## Abstract

This article describes the development of a novel U-Net-enhanced Wavelet Neural Operator (U-WNO), which combines wavelet decomposition, operator learning, and an encoder-decoder mechanism. This approach harnesses the superiority of the wavelets in time frequency localization of the functions, and the combine down-sampling and up-sampling operations to generate the segmentation map to enable accurate tracking of patterns in spatial domain and effective learning of the functional mappings to perform regional segmentation. By bridging the gap between theoretical advancements and practical applications, the U-WNO holds potential for significant impact in multiple science and industrial fields, facilitating more accurate decision-making and improved operational efficiencies. The operator is demonstrated for different pregnancy trimesters, utilizing two-dimensional ultrasound images.

**Keywords:** Operator Learning, Wavelet Neural Operator, Image Segmentation, Computer Vision, Neural Networks.

## 1 Introduction

Over the years, research in deep learning and computer vision has undergone significant advancements, revolutionizing the way machines perceive and interpret visual information. The development of neural networks marked the early stages of this evolution, providing foundational models for image recognition and classification. The continuous refinement of these models has led to the creation of more sophisticated architectures that can process complex visual inputs with remarkable accuracy.

This article presents a novel model called U-Net-enhanced Wavelet Neural Operator (U-WNO). The model is a combination of operator learning, Convolutional Neural Network (ConvNet), and the encoder-decoder mechanism. Operator learning focuses on learning the mapping function of an operator that transforms one function into another.

Some noteworthy neural operators include the Wavelet Neural Operator (WNO) ([Tripura and Chakraborty, 2022](#)), Fourier Neural Operator (FNO) ([Li et al, 2021](#); [Wen et al, 2022](#)) and a few others, designed to efficiently approximate complex functions, particularly for solving

partial differential equations (PDEs). FNO integrates the Fourier transform with neural network architectures to process data in the frequency domain, allowing it to capture global patterns and interactions more effectively than traditional methods. By operating on the frequency components of the data, FNO can learn and approximate operators that map inputs to outputs with high accuracy and reduced computational cost. WNO combines the principles of wavelet transforms with neural network architecture to efficiently learn and approximate complex functions, particularly in the context of solving partial differential equations (PDEs) and other mathematical problems. Wavelet transforms decompose data into different frequency components, which helps in capturing both local and global features of the data at various scales. When integrated into neural networks, this approach enables the model to handle multi-scale and multi-resolution data more effectively. The neural network uses wavelet-based representations to learn the underlying operators that map inputs to outputs, enhancing its ability to model and predict complex systems with high accuracy. Recent studies [Tripura and Chakraborty \(2022\)](#) have shown that WNO, upon which the proposed network is built, exhibits superior performance compared to FNO in the spatial domain, as it provides a multi-resolution analysis that captures both frequency and spatial localization, whereas FNO decomposes signals into their global frequency components, which may not be as effective for capturing fine details in an image.

The study explains the development of U-WNO in detail. It combines operator learning and wavelet decomposition, extracting father and mother wavelets to understand features and coefficients depending upon amplitude and frequency values, ConvNet for feature transformation without altering the original shape, and finally, the U-Net to generate segmentation maps.

Ultrasound imaging ([Wells, 2006](#)) is a commonly employed medical modality for the purpose of diagnosing, screening, and treating a wide range of disorders. It is particularly favoured for its portability, affordability, and non-invasive characteristics. Furthermore, it is often regarded as the preferred approach for monitoring fetal development throughout the course of pregnancy. The use of multiple trimesters ultra-sonography is recommended for the assessment and identification of

fetal anatomy, fetal anomalies ([Dias et al, 2014](#)), gestational age, fetal growth, fetal presentation, possible multiple gestation, placental placement, and cervical insufficiency in a pregnant woman who does not exhibit any symptoms.

