PATHWISE OPTIMIZATION FOR BRIDGE-TYPE ESTIMATORS AND ITS APPLICATIONS

ALESSANDRO DE GREGORIO AND FRANCESCO IAFRATE

Abstract. Sparse parametric models are of great interest in statistical learning and are often analyzed by means of regularized estimators. Pathwise methods allow to efficiently compute the full solution path for penalized estimators, for any possible value of the penalization parameter λ . In this paper we deal with the pathwise optimization for bridge-type problems; i.e. we are interested in the minimization of a loss function, such as negative log-likelihood or residual sum of squares, plus the sum of ℓ^q norms with $q \in (0, 1]$ involving adpative coefficients. For some loss functions this regularization achieves asymptotically the oracle properties (such as the selection consistency). Nevertheless, since the objective function involves nonconvex and nondifferentiable terms, the minimization problem is computationally challenging.

The aim of this paper is to apply some general algorithms, arising from nonconvex optimization theory, to compute efficiently the path solutions for the adaptive bridge estimator with multiple penalties. In particular, we take into account two different approaches: accelerated proximal gradient descent and blockwise alternating optimization. The convergence and the path consistency of these algorithms are discussed. In order to assess our methods, we apply these algorithms to the penalized estimation of diffusion processes observed at discrete times. This latter represents a recent research topic in the field of statistics for time-dependent data.

Keywords: adaptive thresholding operators, gradient descent, nonconvex optimization, path consistency, proximal maps, regularized estimators, stochastic differential equations

1. INTRODUCTION

It is well known that the optimization methods play a crucial role in machine learning, statistics and signal/image processing. Many practical problems arising in statistical learning fall into the following class of problems

(1.1)
$$
\min_{\theta} \left\{ f(\theta) := g(\theta) + \sum_{i=1}^{m} h_i(\theta) \right\},
$$

where $g : \mathbb{R}^p \to \mathbb{R}$ is a loss function, while the functions $h_i : \mathbb{R}^{p_i} \to \mathbb{R}$, with $\sum_{i=1}^n p_i = p$, represent nonsmooth and possibly nonconvex regularization terms.

Sparse parametric models are of great interest in statistical learning and are often analyzed by means of regularized estimators. A classical example is the linear regression model $y = \mathbf{X}\theta + \varepsilon$, where y is the response vector and **X** is the $n \times p$ predictor matrix, $\theta := (\theta_1, ..., \theta_p)^\top \in \mathbb{R}^p$ is the parametric vector and ε is a centered sub-Gaussian random vector with independent components. In the high dimensional case, when $p > n$, the

Date: December 6, 2024.

parameters can be estimated by means of regularized estimator, such as the LASSO, and many statistical guarantees can be obtained under the sparsity assumption, i.e. $\|\theta\|_0 = s < p$. A more general regularized least squares problem is obtained by solving the [\(1.1\)](#page-0-0) with $g(\theta) = ||y - \mathbf{X}\theta||^2$ and involving a ℓ^q -penalty $h(\theta) = \lambda ||\theta||_q^q$. This leads to the bridge estimator $\hat{\theta}$ (bridge), which is obtained (see [\[18\]](#page-25-0)); i.e.

(1.2)
$$
\min_{\theta} \left\{ ||y - \mathbf{X}\theta||^2 + \lambda ||\theta||_q^q \right\},
$$

where $||\theta||_q := \left(\sum_{j=1}^p |\theta_j|^q\right)^{1/q}, q \in (0,1].$ $||\theta||_q := \left(\sum_{j=1}^p |\theta_j|^q\right)^{1/q}, q \in (0,1].$ $||\theta||_q := \left(\sum_{j=1}^p |\theta_j|^q\right)^{1/q}, q \in (0,1].$ The latter performs simultaneously both parameter estimation and variable selection. The ℓ^q -penalties exhibit singularities (they are not differentiable); this allows for sparse estimation. For $q = 1$, the estimator [\(1.2\)](#page-1-1) becomes the Least Absolute Shrinkage and Selection Operator (LASSO) introduced in [\[38\]](#page-25-1) and the optimization problem is convex. Since for $q \in (0,1)$, The ℓ^q regularization term represents a bridge between the ℓ^0 -norm $\sum_{j=1}^p 1_{\theta_j \neq 0}$ and ℓ^1 penalty. The reader can consult [\[19\]](#page-25-2),[\[21\]](#page-25-3) and [\[22\]](#page-25-4) for a discussion about the asymptotic properties of the bridgetype estimator. [\(1.2\)](#page-1-1) represents a non-convex and non-smooth optimization problem and as such, despite its interesting theoretical properties, efficient computation of the path solutions for [\(1.2\)](#page-1-1) is a non-trivial matter.

Other types of nonconvex penalties have been dealt with in [\[17\]](#page-25-5) (Smoothly Clipped Absolute Deviation), [\[46\]](#page-26-0) (Minimax Concave Penalty) and [\[11\]](#page-24-0) (Log-Sum). In literature, some algorithms and methods have been proposed for nonconvex optimization problems such as local quadratic approximation (LQA) ([\[17\]](#page-25-5)), minorization-maximization (MM) $([23])$ $([23])$ $([23])$,local linear approximation (LLA) $([48])$ $([48])$ $([48])$, and coordinate descent $([10]$ $([10]$ and $[32])$.

Although the non-convexity of the penalties leads to overall non-convex optimization problems (and then computationally hard), numerous empirical studies have shown that gradient-based optimization methods, while only guaranteed to find local optima, often produce estimators having the oracle properties with consistently smaller estimation error than the LASSO estimators (see, e.g., [\[17\]](#page-25-5) and [\[48\]](#page-26-1)).

A recent interesting application of the penalized estimation [\(1.1\)](#page-0-0) concerns the model selection for sparse stochastic processes; see, for instance, $[15]$, $[31]$, $[26]$, $[13]$ and $[14]$, [\[27\]](#page-25-12). Therefore in this setting the regularization methods involve a loss function given, for instance, by the negative log-likelihood $\mathfrak{L}_n(\theta)$ (which is generally not convex).

Mixed-rates asymptotics. There are several econometric models where the exact evaluation of the structural parameters requires estimators that exhibit mixed-rates asymptotics (in [\[1\]](#page-24-3) some examples are discussed). This highlights the need for sparse parametric models where different rates of convergence must be considered simultaneously. Then the problem becomes

(1.3)
$$
\min_{\theta} \left\{ \mathfrak{L}_n(\theta) + \sum_{i=1}^m h_i(\theta) \right\}.
$$

where each group of parameters has a different regularization term.

¹Even though $||\theta||_q := \left(\sum_{j=1}^p |\theta_j|^q\right)^{1/q}, q \in (0,1)$, is not a norm, we may still use this terminology as it is customary in literature.

A motivating example is given by discretely observed diffusion processes $(X_t)_{t\geq0}$ solution to the stochastic differential equation

$$
dX_t = b(X_t, \alpha)dt + \sigma(X_t, \beta)dW_t
$$

with parametric vectors $\alpha \in \mathbb{R}^{p_1}$ and $\beta \in \mathbb{R}^{p_2}$ appearing in the drift and diffusion term, respectively. A suitable estimator of α and β involves two different rates of convergence (see, e.g., [\[45\]](#page-26-2)) and then the penalty term is split by grouping the parameters related to b and σ . In this framework, bridge and LASSO-type estimators have been studied in [\[15\]](#page-25-8), [\[37\]](#page-25-13) and [\[16\]](#page-25-14), where $h_1(\alpha)$ and $h_2(\beta)$ are weighted ℓ^{q_i} penalties with $q_i \in (0,1], i = 1,2$.

By resorting to the same approach introduced in [\[16\]](#page-25-14), it is possible to generalize the case of diffusion process to an arbitrary number of penalization terms. In order to take into account the multiple asymptotic behavior of the non-regularized estimator, we suggest to penalize different sets of parameters with different ℓ^q norms. Therefore, we are interested in to the estimator obtained as minimizer of the objective function [\(1.3\)](#page-1-2), where h_i represents an ℓ^{q_i} penalty. We highlight again that the penalties as well as \mathfrak{L}_n are not convex in general. The aim of this paper is to compute efficiently the solutions for the estimation/selection problems of type [\(1.3\)](#page-1-2) representing a non-convex optimization problem with non-differentiable penalties. We observe that [\(1.2\)](#page-1-1) falls into the class (1.3) .

The classical convex optimization tools are not useful to compute efficiently the estimator minimizing [\(1.3\)](#page-1-2). For this reason, in the last decades, there has been an increasing interest for the nonconvex optimization problems and some algorithms has been proposed in literature (see, e.g., [\[8\]](#page-24-4) and [\[29\]](#page-25-15)). By resorting to the recent advances in the nonconvex optimization theory, we propose some algorithms for computing the pathwise solution (as the tuning coefficient varies) for a bridge-type estimators with multiple penalties arising from problem [\(1.3\)](#page-1-2). Up to our knowledge, this is the first attempt in the statistical literature to compute efficiently the pathwise solution of a problem involving bridge-type constraints, without using convex relaxation of the penalties. Essentially, the present paper represents the follow-up of [\[16\]](#page-25-14), where we focus on the computational and algorithmic issues of the same problem.

The paper is organized as follows. in Section [2](#page-3-0) we recall some notions from nonconvex optimization theory which are needed to deal with bridge-type estimators. Further details are given in the Appendix. In Section [3](#page-6-0) we introduce the adaptive bridge-type estimators and the general statistical setting. The pathwise optimization algorithms are introduced in Section [4,](#page-8-0) where two methods are proposed: the first one is an accelerated gradient descent algorithm, while the second approach is based on the blockwise proximal alternating minimization. Furthermore, the convergence properties of the updates produced by the two methods are investigated. Section [5](#page-12-0) allows an analysis of the path consistency for each parameters. This property is close to the oracle features of the bridge estimators. Finally, Section [6-](#page-15-0)[7](#page-18-0) contain the applications of our methods. In particular, the algorithms are applied to a generalized linear models based on an exponential family of distributions (Section [6\)](#page-15-0) and to an ergodic diffusion process (Section [7\)](#page-18-0). Some simulations are performed and the results compared for different estimators.

