictatorship) as measured by reducing the number of placements that a child experiences while in foster care. In our preliminary simulations, placement stability—or persistence—can increase by up to 25.4% in small markets with five to ten children matched every day and up to 39.9% in large markets with twenty to fifty children matched every day. We use a new property, outcome sufficiency, to characterize mechanisms that maintain the status quo while improving outcomes for all children. Our mechanism, Linear Exchange, satisfies outcome sufficiency, though it (and all outcome sufficient mechanisms) fails strategy proofness. Nevertheless, it has some robustness against strategic manipulations as it is non-obviously manipulable. We show that outcome sufficiency can be strengthened in some ways, but Linear Exchange only satisfies the stronger properties with further restrictions on the preference domain.

As a final note, while our application focuses on child welfare, outcome sufficient mechanisms can be applied to many other one-sided matching markets where welfare maximization is a goal in tandem with efficiency requirements. The one caveat that other settings must satisfy is Assumption 1, but this preference restriction is flexible enough that it captures many real-life preferences. Examining these other applications and more general preference spaces wherein outcome sufficient matchings can be computed in polynomial time is an area with great potential for future research.

Appendix

Proofs that did not appear in the main text are detailed here.

Theorem 1. Linear Exchange is outcome sufficient.

Proof. Note that we also prove exclusive outcome sufficiency in the case for top-single preferences in this proof. First, we show that the algorithm produces a weakly Pareto efficient matching. Suppose, for a contradiction, that ϕ_{LE} is not weakly Pareto efficient. Note first that if $h \notin H^k$ for some round k, then $h \notin H^{k'}$ for any k' > k as if a child is unmatched from a home, another child is matched to that home. Suppose that $h \succ_c \phi_{LE}(c)$ for some h with $\phi_{LE}(h) = \varnothing$. Let i be the round when c exits the exchange. If $h \in T(c)$, then it cannot be that c exited the exchange in this round. Hence, $h \in B(c)$ and $\phi_{LE}(c) = \varnothing$. However, this implies that h was a tradable home for c. Hence, there exists some $c' \notin C^i$ such that $h \succ_{c'} \phi_{LE}(c')$. Similarly, at round i' when c' left the exchange, c' only leaves if $h \notin T(c')$. Hence, $h \in B(c')$ and $\phi_{LE}(c') = \varnothing$. We can consider the first c'' that exits the exchange and prefers an unmatched home. As we showed above, there must be another child that exited the exchange earlier with no match and prefers the same unmatched home. This is a contradiction, therefore, no c prefers an unmatched home over $\phi_{LE}(c)$.

This implies that ϕ_{LE} must contain a strictly Pareto improving cycle. Let $(c_1, c_2, ..., c_n)$ be a strictly Pareto improving cycle where $\mu(c_{j+1}) \succ_c \mu(c_j)$ for all $j \neq n$ and $\mu(c_1) \succ_{c_n} \mu(c_n)$. Note that since all children strictly improve and exchange homes, it must be that $\phi_{LE}(c_j) \in B(c_j)$ for all c_j in the cycle. Hence, any child in the cycle must exit the exchange in some round. Consider the last c in the cycle that exits the exchange in some round i. $\mu^{i+1}(c) = \phi_{LE}(c)$ only if no cycle would form as a result. This is a contradiction. Therefore, ϕ_{LE} cannot contain a strictly Pareto improving cycle.

Next, we prove, by strong induction, that ϕ_{LE} is not outcome dominated by any other weakly Pareto efficient matching w that ϕ_{LE} does not Pareto dominate. Denote c^n as the c choosing in round n. Our induction statement is this: in any round n, for any c, h such that:

- 1. $c \notin C^n$,
- 2. h is acceptable to c, and
- 3. $h >_c \mu^n(c)$

then, for any weakly Pareto efficient matching w with w(c) = h, we have $\mu^n(c') >_{c'} w(c')$ for some $c' \neq c$.

Base case: n=1. The statement trivially holds since $C^1=C$.

Induction step: We assume that the statement holds for all rounds $k \leq n$ and prove that it holds for round n+1. Note that if $c^n \in C^{n+1}$, the statement trivially holds, so we consider only rounds when $c^n \notin C^{n+1}$ and prove the statement by cases.