Fetal ultrasound is crucial in prenatal care as it provides essential insights into the health and development of the fetus, enabling early detection of congenital anomalies, accurate assessment of fetal growth, and monitoring of placental and amniotic fluid health. It also helps to determine gestational age, guides prenatal interventions and procedures, and reassures expectant parents by visualizing the fetus and confirming normal development. This non-invasive imaging technique not only facilitates timely medical interventions and planning for delivery but also enhances long-term outcomes by identifying potential issues early, ensuring both the mother and baby's well-being.

Artificial Intelligence (AI) ([Fiorentino et al, 2022](#)) in fetal ultrasound is transformative for maternal care, offering enhanced accuracy and efficiency in interpreting complex imaging data. Algorithms, particularly combining machine learning and computer vision, enables automated segmentation, anomaly detection, and growth assessment by analyzing ultrasound images with precision. This aids in early diagnosis of fetal conditions, improves the consistency of measurements, and supports real-time monitoring of fetal health, thereby reducing the risk of human error and enhancing clinical decision-making. AI-driven insights lead to more personalized care, timely interventions, and ultimately better outcomes for both the fetus and the mother.

Image segmentation ([Sobhaninia et al, 2019](#)) in fetal ultrasound is essential for precisely identifying and analyzing distinct anatomical structures and regions, such as the fetal head, organs, and placenta, enhancing the accuracy of diagnosis and monitoring.

The developed technique, is illustrated for the semantic segmentation of fetal head in two dimensional ultrasound images. The operator is optimized for the particular problem statement, and judged using dice score as the main metric. The implementation of U-WNO in fetal head segmentation not only tests the performance of the model in this domain but also indicates that the implementation of such aids would prove highly beneficial in preparing students to attain a certain

level of proficiency prior to engaging in ultrasound imaging procedures on expectant mothers. In the absence of actual patients and instructors, students would have the opportunity to engage in simulated practice, acquire knowledge, and refine their sonography performance and interpretation abilities to a specific degree of competence. Section 2 provides a comprehensive description of the dataset, section 3 provides an elucidation of the model architecture, section 4 presents a detailed analysis of the attained results, and section 5 offers a conclusion and outlines potential avenues for further research.

## 2 Dataset

The **2D - USG dataset** is used as the main training dataset for U-WNO. The image dataset comprises ultrasound images sourced from HC18 challenge<sup>1</sup>. Each image has been resized to the shape of 128\*128 pixels and is stored in PNG format. The dataset includes two-dimensional ultrasound scans from various stages of pregnancy across different trimesters. It consists of approximately 976 images and their corresponding masks, which were converted into filled masks, with the fetal head designated as the target label, as shown in Figure 1. The model was inferred over the test set containing around 325 images in the same format. This facilitates model training, hyperparameter tuning, and unbiased evaluation. Each subset maintains a balanced representation to prevent any bias in the learning process and to ensure its generalization across different scenarios.

## 3 Model Architecture

This section details the architecture of U-WNO and provides a step-by-step explanation of the development and integration process for U-WNO. The U-WNO combines wavelet-based feature extraction, ConvNet, and U-Net into a unified architecture. The initial part of this section discusses the Wavelet Neural Operator (WNO) (Tripura and Chakraborty, 2022), followed by a detailed explanation of how each sub-module is integrated into the complete model. The resulting

**Fig. 1** 2D USG Image (left) and its mask(right). This is a sample from the used dataset.

operator is particularly effective for regional segmentation tasks, as illustrated in the subsequent steps.

The WNO framework enhances the concept of neural operators by leveraging wavelet transforms to capture complex, multi-scale patterns in both spatial and temporal data. By operating within the wavelet domain, it enables adaptive representation across different resolutions. In WNO,

---

<sup>1</sup><https://hc18.grand-challenge.org/>

the kernel acts as a convolutional operator in the wavelet domain, facilitating efficient, localized learning at varying scales. Mathematically, this is represented by the kernel application on wavelet-transformed coefficients:

$$\mathcal{K}_\psi(u)(x) = \mathcal{W}^{-1}(\mathcal{K} \cdot \mathcal{W}(u))(x),$$

where  $\mathcal{W}$  denotes the wavelet transform and  $\mathcal{W}^{-1}$  its inverse. This approach allows WNO to parameterize in the wavelet space, ensuring computational efficiency by avoiding direct convolutions in physical space.