2. PRELIMINARIES ON ℓ^q regularizers

Let us assume that the function f is not differentiable and not necessarily convex. If $f = g + h$, where g is differentiable and h is not, it is possible to apply a proximal map method by minimizing the quadratic approximation to g and leave h alone. Define a proximal map (in set-valued sense) as

(2.1)
$$
\text{prox}_{s,h}(x) := \arg \min_{u} \left\{ \frac{1}{2s} ||x - u||^2 + h(u) \right\}
$$

given $x \in \mathbb{R}^p$ and $s > 0$. We observe that for $s > 0$

$$
\operatorname{prox}_{s,h}(x) = \operatorname{prox}_{1,sh}(x)
$$

and $\text{prox}_{h}(x) := \text{prox}_{1,h}(x)$. Then a proximal gradient descent algorithm seeks a minimizer by performing successive updates as follows (see for more details on this method [\[9\]](#page-24-5) and [\[7\]](#page-24-6))

(2.2)
$$
\theta^{t} \in \arg\min_{\theta} \left\{ g(\theta^{t-1}) + \nabla g(\theta^{t-1})^{\top}(\theta - \theta^{t-1}) + \frac{1}{2s_t} ||\theta - \theta^{t-1}||^2 + h(\theta) \right\}
$$

$$
= \arg\min_{\theta} \left\{ \frac{1}{2s_t} ||\theta - (\theta^{t-1} - s_t \nabla g(\theta^{t-1}))||^2 + h(\theta) \right\}
$$

$$
= \text{prox}_{s_t, h}(\theta^{t-1} - s_t \nabla g(\theta^{t-1})).
$$

A crucial point is the choice of the stepsize: a common choice is to use a backtracking rule.

In order to exploit algorithms based on the gradient descent in our framework, it is crucial to introduce a suitable proximal map [\(2.1\)](#page-3-1) with $h(\theta) = \lambda \sum_{i=1}^{p} w_i |\theta_i|^q, q \in$ $(0, 1]$, $\lambda > 0$. For this reason, we deal with the proximity operator

$$
(2.3) \ \ \text{prox}_{\lambda \| \cdot \|_q^q}(z) = \arg \min_{\theta} \left\{ \frac{1}{2} \|z - \theta\|^2 + \lambda \| \theta \|_q^q \right\} = (\text{prox}_{\lambda | \cdot |^q}(z_1), \cdots, \text{prox}_{\lambda | \cdot |^q}(z_p))
$$

where $z = (z_1, ..., z_p)^\top \in \mathbb{R}^p$. Therefore, it is sufficient to solve the one-dimensional optmization problem

(2.4)
$$
T_{\lambda}^{q}(z) := \text{prox}_{\lambda|\cdot|^{q}} = \arg \min_{\theta \in \mathbb{R}} \left\{ \frac{1}{2} (z - \theta)^{2} + \lambda |\theta|^{q} \right\}, \quad z \in \mathbb{R},
$$

where T_{λ}^{q} ^q denotes the adaptive thresholding map associated to the ℓ^q metric. It is possible to show that for $0 < q < 1$ (see Theorem 1 in [\[30\]](#page-25-16) and [\[12\]](#page-24-7)) the operator T_{λ}^{q} $\frac{q}{\lambda}$ can be expressed in the following form

(2.5)
$$
T_{\lambda}^{q}(z) = \begin{cases} 0 & |z| < t_{q,\lambda} \\ \{0, \text{sgn}(z)\theta_{q,\lambda}\} & |z| = t_{q,\lambda} \\ \text{sgn}(z)\theta^{*}(z) & |z| > t_{q,\lambda} \end{cases}
$$

where

(2.6)
$$
\theta_{q,\lambda} = [2\lambda(1-q)]^{\frac{1}{2-q}}, \quad t_{q,\lambda} = \theta_{q,\lambda} + \lambda q \theta_{q,\lambda}^{q-1}
$$

and for $|z| > t_{q,\lambda}, \theta^*(z)$ is the solution to

(2.7)
$$
\theta + \lambda q \theta^{q-1} = |z|, \quad \theta \in (\theta_{q,\lambda}, |z|).
$$

We have that

$$
\lim_{q \to 0^+} T_\lambda^q(z) =: T_\lambda^0(z) = \begin{cases} z & |z| > \sqrt{2\lambda} \\ \{0, z\} & |z| = \sqrt{2\lambda} \\ 0 & |z| < \sqrt{2\lambda} \end{cases}
$$

and

(2.8)
$$
\lim_{q \to 1^{-}} T_{\lambda}^{q}(z) =: S_{\lambda}(z) = \text{sgn}(z)(|z| - \lambda)_{+} = \begin{cases} \text{sgn}(z)(|z| - \lambda) & |z| > \lambda \\ 0 & \text{otherwise} \end{cases}
$$

representing the hard and soft-thresholding operators, respectively, used in best-subset selection and LASSO regression, respectively (see, e.g., [\[20\]](#page-25-17) and [\[30\]](#page-25-16)).

Let us note that there are two solutions at $|z| = t_{q,\lambda}$, but for practical purposes we will set T_{λ}^{q} $\lambda^{q}(\pm t_{q,\lambda}) = 0$. In general it is not possible to solve [\(2.7\)](#page-4-0) analytically and a numerical scheme is to be adopted, which can be done rapidly and allows a solution θ^* (see equation (5) in $[30]$).

Besides the case $q = 1$ (which recovers the soft-thresholding operator [\(2.8\)](#page-4-1)), explicit expression for T_λ^q ⁿ/₂ are available only in the cases $q = \frac{1}{2}$ $\frac{1}{2}$ and $q = 2/3$. Nevertheless, $q = 1/2$ is considered to be superior in some applications (see [\[44\]](#page-26-3)). In particular for $q = 1/2$ one has

(2.9)
$$
T_{\lambda}^{\frac{1}{2}}(z) = \begin{cases} 0 & |z| \le \frac{3}{2}\lambda^{\frac{2}{3}} \\ \frac{2}{3}z \left(1 + \cos\left(\frac{2\pi}{3} - \frac{2}{3}\arccos\left(\frac{\lambda}{4}\left(\frac{|z|}{3}\right)^{-\frac{3}{2}}\right)\right)\right) & |z| > \frac{3}{2}\lambda^{\frac{2}{3}} \end{cases}
$$

with a slight modification w.r.t. to Theorem 1 in [\[44\]](#page-26-3) to account for a factor of $1/2$ in the objective function (see also [\[12\]](#page-24-7)). Examples of the operators T_{λ}^{q} λ^{q} are shown in [Figure 1.](#page-5-0) In particular in [Figure 1a,](#page-5-0) the operators corresponding to several different values of q are depicted. Notice how T_{λ}^{q} $\lambda(z)$ it is not a continuous function of z: the operators jump to zero, but the width of the jump is smaller than the hard-thresholding operator T_{λ}^0 .

Notice also that the jump points of T_{λ}^{q} λ ^q do not change monotonically with q. In [Figure 1b](#page-5-0) a comparison between $T_{\lambda}^{\frac{1}{3}}$ and S_{λ} is shown. Notice how for large values of $|z|, T_{\lambda}^q$ $\chi^q(z)$ approaches the bisector, i.e. T^q_λ $\lambda^{q}(z) \approx z, |z| \gg t_{q,\lambda}$ (for $q = 1/2$ this can be checked by a direct computation in [\(2.9\)](#page-4-2)). This is a desirable behavior because values of the input away from zero remain unchanged. This corresponds to the fact that the l^q penalty, being concave, applies smaller penalization to large values of the parameters. The soft-thresholding operator instead systematically shifts the input to zero no matter its magnitude. In a sense we can say that operators T_{λ}^{q} $\lambda^{q}, 0 < q < 1$, interpolate between hard-thresholding and soft-thresholding. From the point of view of pathwise estimation this leads to discontinuous paths.

Let $z = (z_1, \ldots, z_p)^\top \in \mathbb{R}^p$, $\mathbf{w} = (w_1, \ldots, w_p)^\top \in \mathbb{R}^p_+$ and $0 < q \le 1$. Let us denote with

(2.10)
$$
\mathbf{T}_{\lambda \mathbf{w}}^q(z) := (T_{\lambda w_1}^q(z_1), \dots, T_{\lambda w_p}^q(z_p))^\top
$$

(A) Family of T_1^q operators for $q = 0.1, 1/3, 0.5, 2/3, 0.9$ from the "furthest" to the x -axis to the "closest" respectively. The bisector is shown in grey.

(B) Comparison of $T_1^{\frac{1}{3}}(z)$ (solid line) and the soft thresholding $S_1(z)$ for larger values of z. The bisector is shown in grey.

FIGURE 1

the adaptive q-thresholding operator which will play a crucial role in the optimization algorithms. For $q \to 1^-$, the operator [\(2.10\)](#page-4-3) reduces to the component-wise adaptive soft thresholding operator as the vector map $\mathbf{S}_{\lambda \mathbf{w}} : \mathbb{R}^p \mapsto \mathbb{R}^p$

(2.11)
$$
\mathbf{S}_{\lambda \mathbf{w}}(z) := (S_{\lambda w_1}(z_1), \dots, S_{\lambda w_p}(z_p))^{\top}.
$$

Finally, by setting $h(\theta) = \lambda \sum_{i=1}^p w_i |\theta_i|^q, q \in (0,1]$, in the proximal map [\(2.2\)](#page-3-2), the above discussion allows to explicit the update as follows

(2.12)
$$
\theta^t = \mathbf{T}_{\lambda s_t \mathbf{w}}^q (\theta^{t-1} - s_t \nabla g(\theta^{t-1})).
$$

3. Bridge-type estimators with multiple penalties

Let us start recalling the shrinking estimators with multiple penalties introduced in [\[16\]](#page-25-14). We deal with a parameter of interest $\theta := (\theta^1, ..., \theta^m)^\top$, where $\theta^i := (\theta_1^i, ..., \theta_{p_i}^i)^\top, p_i \in$ [10]. We deal with a parameter of interest $\theta := (\theta_1, ..., \theta_n)$, where $\theta := (\theta_1, ..., \theta_p)$, $p_i \in \mathbb{N}, i = 1, ..., m$. Furthermore, $\theta \in \Theta := \Theta_1 \times \cdots \times \Theta_m \subset \mathbb{R}^p, \mathfrak{p} := \sum_{i=1}^m p_i$, where Θ_i is a bounded convex subset of \mathbb{R}^{p_i} . We denote by $\theta_0 := (\theta_0^1, ..., \theta_0^m)^\top \in \text{int}(\Theta)$, where $\theta_i^i := (\theta_i^i - \theta_i^i)^\top$ i $i = 1, ..., m$ stands for the true value of θ . Furthermore, we assume $\theta_0^i := (\theta_{0,1}^i, ..., \theta_{0,p_i}^i)^\top, i = 1, ..., m$, stands for the true value of θ . Furthermore, we assume that $0 \in \text{int}(\Theta)$.