Case 1: $\mu^{n+1}(c^n) = m^*(c^n|H^n)$. Since $\mu^{n+1}(c) = \mu^n(c)$ for all $c \notin C^n$, if (1)-(3) hold for c in round n, then the statement must hold for c in round n+1. We show it holds also for c^n . Clearly, (1) holds for c^n in round n+1. Suppose (2)-(3) also hold for some h'. We have:

$$h' \notin H^n$$

Otherwise:

$$h' >_{c^n} m^*(c^n|H^n)$$

which is a contradiction. Denote $c' \equiv \mu^{n+1}(h')$. In any weakly Pareto efficient matching w with $w(c^n) = h$, $w(c') \neq h$. If $h' >_{c'} w(c')$, then we are done. Otherwise, since w is

weakly Pareto efficient, w(c') is acceptable to c'. If $w(c') >_{c'} h'$, then, by the inductive assumption, there must exist another c'' such that $\mu^n(c'') = \mu^{n+1}(c'') >_{c''} w(c'')$.

Case 2: $\mu^{n+1}(c^n) \neq m^*(c^n|H^n) \implies NT^n(c^n) \neq H^n$. As we demonstrated above, c^n cannot improve to any $h' \notin H^n$. Hence, if the statement does not hold, (2)-(3) must be true for some $h \in H^n - NT^n(c^n)$. However, in any weakly Pareto efficient w with $w(c^n) = h$, we must have that $w(c') \neq \mu^n(c')$ for some $c' \notin C^n$. Otherwise, there would be a strictly Pareto improving cycle on w. If $\mu^n(c') = \mu^{n+1}(c') >_{c'} w(c')$, we are done. If $w(c') >_{c'} \mu^{n+1}(c'')$, then, by the inductive assumption, there must exist another c'' such that $\mu^n(c'') = \mu^{n+1}(c'') >_{c''} w(c'')$.

Note that if ϕ_{LE} is outcome dominated by any w, there must be an outcome improvement cycle $Y=(c_1,c_2,...,c_m)$ on ϕ_{LE} where $\phi_{LE}(c_{j+1})>_c \phi_{LE}(c_j)$ for all $j\neq m$ and $\phi_{LE}(c_1)>_{c_m}\phi_{LE}(c_m)$. (There may also be a chain where c_m 's outcome improving home is vacant. This case is ruled out by ruling out cycles, so we do not write it explicitly.) By the induction above, any outcome improvement cycle Y that maintains weak Pareto efficiency cannot involve any c such that $c\notin C^n$ for any n. Any $c_k\in Y$ must satisfy $c_k\in C^n$ for all n, so $\phi_{LE}(c_k)\in T(c_k)$. Let w be the weakly Pareto efficient matching implied by executing the trades on Y. Consider the c_j that chooses in the earliest round i such that all other children in the cycle choose after c_j . Since $\phi_{LE}(c_j)=m^*(c_j|T^i(c_j))$, $w(c_j)>_{c_j}\phi_{LE}(c_j)\Longrightarrow w(c_j)\notin T^i(c_j)$. Additionally, $w(c_j)\in H^i$ since Y only involves children remaining in the exchange. These facts imply that $w(c_j)\in B(c_j)$. Because $\phi_{LE}(c_k)\in T(c_k)$ for all $c_k\in Y$, w is Pareto dominated by ϕ_{LE} . Therefore, any such w that outcome dominates ϕ_{LE} must be Pareto dominated by ϕ_{LE} , and there cannot exist a weakly Pareto efficient w that outcome dominates ϕ_{LE} that is not Pareto dominated by ϕ_{LE} .

Suppose, instead, that preferences are top-single. Any outcome improvement cycle Y that maintains weak Pareto efficiency involves only children remaining in the exchange. However, all of this children have their only most preferred option. The cycle (or chain) must reassign all children to a less preferred option to improve their outcomes. ϕ_{LE} will strictly improve all such children. Therefore, there cannot be any outcome improvement cycles maintaining weak Pareto efficiency if preferences are top-single.

Proposition 1. Linear Exchange is not exclusively nor strong exclusively outcome sufficient.