The choice of Daubechies 4 (db4) as the primary wavelet basis strikes a balance between time and frequency localization, allowing the operator to capture intricate, localized patterns without redundancy. Although simpler wavelets like Haar or smoother ones like symlet could be used, db4 is particularly effective for handling data with sharp gradients and multi-scale features. The scaling parameter  $s$  and translational parameter  $\tau$  in the wavelet transform make WNO adaptable to varying data frequencies and structures, with the wavelet function defined as:

$$\psi_{s,\tau}(t) = \frac{1}{\sqrt{s}}\psi\left(\frac{t-\tau}{s}\right).$$

Additionally, the **\*\*admissibility constant\*\***  $C_\psi$ , defined as:

$$C_\psi = \int_{-\infty}^{+\infty} \frac{|\hat{\psi}(\omega)|^2}{|\omega|} d\omega,$$

plays a crucial role in ensuring that the wavelet provides a stable, lossless representation of data across different scales.

WNO's strength lies in its ability to efficiently handle multi-resolution data, making it ideal for applications such as weather prediction, turbulence modeling in fluid dynamics, and real-time biomedical image analysis. It can capture both large-scale patterns and localized phenomena by learning from multi-scale data, thus improving model robustness and interpretability, unlike traditional convolutional neural operators that work directly in physical space. WNO's use of wavelet transformations allows it to focus computational resources on critical areas with high-detail information while reducing redundant computations in regions with homogeneous features. This distinct approach, paired with wavelet-based kernel

parameterization, positions it as a powerful tool for efficiently solving complex problems across a wide range of scientific domains.

**Fig. 2** U-Net-enhanced Wavelet Neural Operator(U-WNO) flow

The father and mother wavelets enabled the extraction of features and coefficients from the ultrasound image by leveraging variations in frequency and amplitude values. These features and weights were used to obtain a transformed approximation based on the process described above. The extracted coefficients were then modified and passed through an inverse wavelet transformation to produce the final output in the spatial domain. Convolutional layers were subsequently employed as the second component of the operator to transform the original image's features without altering its shape.

Lastly, we developed the third submodule, U-Net. The encoder, or contracting path, progressively reduces the spatial dimensions of the input image while increasing the number of feature channels. This is achieved through a series of convolutional layers and max-pooling operations. Each block in the encoder typically consists of two convolutional layers, followed by a ReLU activation function and a max-pooling operation. The decoder, or expansive path, reconstructs the spatial dimensions of the input image while reducing the number of feature channels. It involves upsampling the feature maps, followed by convolutional layers. Each block in the decoder includes an upsampling operation, concatenation with the corresponding feature map from the encoder, and convolutional layers. The final layer is a  $1 \times 1$  convolution that maps the multi-channel feature maps from the decoder to the desired number of classes for segmentation, producing the output segmentation map.

Finally, we concatenated the three submodules using the same image as input: the wavelet decomposition ( $x_1$ ), ConvNet ( $x_2$ ) and the segmentation

maps ( $x_3$ ) produced by U-Net ,together to obtain the final output, by the process shown in Figure 2

$$x_1 + x_2 + x_3$$

This operation was followed by final fully convolutional layers, using ReLU as the main activation function and Adam as the optimizer. The inclusion of Adam’s momentum term contributed to improved convergence throughout the process.

## 4 Results

This section presents the complete results of the model pipeline, including a description of the metrics used and their respective values. The model was trained for 500 epochs with a batch size of 8, and the image size was kept relatively small due to GPU limitations. To assess the model’s performance, we used the Dice Score (DS) as the primary metric. In this context, each pixel is classified as either part of the object (foreground) or background. The Dice score is calculated based on True Positives (TP), False Positives (FP), and False Negatives (FN) as follows:

$$DS = \frac{2 \cdot TP}{2 \cdot TP + FP + FN}$$

where:

- TP (True Positives) is the number of correctly predicted positive pixels.
- FP (False Positives) is the number of pixels incorrectly predicted as positive.
- FN (False Negatives) is the number of positive pixels that are not predicted as positive.