Let us assume that there exists a loss function $\theta \mapsto \mathfrak{L}_n(\theta)$ and

$$
\tilde{\theta}_n = (\tilde{\theta}_n^1, ..., \tilde{\theta}_n^m)^\top \in \arg\min_{\theta} \mathfrak{L}_n(\theta).
$$

Usually $\mathfrak{L}_n(\theta)$ is a (negative) log-likelihood function or the sum of squared residuals. Furthermore, suppose that $\hat{\theta}_n$ admits a mixed-rates asymptotic behavior in the sense of [\[35\]](#page-25-18); that is for the asymptotic estimation of θ_0^i , $i = 1, ..., m$, is necessary to consider simultaneously different rates of convergence for $\tilde{\theta}_n^i$, $i = 1, ..., m$. More precisely, we deal with r_n^i , $i = 1, ..., m$, representing sequences of positive numbers tending to 0 as $n \to \infty$. I_m stands for the identity matrix of size m. Furthermore, we introduce the following matrices

$$
A_n := \mathrm{diag}(r_n^1 \mathbf{I}_{p_1}, ..., r_n^m \mathbf{I}_{p_m}).
$$

For the estimator $\tilde{\theta}_n$ the following assumptions hold true: 1) the estimator $\tilde{\theta}_n$ is consistent; i.e.

(3.1)
$$
A_n^{-1}(\tilde{\theta}_n - \theta_0) = \left(\frac{1}{r_n^1}(\tilde{\theta}_n^1 - \theta_0^1), \dots, \frac{1}{r_n^m}(\tilde{\theta}_n^m - \theta_0^m)\right)^{\top} = O_p(1);
$$

 $\tilde{\theta}_n$ is asymptotically normal; i.e.

$$
A_n^{-1}(\tilde{\theta}_n-\theta_0)=\left(\frac{1}{r_n^1}(\tilde{\theta}_n^1-\theta_0^1),...,\frac{1}{r_n^m}(\tilde{\theta}_n^m-\theta_0^m)\right)^\top\stackrel{d}{\longrightarrow}N_{\mathfrak{p}}(0,\mathfrak{I}),
$$

where $\mathfrak{I} := \Gamma^{-1}$ and Γ is a $\mathfrak{p} \times \mathfrak{p}$ positive definite symmetric matrix.

We assume that θ_0 is sparse (i.e., some components of θ_0 are exactly zero). Let $p_i^0 := |\{j : \theta_{0,j}^i \neq 0\}|, i = 1, ..., m$, and $\mathfrak{p}^0 := \sum_{i=1}^m p_i^0$. For the sake of simplicity, hereafter, we assume $\theta_{0,j}^i \neq 0, j = 1, ..., p_i^0$, and it is equal to 0 otherwise, for any $i = 1, \ldots, m$. Therefore, our target is the sparse recovery of the model; i.e. we want to identify the true model θ_0 by exploiting a multidimensional random sample $(X_n)_n$ on some probability space. For this reason we use a penalized approach involving suitable shrinking terms. Since θ_n admits a mixed-rates structure, we penalize different sets of parameters with different norms. Therefore, the adaptive objective function with weighted ℓ^{q_i} penalties should be given by

(3.2)
$$
\mathfrak{L}_n(\theta) + \left[\sum_{j=1}^{p_1} \lambda_{n,j}^1 |\theta_j^1|^{q_1} + \sum_{j=1}^{p_2} \lambda_{n,j}^2 |\theta_j^2|^{q_2} + \dots + \sum_{j=1}^{p_m} \lambda_{n,j}^m |\theta_j^m|^{q_m} \right]
$$

where $q_i \in (0,1]$ and $(\lambda^i_{n,j})_{n\geq 1}, j=1,\dots,p_i, i=1,\dots,m$, are sequences of real positive random variable representing an adaptive amount of the shrinkage for each element of θ^i .

Hereafter, the sequences of weights $(\lambda_{n,j}^i)_{n\geq 1}$ will take the form

(3.3)
$$
\lambda_{n,j}^i = \lambda w_{n,j}^i, \ j = 1, ..., p_i, i = 1, ..., m
$$

where $\lambda > 0$ is a constant not depending on n and $w_{n,j}^i > 0$ (possibly random). Moreover for a vector $z = (z_1, \ldots, z_p)^\top \in \mathbb{R}^p$ and $\mathbf{w} = (w_1, \ldots, w_p)^\top \in \mathbb{R}^p_+$, we denote the w–weighted ℓ^q norm with

(3.4)
$$
\|\theta\|_{q,\mathbf{w}}^q := \sum_{j=1}^p w_j |\theta_j|^q, \quad q > 0.
$$

We follow two possible approaches. The first estimator is obtained by minimizing the cost function [\(3.2\)](#page-7-0). In order to obtain a reasonable algorithm for the above problem, we must enforce some assumptions on \mathfrak{L}_n .

Definition 1. Let \mathfrak{L}_n be a proper, coercive and C^2 function. We define the adaptive bridge-type estimator $\check{\theta}_n : \mathbb{R}^{(n+1)\times d} \to \overline{\Theta}$ as follows

(3.5)
$$
\check{\theta}_n = (\check{\theta}_n^1, ..., \check{\theta}_n^m)^\top \in \arg\min_{\theta \in \overline{\Theta}} \mathcal{G}_n(\theta; \mathbf{q})
$$

where

(3.6)
$$
\mathcal{G}_n(\theta; \mathbf{q}) := \mathfrak{L}_n(\theta) + \lambda \sum_{i=1}^m \|\theta^i\|_{q_i, \mathbf{w}_n^i}^{q_i}
$$

with $\mathbf{w}_n^i = (w_{n,1}^i, w_{n,2}^i, ..., w_{n,p_i}^i)^\top$, $\mathbf{q} = (q_1, ..., q_m)$, and $q_i \in (0,1]$, $i = 1, ..., m$. For $q_i = 1, i = 1, ..., m, (3.5)$ $q_i = 1, i = 1, ..., m, (3.5)$ becomes a LASSO-type estimator.

For $m = 1$, the estimator [\(3.5\)](#page-7-1) has been studied in [\[26\]](#page-25-10) with one penalty. The authors obtained the selection consistency and the convergence in law of [\(3.5\)](#page-7-1) by means of a polynomial type large deviation inequality for the statistical random field associated to \mathfrak{L}_n . We shed in light that the ℓ^{q_i} -norms, with $q_i \in (0,1]$, allows non-differentiable terms with some singularities. This choice is crucial to perform the selection of the true sub-model.

By setting

(3.7)
$$
\mathfrak{L}_n(\theta) := \frac{1}{2} (\theta - \tilde{\theta}_n)^\top G_n (\theta - \tilde{\theta}_n),
$$

where G_n be a $\mathfrak{p} \times \mathfrak{p}$ almost surely positive definite symmetric random matrix depending on n, $\check{\theta}_n$ becomes the least squares approximated estimator studied in [\[42\]](#page-26-4), [\[37\]](#page-25-13) and

[\[16\]](#page-25-14). In this case, under suitable assumptions on G_n and $\tilde{\theta}_n$, the regularized estimator [\(3.5\)](#page-7-1) has the desirable oracle properties; that is $\check{\theta}_n$ is consistent, selects correctly the true sparse model and is asymptotically normal with reduced covariance matrix (see Theorem 1-3 in [\[16\]](#page-25-14)). For a discussion on the oracle features of a penalized estimator the reader can consult [\[17\]](#page-25-5).

The loss function [\(3.7\)](#page-7-2) is particularly useful in our framework, because allows to perform penalized estimation for diffusion processes. Therefore, hereafter $\hat{\theta}_n$ stands for the bridge estimator arising from problem [\(3.5\)](#page-7-1) with loss function [\(3.7\)](#page-7-2).

Finally, we introduce the following notation.

• For the $\mathfrak{p} \times \mathfrak{p}$ matrix $G_n = (g_{k\ell} : k, \ell = 1, \ldots, \mathfrak{p}),$ with $\mathfrak{p} = \sum_{h=1}^m p_h$, we write G_i to denote the *i*−th block of rows of the matrix, i.e. the $p_i \times \mathfrak{p}$ matrix

$$
G_i := \left(g_{k\ell} : k = \sum_{h=1}^{i-1} p_h + 1, \ldots, \sum_{h=1}^{i} p_h, \, \ell = 1 \ldots, \mathfrak{p} \right),
$$

for $i = 1, \ldots, m$.

• Let G_{ij} the j−th row vector of the matrix G_i , i.e.

$$
G_{ij} := \left(g_{k\ell} : k = \sum_{h=1}^{i-1} p_h + j, \, \ell = 1, \dots \mathfrak{p} \right),
$$

for $i = 1, ..., m, j = 1, ..., p_i$.

• We use the notation \mathfrak{G}_i to denote the principal submatrix of G with columns and rows corresponding to the *i*−th block, i.e. the $p_i \times p_i$ matrix defined as

$$
\mathfrak{G}_i := \left(g_{k\ell} : k, \ell = \sum_{h=1}^{i-1} p_h + 1, \ldots, \sum_{h=1}^{i} p_h\right).
$$

- For a positive definite matrix G denote with $\Lambda(G)$ its largest eigenvalue.
- We denote with D_i the $p_i \times p_i$ diagonal matrix with entries g_{kk} , i.e.

$$
D_i := \text{diag}\left(g_{kk} : k = \sum_{h=1}^{i-1} p_h + 1, \dots, \sum_{h=1}^{i} p_h\right).
$$

4. Pathwise optimization for bridge-type estimators

In practise, it is not easy to calculate the values of (3.5) for any value of λ . This depends on the nonconvex and nonsmooth nature of our problem which falls into the class [\(1.1\)](#page-0-0). By resorting to some tools arising from the nonconvex optimization theory, we introduce efficient algorithms for computing the adaptive bridge-type estimator [\(3.5\)](#page-7-1). In particular we focus our attention on the pathwise solution of the estimator.