Proof. First, Linear Exchange need not be Pareto efficient, therefore it is not strong exclusively outcome sufficient. The counterexample is the Illustrative Example, where (2,4,1,5,3) is not Pareto efficient because c can swap with either b or a. Additionally, there may exist weak Pareto efficient matchings that outcome dominate it. We show this case through another counterexample.

Consider the market $C = \{a, b\}$ and $H = \{1, 2, 3\}$ with the following preferences and outcomes:

$$a$$
 b
 $\succ_a: [1], [2]$ $\succ_b: [1, 2], [3]$
 $\gt_a: 2, 1$ $\gt_b: 3, 1, 2$

Let the order be: a, b. The resultant matching is $\phi_{LE} = (1, 2)$. Consider another matching w = (2, 1). a can only improve if b has a different match. However, b cannot

strictly improve further from any other match. Therefore, w is weakly Pareto efficient. We also have that ϕ_{LE} OD w.

Proposition 2. Linear Exchange is exclusively outcome sufficient if preferences are top-single, and it is strong exclusively outcome sufficient if preferences are strict-single.

Proof. The first part for top-singleness is proven in Theorem 1. For strong exclusive outcome sufficiency, since strict-single preferences are a specific case of top-single preferences, Linear Exchange is exclusively outcome sufficient. Under strict-single preferences, all preferences are strict. However, weak Pareto efficiency is equivalent to Pareto efficiency when preferences are strict. Therefore, Linear Exchange produces a Pareto efficient matching. Furthermore, it is not outcome dominated by any weak Pareto efficient matching therefore it is not outcome dominated by any Pareto efficient matching.

Theorem 3. Linear Exchange is non-obviously manipulable.

Proof. Fix some c and arbitrary report \succ'_c . We prove the Theorem by three cases. First, note that for any of the following cases, one can take a profile (\succ'_{-c}, \gt'_{-c}) where there exists at least one $h \in T(c)$ such that $h \notin T(c') \cup B(c')$ for any c'. Under truth-telling, h is either unmatched or matched to c. By Theorem 1, c cannot prefer an unmatched home over $\phi_{LE}(c)$, hence $\phi_{LE}(c) \succ_{c}, \succ'_{-c}, \gt_{c}, \gt'_{-c}) \in T(c)$. Therefore, the best case for c under truth-telling is always one of her most preferred homes. Next, we show that the worst-case under truth-telling is always weakly preferred to any other report.

Case 1: $|C| \ge |T(c)| + |B(c)|$. Let (\succ'_{-c}, \gt'_{-c}) be a profile where a distinct child c' has $h \in T'(c')$ and $h = m^*(c'|T'(c'))$ for every $h \in T(c) \cup B(c)$. Under the order of RLE where c goes last in some round n, we have that $H^n \cap (T(c) \cup B(c)) = \emptyset$. Therefore, $\phi_{LE}(\succ'_c, \succ'_{-c}, \gt_c, \gt_{-c}) = \emptyset$. In this case, c's assignment under the worst-case truth-telling assignment is trivially weakly preferred.

Case 2: $|T(c)| + |B(c)| > |C| \ge |T(c)|$. Under any report, as above, we can ensure that under a profile (\succ'_{-c}, \gt'_{-c}) , c cannot be matched to any of her most preferred homes. However, at least one of her least preferred homes must be unmatched. When c is truthtelling, by Theorem 1 again, her worst-case assignment must be some home in her least preferred set. Since c is not matched to any of her most preferred homes in the worst-case scenario under any report, c must weakly prefer truth-telling's worst-case.

Case 3: |T(c)| > |C|. Under any reports, at least one of c's most preferred homes must be unmatched. In this case, by Theorem 1, c's worst-case assignment under truthtelling is one of her most preferred homes. Therefore, c must weakly prefer truth-telling's worst-case. This concludes the proof.

Algorithm 3. Serial Dictatorship: Choose the next child c in some predetermined order. Set c's match to be a random home from her most preferred homes if one is available. If not, set her match to be a random home from her less preferred homes if one is available. If not, set her match to \varnothing . Continue to the next child until either no children or no homes remain.