Here’s a refined version with enhanced grammar, structure, and readability:

We achieved a maximum DS of approximately 0.65, indicating that integrating the Wavelet Neural Operator (WNO) with U-Net as a unified operator yields strong performance in the segmentation task. This result is particularly notable given the challenges encountered, including resizing images to smaller dimensions due to computational constraints and handling significant noise in the data. The relatively high DS highlights the robustness of our approach in managing these limitations.

Figure 3 shows representative samples of the output generated by applying U-WNO on the test

set. These visualizations underscore the model’s capability to discern intricate patterns despite the noisy background and reduced image size.

The implications of these findings are significant, suggesting that U-WNO could serve as a valuable tool across various applications beyond this study. Its ability to effectively segment images under challenging conditions opens pathways for its adoption in multiple fields. Future work could focus on further model refinement and exploring its adaptability to diverse data types, enhancing its practical utility.

To support validation and reproducibility, the complete code repository and dataset utilized in this study are available here<sup>2</sup>. The access of the repository will be granted after the manuscript review process is completed. We encourage other researchers to explore this repository to facilitate ongoing advancements in the field.

## 5 Conclusion and Future Scope

The development of the U-WNO represents a significant advancement in image segmentation. One of U-WNO’s key strengths lies in its use of wavelet decomposition, which enables multi-resolution analysis of ultrasound images. This capability allows the model to break down images into various frequency components, isolating critical features that conventional methods might miss. Such a multi-scale approach is especially valuable in ultrasound imaging, where data quality often varies due to noise or low contrast. By incorporating wavelet decomposition, U-WNO improves reliable detection of regions of interest, even in complex scenarios like pregnancy scans.

U-Net performs the segmentation through its well-established encoder-decoder structure, effectively combining down-sampling and up-sampling operations. This architecture enables the model to retain essential spatial information during down-sampling while reconstructing the segmented image accurately during up-sampling. The integration of operator learning with wavelet-based localization and U-Net leads to more refined segmentation outputs.

**Fig. 3** Samples from the test set and their corresponding segmentation outputs obtained through U-WNO. The top and bottom rows show two different test samples and their respective results.

U-WNO’s application in ultrasound imaging could greatly impact clinical practice. The model’s

ability to accurately track and label key anatomical features during routine scans can assist healthcare professionals in monitoring fetal development and identifying potential complications, where precision is essential for maternal and fetal health. U-WNO’s deployment, following thorough testing, has the potential to reduce human error and increase efficiency in ultrasound procedures within clinical settings.

Accurate segmentation also serves as a valuable educational tool, teaching healthcare professionals to interpret ultrasound images, particularly in challenging cases like late-stage pregnancy. U-WNO could support trainee education by helping them navigate complex images and identify regions of interest with greater confidence. This dual functionality—serving both clinical and educational needs—highlights U-WNO’s versatility and applicability in healthcare and other fields.

In summary, U-WNO offers a powerful tool for enhancing image segmentation accuracy and efficiency. Through the integration of wavelet decomposition, operator learning, and U-Net architecture, it enables precise and reliable tracking of regions of interest, even in challenging imaging scenarios. As AI evolves, models like U-WNO illustrate how advanced computational techniques can address real-world challenges.

The operator’s design is particularly noteworthy for managing infinite-dimensional feature vector spaces, a challenging aspect in computer vision. By leveraging wavelet’s multi-resolution capabilities, the U-WNO operator can handle varying levels of image detail. Integrating wavelet decomposition with deep learning techniques enhances feature extraction and representation.

This amalgamation of techniques also paves the way for future technologies, such as digital twin systems. This paper reflects a shift towards sophisticated, effective solutions in imaging and predictive systems, emphasizing the potential for these models to play a pivotal role in future technological advancements.