A linear approximation to the bridge penalty around an initial estimate θ (see [\[48\]](#page-26-1)) has been considered in the literature. This approach regains convexity and results in a "modified" soft-thresholding operator. We suggest two procedures which don not require convex relaxation of the penalties; they are obtained by specializing the following two optimization algorithms:

• Accelerated gradient descent approach for non-convex problems as in [\[29\]](#page-25-15), which is a modification of the algorithm introduced in [\[4\]](#page-24-8).

10 ALESSANDRO DE GREGORIO AND FRANCESCO IAFRATE

• Block coordinate optimization for non-convex problems, see [\[8\]](#page-24-4) (see also [\[43\]](#page-26-5) or [\[34\]](#page-25-19)). This respects the grouped structure of the original problem.

Hereafter, we assume that for any starting point $\theta^0 \in \text{int}(\Theta)$ of the algorithm, the associated level set; i.e. $\{\theta \in \mathbb{R}^p : \mathcal{G}_n(\theta) \leq \mathcal{G}_n(\theta^0)\}\$, is contained within $\text{int}(\Theta)$.

4.1. Accelerated proximal gradient algorithm. A popular approach to penalized problems is to consider iterative proximal gradient algorithms (see Section [2\)](#page-3-0). Accelerated algorithms rely on an interpolation between the current estimate and the previous steps. This ideas are exploited in the Fast Iterative Shrinkage-Thresholding Algorithm (FISTA) in [\[33\]](#page-25-20), [\[5\]](#page-24-9) and [\[4\]](#page-24-8) in the convex framework. FISTA has widely been applied for ℓ^1 penalized estimation problems. Essentially, at each iteration the accelerated algorithm extrapolates a point by combining the current point and the previous point, then a proximal map function is iteratively applied till the convergence of the algorithm is reached.

Let us introduce the fast optimization method extending the FISTA algorithm to the nonconvex problem [\(3.5\)](#page-7-1). First, we observe that for the gradient descent approach with function h given by the weighted l^q norm [\(3.4\)](#page-7-3), the proximal map is equal to (see Section [2\)](#page-3-0)

(4.1)
$$
\text{prox}_{s, \lambda ||\cdot ||_{q, \mathbf{w}}^q}(x) = \arg \min_{u} \left\{ \frac{1}{2s} ||x - u||^2 + \lambda ||u||_{q, \mathbf{w}}^q \right\} = \mathbf{T}_{\lambda s \mathbf{w}}^q(x)
$$

where $x \in \mathbb{R}^p$, $s > 0, 0 < q \leq 1$ and \mathbf{T}_3^q $\chi^q_{\lambda w}$ is the component-wise adaptive hardthresholding operator [\(2.10\)](#page-4-3). Let us introduce

(4.2)
$$
\overline{\mathbf{T}}_{\lambda s\mathbf{w}}^{\mathbf{q}}(\theta) := (\mathbf{T}_{\lambda s\mathbf{w}^i}^{q_i}(\theta^i - s\nabla_i \mathfrak{L}_n(\theta)) : i = 1,\dots,m), \quad s > 0, \theta \in \Theta,
$$

where $\nabla_i g$ stands for the "partial" gradients obtained deriving g w.r.t. the components of θ^i , $i = 1, 2, ..., m$. For $q_i = 1, i = 1, 2, ..., m$, the proximal map [\(4.2\)](#page-9-0) reduce to the soft-thresholding operator

(4.3)
$$
\overline{\mathbf{S}}_{\lambda s \mathbf{w}}(\theta) := (\mathbf{S}_{\lambda s \mathbf{w}^i}(\theta^i - s \nabla_i \mathfrak{L}_n(\theta)) : i = 1, ..., m), \quad s > 0,
$$

where $\mathbf{S}_{\lambda s\mathbf{w}^i}$ is given by [\(2.11\)](#page-6-1).

For any fixed $n \in \mathbb{N}$ and $\lambda > 0$, we present an implementation of the *monotone* Accelerated Proximal Gradient (APG) proposed in [\[29\]](#page-25-15) for problem [\(3.6\)](#page-7-4) involving nonconvex and nonsmooth multiple adaptive penalties. We denote by $\hat{\theta}_n(\lambda)$ the bridge-type estimator. For the sake of simplicity, in what follows we set $h := h(\theta) := \lambda \sum_{i=1}^{m} ||\theta^i||_{q_i}^{q_i}$ $q_i^{}_{,\mathbf{w}^i},$ $\check{\theta}^t := \check{\theta}^t(\lambda)$ and drop the subscript n. Furthermore, since \mathfrak{L}_n is C^2 follows that it has Lipschitz continuous gradient with global Lipschitz constant $L(\mathfrak{L}_n)$ (see Appendix for the exact definition).

Algorithm 1 Pathwise accelerated proximal gradient descent algorithm

1. Fix $\lambda > 0$ and an initial values $\eta^0 \in \text{int}(\Theta)$ (possibly depending on λ). Initialize $\check{\theta}^1 = \check{\theta}^0 = \eta^0, c_1 = 1, s < \frac{1}{L}, u < \frac{1}{L}$, where L is an upper bound of $L(\mathfrak{L}) := L(\mathfrak{L}_n)$. 2. At step $t = 1, 2, \dots$, compute

(4.4)
$$
\eta^t = \check{\theta}^t + \frac{c_{t-1}}{c_t} (\zeta^t - \check{\theta}^{t-1}) + \frac{c_{t-1} - 1}{c_t} (\check{\theta}^t - \check{\theta}^{t-1})
$$

(4.5)
$$
\zeta^{t+1} = \text{prox}_{s,h}(\eta^t - s \nabla \mathfrak{L}_n(\eta^t)) = \overline{\mathbf{T}}^{\mathbf{q}}_{\lambda s \mathbf{w}}(\eta^t),
$$

 (4.6) $t^{t+1} = \text{prox}_{u,h}(\check{\theta}^t - u \nabla \mathfrak{L}_n(\check{\theta}^t)) = \overline{\mathbf{T}}_{\lambda u\mathbf{w}}^{\mathbf{q}}(\check{\theta}^t),$

(4.7)
$$
c_{t+1} = \frac{1 + \sqrt{1 + 4c_t^2}}{2}
$$

(4.8)
$$
\check{\theta}^{t+1} = \begin{cases} \zeta^{t+1} & \text{if } \mathcal{G}(\zeta^{t+1}) \leq \mathcal{G}(v^{t+1})\\ v^{t+1} & \text{otherwise} \end{cases}
$$

3. Repeat the previous steps over a grid of λ values to get the full path of the coefficient estimates.

From (2.3) , (2.4) , (4.1) and (4.2) , it is not hard to verify (4.5) and (4.6) hold. Further-more, Algorithm [1](#page-10-2) as shown in [\[5\]](#page-24-9) and [\[29\]](#page-25-15) can achieve a $O(1/t^2)$ rate a of convergence for convex cost functions and the monotony in the nonconvex case, in contrast to the non-accelerated proximal gradient algorithm. The crucial point is the monitor v (see [\[29\]](#page-25-15)), which allows to correct the accelerated term η^{t+1} when it has the potential to fail; this "monitored acceleration" ensure that the accumulation point is a critical point and then it guarantees the convergence of the updates $\hat{\theta}^t$, $t = 1, 2, ...$ We observe that the constant stepsizes appearing in Algorithm [1,](#page-10-2) could be computed by backtracking line search which allows to provide steps with different length at each iteration (see for more details [\[29\]](#page-25-15)).

It is an easy task to verify the assumptions required in Theorem 1 in [\[29\]](#page-25-15) for the convergence of Algorithm [1.](#page-10-2) Therefore, for each $\lambda > 0, n \in \mathbb{N}$ and $q_i \in (0,1], i = 1, \ldots m$, the sequences of bounded estimates $\{\check{\theta}_n^t : t = 1, 2, \ldots\}$ $\{\check{\theta}_n^t : t = 1, 2, \ldots\}$ $\{\check{\theta}_n^t : t = 1, 2, \ldots\}$ produced by Algorithm 1 converge to a critical point $\check{\theta}_n^*$ of $\mathcal{G}_n(\theta; \mathbf{q})$; i.e.

(4.9)
$$
\check{\theta}_n^* := \lim_{t \to \infty} \check{\theta}_n^t, \quad \text{with } 0 \in \partial \mathcal{G}_n(\check{\theta}_n^*; \mathbf{q}).
$$

For other results on the convergence of the algorithm the reader can consult Theorem 3 in [\[29\]](#page-25-15).

Remark 4.1. If $\mathfrak{L}_n(\theta) := \frac{1}{2}(\theta - \tilde{\theta}_n)^\top G_n(\theta - \tilde{\theta}_n)$, the bridge-type estimator $\hat{\theta}_n$ reduces to the regularized estimator studied in $[37]$ and $[16]$. Clearly the proximity operator [\(4.2\)](#page-9-0) becomes $\overline{\mathbf{T}}_{\lambda s\mathbf{w}}^{\mathbf{q}}(\theta) := \left(\mathbf{T}_{\lambda s\mathbf{w}^i}^{q_i}(\theta^i - sG_n(\theta - \tilde{\theta}_n)) : i = 1, \ldots, m\right), \quad s > 0, \theta \in \Theta.$ Furthermore, if $q_i = 1, i = 1, 2, ..., m$, \mathcal{G}_n becomes a convex cost function and the the LASSO-type estimator $\check{\theta}_n$ represents the global minimum of the problem. Furthermore, since $\nabla \mathfrak{L}_n(\theta) = G_n(\theta - \theta_n)$, the Lipschitz constant $L(\mathfrak{L}_n)$ becomes by the spectral norm

 $||G_n|| = \Lambda(G_n)$ where $\Lambda(G_n)$ stands the largest eigenvalue of G_n . Therefore, from The-orem 2 in [\[29\]](#page-25-15), we can conclude that for $q_i = 1$ the sequence $\{\hat{\theta}_n^t, t = 1, 2, \ldots\}$ generated by Algorithm [1](#page-10-2) by applying the proximal map [\(4.3\)](#page-9-2), approaches to the LASSO-type estimator $\hat{\theta}_n$ with an $O(1/t^2)$ convergence rate; i.e.

(4.10)
$$
\mathcal{G}_n(\hat{\theta}_n^t) - \mathcal{G}_n(\hat{\theta}_n) \leq \frac{2\Lambda(G_n)||\hat{\theta}_n^0 - \hat{\theta}_n||^2}{\alpha(t+1)^2}, \quad \hat{\theta}_n^0 \in int(\Theta).
$$

4.2. Blockwise proximal alternating minimization. In order to take into account the multiple-penalties structure of our problem, we also consider a (non-accelerated) block coordinate descent approach, i.e. we update one block of parameters at each step. The main point is to consider the approximations of our cost function by means of the standard proximal linearization (see (2.2)) of each subproblem and alternating minimization on each block $\theta^i \in \Theta_i$, $i = 1, ..., m$, by the proximal maps. This scheme is known in the literature as Proximal Alternating Linearized Minimization (PALM) and it has been introduce in [\[8\]](#page-24-4).

For the sake of simplicity, in what follows we set $\mathcal{G}(\theta) := \mathcal{G}_n(\theta; \mathbf{q}), \check{\theta}^t := \check{\theta}_n^t(\lambda)$ and drop the subscript n. Let us generate a sequence of estimates $\{\check{\theta}^t : t = 1, 2, ...\}$ as follows. Let £ be a KL function (see Appendix for the definition) and $q_i \in (0,1] \cap \mathbb{Q}, i = 1,2,...,m$.

Algorithm 2 Pathwise PALM algorithm

- 1. Fix $\lambda > 0$, some initial values $\check{\theta}^0(\lambda) \in \text{int}(\Theta)$.
- 2. At step $t = 1, 2, ...,$ cycling through the block components of $\theta = (\theta^1, ..., \theta^m)^\top$ (block proximal qradient) update the i–th block as

(4.11)
$$
\check{\theta}^{i,t} = \text{prox}_{\lambda s^i \| \cdot \|_{q_i, \mathbf{w}^i}^{q_i}} (\check{\theta}^{i,t-1} - s^i \nabla_i \mathfrak{L}(\check{\theta}^{1,t}, ..., \check{\theta}^{i-1,t}, \check{\theta}^{i,t-1}, ..., \check{\theta}^{m,t-1})
$$

$$
= \mathbf{T}_{\lambda s^i \mathbf{w}^i}^{q_i} (\check{\theta}^{i,t-1} - s^i \nabla_i \mathfrak{L}(\check{\theta}^{1,t}, ..., \check{\theta}^{i-1,t}, \check{\theta}^{i,t-1}, ..., \check{\theta}^{m,t-1}))
$$

with step size $s^i = \alpha_i / L_i(\mathfrak{L})$ with $0 < \alpha_i < 1$.

3. Repeat the previous steps over a grid of λ values to get the full path of the coefficient estimates.

As observed for Algorithm [1,](#page-10-2) it is not hard to prove [\(4.11\)](#page-11-0). Note that in this case constant step sizes are used but, as noted in [\[34\]](#page-25-19), it is possible to implement backtracking rules also in the block coordinate case.

Algorithm [2](#page-11-1) has two fine properties: 1) for the updates (4.11) the statement (4.9) fulfills; i.e. the bounded sequence $\{\check{\theta}^t : t = 1, 2, ...\}$ is convergent to some accumulation/critical points; 2) if we chose a starting point quite close to the bridge-type estimate $\check{\theta}_n$, then $\{\check{\theta}^t : t = 1, 2, ...\}$ tends to $\check{\theta}_n$ (see Theorem 2.12 in [\[3\]](#page-24-10) for the a detailed statement).

The adaptive norms $\|\cdot\|_{q_i,\mathbf{w}^i}^{q_i}$ are semi-algebraic functions (see Appendix) and then \mathcal{G}_n is a KL function. We observe that $\|\cdot\|_{q_i,\mathbf{w}^i}^{q_i}$ are bounded level sets and then the updates sequence $\{\check{\theta}^t : t = 1, 2, ...\}$ is bounded. Since it is easy to check that \mathcal{G}_n satisfies Assumption 1-2 in [\[8\]](#page-24-4) (see also Remark 3 in the cited paper), the property 1) follows from Theorem 1 in [\[8\]](#page-24-4). The property 2) is a consequence of Lemma 3-4 in [\[8\]](#page-24-4) and Theorem 2.12 in [\[3\]](#page-24-10).

Remark 4.2. Clearly, a fine example is given again by $\mathfrak{L}_n(\theta) = \frac{1}{2}(\theta - \tilde{\theta}_n)^\top G_n(\theta - \tilde{\theta}_n)$. In this case, the i-th block is updated with

$$
(4.12) \qquad \hat{\theta}^{i,t} = \mathbf{T}_{\lambda s^i \mathbf{w}^i}^{q_i} \left(\hat{\theta}^{i,t-1} - s^i G_i \left((\hat{\theta}^{1,t}, ..., \hat{\theta}^{i-1,t}, \hat{\theta}^{i,t-1}, ..., \hat{\theta}^{m,t-1})^\top - \tilde{\theta}_n \right) \right).
$$

Moreover, $\frac{1}{2}(\theta - \tilde{\theta}_n)^\top G_n(\theta - \tilde{\theta}_n)$ is a semi-algebraic function (see the discussion in Appen $dix)$ and then \mathcal{G}_n is semi-algebraic as well. Therefore, the convergence results following Remark 6 in [\[8\]](#page-24-4), hold true.

5. Path consistency

Define λ_{max} as the smallest penalization value such that the null vector is a stationary point for [\(3.2\)](#page-7-0). From result [\(4.9\)](#page-10-3), we derive that a sufficient condition for this to happen is that the null-vector is a fixed point of the threshold updates $\overline{T}_{\lambda s w}^{\mathbf{q}}$. So we define

(5.1)
$$
\lambda_{\max} := \sup_s \inf \{ \lambda > 0 : \overline{\mathbf{T}}^{\mathbf{q}}_{\lambda s \mathbf{w}}(0) = 0 \},
$$

with $0 \in \mathbb{R}^p$, where s is suitably bounded, e.g. $s < 1/L(\mathfrak{L}_n)$.

For the bridge-type estimator obtained by means of the least squares approximation, we replace $\overline{T}_{\lambda s\mathbf{w}}^{\mathbf{q}}$ with $\widetilde{T}_{\lambda s\mathbf{w}}^{\mathbf{q}}$.

Remark 5.1. The sequence of λ values should start with the smallest λ_{max} such that all the parameter as estimated as zero and proceed backwards, using the previous estimate as starting point. This allows for greater efficiency in practice (see, e.g., Chapter 5, $[20]$.)

Proposition 1. For Algorithm 1, if $0 < q_i < 1, i = 1, 2, ..., m$,

(5.2)
$$
\lambda_{\max} = \max_{\substack{1 \le i \le m \\ 1 \le j \le p_i}} (w_j^i)^{-1} (|\nabla_{ij} \mathfrak{L}_n(0)| / c_{q_i})^{2 - q_i} L(\mathfrak{L}_n)^{q_i - 1}.
$$

For Algorithm 1-2 with LASSO-type penalty $(q_i = 1)$, we get

(5.3)
$$
\lambda_{\max} = ||W_n^{-1} \nabla \mathfrak{L}_n(0)||_{\infty},
$$

where W_n is the diagonal matrix containing the weights $\mathbf{w}_n = (\mathbf{w}_n^1, ..., \mathbf{w}_n^m)^\top$ on the main diagonal.

Proof. In the LASSO-type case it is possible to directly manipulate subdifferentials. In fact, in order for $\theta = 0$ to be a solution (dropping the subscript n), it is required that

$$
0 \in \nabla_{ij} \mathfrak{L}(0) + \lambda w_j^i s_{ij} \Leftrightarrow \frac{1}{w_j^i} \nabla_{ij} \mathfrak{L}(0) \in [-\lambda, \lambda] \quad \forall i, j.
$$

For $q_i < 1$ we can proceed as follows. Note that the threshold value in [\(2.6\)](#page-3-5) can be rewritten as

(5.4)
$$
t_{q,\lambda} = \lambda^{\frac{1}{2-q}} c_q, \qquad c_q = [2(1-q)]^{\frac{1}{2-q}} \left(1 + \frac{q}{2(1-q)}\right)
$$

In order for a solution obtained by updates of the form [\(4.2\)](#page-9-0) to remain null it suffices that

$$
\overline{\mathbf{T}}_{\lambda s\mathbf{w}}^{\mathbf{q}}(0) = 0 \Leftrightarrow |s\nabla_{ij}\mathfrak{L}(0)| \leq c_{q_i}(w_j^i s\lambda)^{\frac{1}{2-q_i}},
$$

14 ALESSANDRO DE GREGORIO AND FRANCESCO IAFRATE

(5.5)
$$
\Leftrightarrow \lambda \ge (c_{q_i}^{-1} |\nabla_{ij} \mathfrak{L}(0)|)^{2-q_i} \frac{s^{1-q_i}}{w_j^i},
$$

 $\forall 1 \leq i \leq m, 1 \leq j \leq p_i$. Since $s < 1/L(\mathfrak{L})$, inequalities [\(5.5\)](#page-13-0) are satisfied by [\(5.2\)](#page-12-1).

Remark 5.2. For block-wise type Algoritm [2,](#page-11-1) one can replace the global Lipschitz constant with the minimum of the partial Lipschitz constants. Note that [\(5.3\)](#page-12-2) can be seen as a special case of [\(5.2\)](#page-12-1) for the quadratic loss case, in the limit as $q_i \to 1^-$.

□

Lemma 1. Under the assumptions

(5.6)
$$
D_n := A_n G_n A_n \xrightarrow{p} D,
$$

where D is a $\mathfrak{p} \times \mathfrak{p}$ positive definite symmetric random matrix

$$
(5.7) \qquad \qquad a_n^i r_n^i = O_p(1),
$$

with $a_n^i = \max\{w_j^i, j \leq p_i^0\}, i = 1, ..., m$, for the bridge-type estimator $\hat{\theta}_n$, $\lambda_{\max}^{(n)} \to \infty$ in probability, as the sample size $n \to \infty$; i.e. $P(\lambda_{\max}^{(n)} > M) \to 1$, for any $M > 0$.

We include here the superscript n to highlight the dependence of the maximal λ on the sample size.

Proof. In this case

$$
\lambda_{\max}^{(n)} = \max_{\substack{1 \le i \le m \\ 1 \le j \le p_i}} c_{q_i}^{q_i - 2} \frac{|G_{ij}\tilde{\theta}|^{2 - q_i}}{w_j^i} ||G||^{q_i - 1}
$$

and note that $G, \tilde{\theta}$, w depend on n. Let $l_n = \min_i r_n^i$. First note that, for every n

$$
||G|| = \max_{||v||=1} v^\top G v = \max_{||v||=1} (A_n^{-1} v)^\top D_n(A_n^{-1} v) \leq l_n^{-2} ||D_n||
$$

and $||D_n|| = O_p(1)$ for the condition [\(5.6\)](#page-13-1).

Denote with $\ell = \ell(h, k)$ the index in $\{1, \ldots, \mathfrak{p}\}\)$ corresponding to group h, position k. Also denote with ν the index (depending on n) of the smallest rate, i.e. $r_n^{\nu} = l_n$.

So, for $j \leq p_0^i$, for any i and n

$$
(5.8)
$$

$$
\frac{1}{w_j^i}|G_{ij}\theta^0|^{2-q_i}||G||^{q_i-1} = \frac{1}{w_j^i}\left|\sum_{h=1}^m\sum_{k=1}^{p_h}(G_{ij})_{\ell(h,k)}\theta_{\ell(h,k)}^0\right|^{2-q_i}||G||^{q_i-1}
$$
\n
$$
= \frac{1}{w_j^i(r_n^i)^{2-q_i}}\left|\sum_{h=1}^m\sum_{k=1}^{p_h}(D_{i,j}^n)_{\ell}\frac{\theta_{\ell}^0}{r_n^h}\right|^{2-q_i}||G||^{q_i-1}
$$
\n
$$
= \frac{1}{w_j^i(r_n^i)^{2-q_i}}\left|\sum_{k'=1}^{p_\nu}(D_{i,j}^n)_{\ell(\nu,k')} \theta_{\ell(\nu,k')}^0 + \sum_{h=1,h\neq\nu}^m\sum_{k=1}^{p_h}(D_{i,j}^n)_{\ell(h,k)} \theta_{\ell(h,k)}^0 \frac{l_n}{r_n^h}\right|^{2-q_i}\frac{||G||^{q_i-1}}{l_n^{2-q_i}}
$$
\n
$$
\geq \frac{1}{a_n^i(r_n^i)^{2-q_i}}\left|\sum_{k'=1}^{p_\nu}(D_{i,j}^n)_{\ell(\nu,k')} \theta_{\ell(\nu,k')}^0 + \sum_{h=1,h\neq\nu}^m\sum_{k=1}^{p_h}(D_{i,j}^n)_{\ell(h,k)} \theta_{\ell(h,k)}^0 \frac{l_n}{r_n^h}\right|^{2-q_i}l_n^{-q_i}||D_n||^{q_i-1}
$$

$$
=: U_n l_n^{-q_i} (r_n^i)^{q_i-1} \to \infty, \quad n \to \infty,
$$

where $a_n^i = \max\{w_j^i, j \leq p_i^0\}$. By assumptions [\(5.6\)](#page-13-1) and [\(5.7\)](#page-13-2), the terms in the absolute value are $O_p(1)$ as well as $||D_n||$, since each $(D_{i,j}^n)_\ell$ converges in probability and $0 \leq$ $l_n \n\t\leq r_n^h$ (implying that the ratios l_n/r_n^h are bounded). Overall $U_n = O_p(1)$ and, since $r_n^i, l_n \to 0$, [\(5.8\)](#page-13-3) is unbounded.

Therefore

$$
(5.9) \qquad \lambda_{\max}^{(n)} = \max_{\substack{1 \le i \le m \\ 1 \le j \le p_i}} c_{q_i}^{q_i - 2} \frac{|G_{ij}\tilde{\theta}|^{2 - q_i}}{w_j^i} ||G||^{q_i - 1} \ge \max_{\substack{1 \le i \le m \\ 1 \le j \le p_i^0}} c_{q_i}^{q_i - 2} \frac{|G_{ij}\tilde{\theta}|^{2 - q_i}}{w_j^i} ||G||^{q_i - 1}
$$

where the constants c_{q_i} do not depend on n. For each term on the RHS, by convexity of $x \mapsto x^{2-q_i}$ we can write

$$
(5.10) \frac{1}{w_j^i} |G_{ij}\tilde{\theta}|^{2-q_i} ||G||^{q_i-1} = \frac{1}{w_j^i} \left[|G_{ij}\tilde{\theta}|^{2-q_i} - |G_{ij}\theta_0|^{2-q_i} + |G_{ij}\theta_0|^{2-q_i} \right] ||G||^{q_i-1}
$$

\n
$$
\geq \frac{1}{w_j^i} \left[(|G_{ij}\tilde{\theta}| - |G_{ij}\theta_0|)(2-q_i) |G_{ij}\theta_0|^{1-q_i} + |G_{ij}\theta_0|^{2-q_i} \right] ||G||^{q_i-1}
$$

\n
$$
\geq \frac{1}{w_j^i} \left[-|G_{ij}(\tilde{\theta} - \theta_0)|(2-q_i) |G_{ij}\theta_0|^{1-q_i} + |G_{ij}\theta_0|^{2-q_i} \right] ||G||^{q_i-1}
$$

\n
$$
= \frac{1}{w_j^i} \left[-|r_n^i G_{ij} A_n A_n^{-1} (\tilde{\theta} - \theta_0)|(2-q_i) \frac{1}{r_n^i |G_{ij}\theta_0|} + 1 \right] |G_{ij}\theta_0|^{2-q_i} ||G||^{q_i-1} \to \infty
$$

where the conclusion follows from [\(5.8\)](#page-13-3) and the fact that $A_n^{-1}(\tilde{\theta}-\theta_0) = O_p(1)$, $r_n^i G_{ij} A_n =$ $O_p(1)$ element-wise, while

$$
r_n^i|G_{ij}\theta_0|=\sum_{h,k}(D_{i,j}^n)_\ell\frac{\theta_\ell^0}{r_n^h}\to\infty
$$

making the terms into square brackets an $O_p(1)$. The proof in the lasso can be performed by adapting the steps above. \Box

The fact that the solution path is identically null from some point on seems in contradiction with the consistency property of the estimators. The following theorem addresses the issue of path consistency.

Theorem 1 (Path consistency). Under the assumptions (3.1) , (5.6) and (5.7) , for the bridge-type estimator $\hat{\theta}_n$, as $n \to \infty$, the path estimates $\{\hat{\theta}_n(\lambda): \lambda > 0\}$ produced either by

- (i) any algorithm in the case with $q_i = 1 \forall i$; (LASSO-type) or
- (ii) the block-wise Algorithm [2,](#page-11-1) for $0 < q_i < 1$, if the starting point is quite close to $\hat{\theta}_n$ (see Theorem 2.12 in $[3]$);

are pointwise consistent with respect to λ , *i.e.*

$$
A_n^{-1}(\hat{\theta}_n(\lambda) - \theta_0) 1_{\{\lambda_{\max}^{(n)} > \lambda\}} = O_p(1), \quad n \to \infty, \forall \lambda > 0.
$$

Under additional technical assumptions as in [\[16\]](#page-25-14), the updates at point (i) and (ii) satisfy the oracle properties of variable selection and asymptotic normality.

Proof. (i) In the LASSO case the stationary point coincides with the global minimum. For any fixed $\lambda > 0$, by Lemma [1](#page-13-4) and recalling that θ_n satisfies the selection consistency property, it is not hard ti prove that for any $\varepsilon > 0$

$$
P(A_{n,\varepsilon}) := P(\{\lambda_{\max}^{(n)} > \lambda\} \cap \{|\hat{\theta}_n(\lambda) - \theta_0| \le \varepsilon\}) \longrightarrow 1,
$$

implying that the path is not identically null at such λ . Then the consistency follows.

(ii) In the bridge case the argument is analogous, where (local) convergence to a global minimum is guaranteed under the same conditions discussed for PALM Algorithm.

□

Remark 5.3. If we consider each coordinate as a single block in a PALM-type algorithm, update [\(4.12\)](#page-12-3) takes the form

$$
(5.11) \qquad \hat{\theta}_{j}^{i,t} = \mathbf{T}_{\lambda s_{j}^{i} w_{j}^{i}}^{q_{i}} \left(\hat{\theta}_{j}^{i,t-1} - s_{j}^{i} G_{ij} \left((\hat{\theta}^{1,t}, ..., \hat{\theta}_{j-1}^{i,t}, \hat{\theta}_{j}^{i,t-1}, ..., \hat{\theta}^{m,t-1})^{\top} - \tilde{\theta} \right) \right)
$$

valid for step-sizes $s_j^i < \alpha/g_{\ell\ell}$, $g_{\ell\ell}$ being the Lipschitz constant of the one-dimensional block. We refer to this algorithm as the bridge version of the coordinate descent algorithm.

We close this section with a comparison between LASSO and Bridge-type solution paths. [Figure 2](#page-16-0) shows typical sample paths outcome of Algorithm [1](#page-10-2) and those arising in the LASSO case. The effect of the discontinuity of the T^q operators on the Bridge paths is apparent. The following sections discuss detailed comparisons of the techniques in terms of estimation performance.

6. Applications to Generalized Linear Models

6.1. Penalized GLMs. Estimator [\(3.5\)](#page-7-1) can be applied to penalize likelihood functions arising from generalized linear models (GLMs). For instance, it is well known that for an exponential family of distributions with natural parameter $\theta \in \Theta \subset \mathbb{R}^p$

(6.1)
$$
f(x; \theta) = \exp \left\{ \sum_{j=1}^{p} \theta_j T_j(x) - \psi(\theta) \right\} h(x)
$$

thenatural parameter space Θ is convex ([\[28\]](#page-25-21), Lemma 2.7.1) and, as an immediate consequence, the density is log-concave. This means that the theoretical results regarding estimator [\(3.5\)](#page-7-1) hold, considering as the loss function \mathfrak{L}_n the negative log-likelihood

(6.2)
$$
H_n(\theta; q) := \sum_{i=1}^n \ell_i(\theta) + \lambda ||\theta||_{q, \mathbf{w}_n}^q,
$$

where $\ell_i(\theta) = -\log f(x_i; \theta)$. Note that in this case, we consider only one parameter group since there is a unique rate of convergence.

We would like to stress the fact that the problem of finding estimators based on [\(6.2\)](#page-15-1) has been considered several times in the statistical literature (e.g. [\[48\]](#page-26-1), [\[21\]](#page-25-3) and [\[19\]](#page-25-2) for regression problems). Nevertheless in all cases due to difficulties caused by the non-convexity of the problem, the solution is computed in terms of some convex approximation. Our work shows that by exploiting non-convex analysis results the exact solution of the bridge estimator can be computed. Moreover the solution retains the

(a) Sample path of the estimates for the LASSO estimator

(b) Sample path of the estimates of Algorithm 1

Figure 2. Comparison between LASSO and Bridge path.

particular features of the estimator, which are variable selection combined with noncontinuous estimation path and penalization vanishing for large values of lambda.

In particular in [\[48\]](#page-26-1) the one-step LLA estimator is introduced, derived as

(6.3)
$$
\arg \min \left\{ \sum_{i=1}^{n} \ell_i(\theta) + \sum_{j=1}^{p} p'_{\lambda}(|\tilde{\theta}_j|) |\theta_j| \right\}
$$

where $\tilde{\theta}$ denotes an initial (unpenalized) estimator for θ and p'_{λ} is the derivative of a penalty function p_{λ} . In the context of bridge estimation the penalty term in [\(6.3\)](#page-17-0) becomes

(6.4)
$$
p'_{\lambda}(|\tilde{\theta}_j|)|\theta_j| \propto \frac{1}{|\tilde{\theta}_j|^{1-q}}|\theta_j|
$$

meaning that the proposed estimator is in fact equivalent to a weighted lasso estimator (e.g. compare with the choice of the weights (7.3)). Note also that in [\[48\]](#page-26-1) a quadratic approximation of the log-likelihood is further considered, making the LLA one step estimator a particular case of the bridge-type estimator with weights given by [\(6.4\)](#page-17-1). In the case of regression problems with othonormal designs, the "linear" approximation of the bridge penalty is capable of retaining the property of the vanishing penalization for large coefficients (for an illustration see Figure 2 in [\[48\]](#page-26-1)). Specifically in this case, it is well known that the lasso solution is the soft-thresholding operator applied to the least squares estimator, incorporating the weights, $\hat{\theta} = S_{q\lambda/|\tilde{\theta}_j|^{1-q}}(|\tilde{\theta}_j|)$. Note that the weights and the input are inversely related, causing the "vanishing penalization" effect.

However, for general quadratic approximation problems, it is not guaranteed that the penalization will vanish for large inputs, since the iterative updates of the form [\(4.3\)](#page-9-2), for example, are based on weights which are now "fixed" with respect to the input of the operator.

6.2. Simulation study. Consider the linear regression model

$$
y = \mathbf{X}\theta_0 + \epsilon
$$

where $y_i \in \mathbb{R}^n$, $\mathbf{X} \in \mathbb{R}^{n \times p}$, $\theta_0 \in \mathbb{R}^p$ and $\epsilon_i \sim N(0, \sigma^2)$ are *i.i.d.* random variables. The goal is to compare the predictive performance of the bridge estimator

$$
\hat{\theta}^q = \arg\min_{\theta} \left\{ ||y - \mathbf{X}\theta||_2^2 + \lambda ||\theta||_q^q \right\},\
$$

its one step LLA approximation as in [\(6.4\)](#page-17-1), denoted with $\hat{\theta}^q_I$ L^q , and the classic lasso estimator $\hat{\theta}^1$.

We consider a high-dimensional setting with $p = 500$. Roughly 2/3 of the components of θ_0 are equal to zero (specifically 346), the others are positive or negative numbers in the range [-10, 10]. Following the same scheme as in [\[47\]](#page-26-6), columns x_i and x_j of **X** have correlation 0.5^{|i−j|}. We set $\sigma = 10$.

The models are fitted by applying Algorithm [1](#page-10-2) using $n = 1000$ training points. The optimal λ value is chosen by cross-validation and the prediction error is measured on 1000 test points. LLA and LASSO solution were computed using existing R libraries, grpreg and glmnet respectively.

The results are summarized in [Table 1,](#page-18-1) showing that Bridge estimator can achieve a better performance in this context. In [Figure 3](#page-18-2) we show the test error as a function of the normalized penalization parameter. In particular we see that Bridge can achieve a

		Bridge LLA LASSO
Test MSE 25.85 26.01		26.9

Table 1. Test error comparison for bridge, one step LLA and LASSO estimators.

Figure 3. Comparison of test errors as a function of normalized penalization parameter $\lambda/\lambda_{\text{max}}$ for bridge (solid line), LLA (dashed), LASSO (dotted). Figure B is a zoom of Figure A around the minimum of the curves.

lower test error for suitable values of the tuning parameter, at the cost of a more rapid increase in bias as the penalization parameter increases.

7. Application to Stochastic Differential Equations

7.1. **Ergodic diffusions.** Let $(\Omega, \mathcal{F}, \mathbf{F} = (\mathcal{F}_t)_{t>0}, P)$ be a filtered complete probability space. Let us consider a d-dimensional solution process $X := (X_t)_{t>0}$ to the following stochastic differential equation (SDE)

(7.1)
$$
dX_t = b(X_t, \alpha)dt + \sigma(X_t, \beta)dW_t, \quad X_0 = x_0,
$$

where x_0 is a deterministic initial point, $b : \mathbb{R}^d \times \Theta_\alpha \to \mathbb{R}^d$ and $\sigma : \mathbb{R}^d \times \Theta_\beta \to \mathbb{R}^d \otimes \mathbb{R}^r$ are Borel known functions (up to unknown parameter vectors α and β) and $(W_t)_{t>0}$ is a r-dimensional standard \mathcal{F}_t -Brownian motion. Let $\theta := (\alpha, \beta) \in \Theta := \Theta_\alpha \times \Theta_\beta \subset \overline{\mathbb{R}}^{p_1+p_2}$ and denote by $\theta_0 := (\alpha_0, \beta_0)$ the true value of θ . As discussed in the Introduction, assume that θ_0 has a sparse representation.

The process X is sampled at $n+1$ equidistant discrete times t_i^n , such that $t_i^n - t_{i-1}^n =$ Δ_n for $i = 1, ..., n$, (with $t_0^n = 0$). Therefore the data are observations $\mathbf{X}_n := (X_{t_i^n})_{0 \le i \le n}$. We consider a *high-frequency* sampling scheme, i.e with the following asymptotics as $n \to \infty$: $n\Delta_n \longrightarrow \infty$, $\Delta_n \longrightarrow 0$ and $n\Delta_n^p \longrightarrow 0$ for some $p \geq 2$, and there exists

 $\epsilon \in (0,(p-1)/p)$ such that $n^{\epsilon} \leq n\Delta_n$ for large n. A widely used loss function in this context, for $p = 2$, is the negative quasi-log-likelihood function

$$
\ell_n(\mathbf{X}_n, \theta) := \frac{1}{2} \sum_{i=1}^n \left\{ \log \det(\Sigma(X_{t_{i-1}^n}, \beta)) + \frac{1}{\Delta_n} (\Delta_i X - \Delta_n b(X_{t_{i-1}^n}, \alpha))^\top \Sigma^{-1}(X_{t_{i-1}^n}, \beta) (\Delta_i X - \Delta_n b(X_{t_{i-1}^n}, \alpha)) \right\}.
$$
\n(7.2)

with $\Sigma(x,\beta) := \sigma \sigma^{\top}(x,\beta)$ and $\Delta_i X := X_{t_i^n} - X_{t_{i-1}^n}$, leading to the quasi-likelihood estimator

$$
\tilde{\theta}_n = (\tilde{\alpha}_n, \tilde{\beta}_n) \in \arg\min_{\overline{\Theta}} \ell_n(\mathbf{X}_n, \theta).
$$

Under mild regularity conditions, for instance the functions b and σ are smooth, Σ is invertible and X is an ergodic diffusion, the quasi likelihood estimator has the following asymptotic properties (see e.g. [\[25\]](#page-25-22) or [\[45\]](#page-26-2)):

- (i) $\tilde{\alpha}_n$ is $\sqrt{n\Delta_n}$ -consistent while $\tilde{\beta}_n$ is \sqrt{n} -consistent; i.e. $(\sqrt{n\Delta_n}(\tilde{\alpha}_n-\alpha_0), \sqrt{n}(\tilde{\beta}_n-\alpha_0))$ (β_0) ^T = $O_n(1)$;
- (ii) $\ddot{\theta}_n$ is asymptotically normal; i.e

$$
(\sqrt{n\Delta_n}(\tilde{\alpha}_n-\alpha_0), \sqrt{n}(\tilde{\beta}_n-\beta_0))^{\top} \stackrel{d}{\longrightarrow} N_{p_1+p_2}(0, \text{diag}((\Gamma^{11})^{-1}, (\Gamma^{22})^{-1})),
$$

where Γ^{11} and Γ^{22} are the components of the Fisher information matrix of the diffusion.

From (i) and (ii) emerge that the estimator $\tilde{\theta}_n$ exhibits a mixed-rates asymptotic regime with two different rates, $\sqrt{n\Delta_n}$ and \sqrt{n} , for the two groups of parameters α and β.

The bridge-type estimator [\(3.5\)](#page-7-1) can be implemented by setting $\mathfrak{L}_n(\theta) := \frac{1}{2}(\theta (\tilde{\theta}_n)^\top G_n(\theta - \tilde{\theta}_n)$, and $G_n = \tilde{\ell}_n(\mathbf{X}_n, \theta)$ (the Hessian matrix). We consider adaptive weights of the form

(7.3)
$$
w_{n,j}^1 = \frac{w_{n,0}^1}{|\tilde{\alpha}_{n,j}|^{\delta_1}}, \qquad w_{n,k}^2 = \frac{w_{n,0}^2}{|\tilde{\beta}_{n,k}|^{\delta_2}} \qquad j = 1, \ldots, p_1, \ k = 1, \ldots, p_2,
$$

where the exponents δ_1 and δ_2 are such that $\delta_i > 1 - q_i, 1, 2$ and $w_{n,0}^i$ have suitable asymptotics (constants will do for $\delta_i > 2 - q_i$). In this setting the oracle properties of the regularized estimator [\(3.5\)](#page-7-1) hold by setting $A_n = \text{diag}(1/(\sqrt{n\Delta_n})\mathbf{I}_{p_1}, 1/\sqrt{n\mathbf{I}_{p_2}})$. See [\[16\]](#page-25-14) for details.

It is worth mentioning that in literature appeared different estimators for ergodic diffusions satisfying the asymptotic properties (i) and (ii), for instance the quasi-Bayesian estimator or the hybrid multistep estimator ([\[40\]](#page-25-23), [\[41\]](#page-26-7), [\[24\]](#page-25-24)).

7.2. Simulation study. Consider a multivariate diffusion process $X = (X^1, \dots X^d)^\top$ $(X_t)_{t\geq 0} \in \mathbb{R}^d$ driven by the SDE

$$
dX_t = AX_t dt + B dW_t
$$

FIGURE 4. A simulated sample path of the solution to (7.4)

where $A = (\alpha_{i,j} : i, j = 1, \ldots d)$ and $B = (\beta_{i,j} : i, j = 1, \ldots d)$ are parameter matrices assumed to be positive definite. In our case $d = 4$ and the true parameter matrices are

(7.5)
$$
A = \begin{bmatrix} 4 & -1.8 & 0 & 0 \\ 0 & 4 & -1.8 & 0 \\ 0 & 0 & 4 & -1.8 \\ 0 & 0 & 0 & 4 \end{bmatrix} \qquad B = \begin{bmatrix} 4 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 \\ 0 & 0 & 4 & 0 \\ 0 & 0 & 0 & 4 \end{bmatrix}
$$

In this case the process components are not independent because of the dependence in the drift term. However the correlation between the components can be ascribed to a specific "causality" structure in the sense of Granger([\[16\]](#page-25-14) and references therein for details): e.g. it is clear that X^4 is not caused by the other components whereas it causes X^3 .

Therefore the goal of this study is to show how the estimator [\(3.5\)](#page-7-1) with $\mathfrak{L}_n(\theta) := \frac{1}{2}(\theta - \theta)$ $(\tilde{\theta}_n)^\top G_n(\theta - \tilde{\theta}_n)$ and $G_n = \ell_n(\mathbf{X}_n, \theta)$, is able to highlight the true dependency structure between the observed random signals by starting with "full" parameter matrices and by setting to zero the parameters corresponding to non-existing relations.

In order for the model to be identifiable the matrix B is restricted to be upper triangular, so the parameters $\beta_{i,j}, i < j$ are set to zero and are not to be estimated. Moreover to enforce positive definiteness the diagonal elements A and B are restricted to be posi-tive^{[2](#page-20-0)}. So the parameter space $\Theta \subset \mathbb{R}^{26}$ is the cartesian product of intervals either of the form $[-50, 50]$ or $[0, 50]$ for diagonal elements.

Discretely sampled data from model [\(7.4\)](#page-19-1) are simulated from the true model. We consider the cases $n = 1000$ and $n = 10000$, corresponding to $\Delta_n = 0.015, T = 15$, $\Delta_n = 0.003$, $T = 30$ respectively, where n denotes the length of the sampled series, Δ_n the time interval between subsequent observations and T is observation horizon.

 2 For A this is only a necessary condition. A further check is made during the optimization process to return a high objective function value if the condition is not met, and the optimization is repeated with a new random starting point until an admissible solution is found.

The initial estimator $\tilde{\theta}_n := (\tilde{\alpha}_n, \tilde{\beta}_n)$ is derived by optimizing [\(7.2\)](#page-19-2). The penalized estimator [\(3.5\)](#page-7-1) is obtained by setting

(7.6)
$$
w_{n,j}^1 = \frac{1}{|\tilde{\alpha}_{n,j}|^4}, \qquad w_{n,k}^2 = \frac{1}{|\tilde{\beta}_{n,k}|^4} \qquad j = 1, \ldots, p_1, \ k = 1, \ldots, p_2.
$$

and for the Bridge estimator we set $q_1 = q_2 = 1/2$.

We estimate the overall relative mean square error $MSE_{\theta_0} = \mathbb{E} \|\hat{\theta} - \theta_0\|^2 / \|\theta_0\|^2$ and the model selection probability P_0 , i.e. the probability of estimating exactly as zero all of the zero parameters and only those. Since the oracle properties are asymptotic results for finite samples a small margin of error in model selection can be expected. Thus we report the estimates for *approximate* P_0 , given by the probability of correctly identifying the true relations with at most one zero parameter not estimated as zero or vice versa. The results of the simulation study are shown in [Table 2.](#page-23-0) The column corresponding to $\tilde{\lambda}_{opt}$ shows the best performance achieved along the path. In all cases $\tilde{\lambda}_{opt} \approx 0.5$. We can draw the following conclusions:

- Adaptive penalized techniques can improve convergence of the estimates in a mean square error sense for mild penalization values with respect to the initial QML estimates. Larger penalization values, closer to λ_{max} , will cause the performance to deteriorate instead, since the estimates are heavily shrunk to zero.
- Penalized techniques with $n = 10000$ reach a high probability of correctly identify the true model. The best accuracy achieved is around 59 % for both methods. If we allow for a small margin of error (at most one parameter not set to zero or vice versa), we obtain an approximate model selection probability higher than 96%. Note that for smaller penalization Bridge selection probability is much higher than the lasso. Bridge selection shows a generally higher selection probability for almost all penalization values, as shown in [Figure 5,](#page-22-0) while at the peak value where they tend to coincide, also for $n = 1000$. This suggests that Bridge estimator is able to speed-up the convergence of the estimator for smaller sample sizes and is more robust to the choice of the tuning parameter. This is useful in real-world applications where the tuning parameter has to be chosen using some validation technique: a sub-optimal choice of λ will impact less bridge estimates.
- Algorithms efficiency. [Figure 6](#page-22-1) shows a comparison of the average number of iteration required by Algorithms 1 and 3, for both bridge and LASSO variants. The block variant is implemented by considering the drift and diffusion parameters as blocks, i.e. $(\theta^1, \theta^2) = (\alpha, \beta)$. We also compare these algorithms with the coordinate descent, which is based on univariate updates of the parameter vector (see [\[39\]](#page-25-25)), and is commonly used in statistical applications([\[20\]](#page-25-17), chapter 5). The coordinate descent for bridge is meant in the sense of block-wise algorithm with one block parameters, as in Remark [5.3.](#page-15-2) The fastest algorithm is the accelerated GD as could be expected. Interestingly enough the block-wise algorithm can achieve a similar performance, even if not accelerated. The results suggest that taking into account the block structure of the problem lead to an improvement in computation time by a factor of $\tilde{3}$ with respect to coordinate-wise algorithms.

FIGURE 5. Model selection proportions for $n = 10^3$ as a function of the normalized penalization parameter.

FIGURE 6. Comparison between algorithms $APGD$ (Alg.1), $PALM$ (Alg. 3), CD (Coordinate Descent) for lasso (dashed) and bridge (solid line): number of iterations as a function of the normalized penalization parameter. In CD in the bridge case is meant to be (Alg.3) with one-parameter blocks $(n = 10⁴)$.

Table 2. Numerical results.

APPENDIX

Let us recall few definitions concerning subdifferential calculus and variational analysis for nonconvex and nonsmooth functions (see, e.g., [\[36\]](#page-25-26)). A function $f : \mathbb{R}^n \to (-\infty, \infty]$ is said to be proper if dom $f \neq \emptyset$, where dom $f = \{x \in \mathbb{R}^n : f(x) < +\infty\}$. Furthermore, h is lower semicontinuous at point x_0 if $\liminf_{x\to x_0} f(x) \ge f(x_0)$. Furthermore f is coercive if it is bounded from below and $f(x) \to \infty$ when $||x|| \to \infty$, where $|| \cdot ||$ stands for the euclidean norm.

A function $f: \mathbb{R}^n \to \mathbb{R}$ is of type $C^{1,1}$; i.e. continuously differentiable with Lipschitz continuous gradient, if

$$
||\nabla f(x) - \nabla f(y)|| \le L(f) ||x - y||, \quad \forall x, y \in \mathbb{R}^n,
$$

where $L(f) > 0$ is the global Lipschitz constant of ∇f .

Now, we introduce the subdifferential for a function. This mathematical tool plays a crucial role in our analysis.

Definition 2 (Subdifferential). Let $f : \mathbb{R}^n \to (-\infty, \infty]$ be a proper and lower semicontinuous function.

(i) The Frechét subdifferential of f at $x \in dom f$, written $\hat{\partial} f(x)$, is defined as follows

$$
\widehat{\partial} f(x) := \left\{ u \in \mathbb{R}^n : \lim_{y \neq x} \inf_{y \to x} \frac{f(y) - f(x) - u^\top (y - x)}{||y - x||} \ge 0 \right\}.
$$

When $x \notin dom f$, we set $\widehat{\partial} f(x) = \emptyset$.

(ii) The limiting-subdifferential, or simply the subdifferential, of f at $x \in \mathbb{R}^n$, written $\partial f(x)$, is defined as follows

$$
\partial f(x) := \{ u \in \mathbb{R}^n : \exists x^k \to x, \ f(x^k) \to f(x), \ and \ \widehat{\partial} f(x^k) \ni u^k \to u \ as \ k \to \infty \}.
$$

(iii) $x \in \mathbb{R}^n$ is called critical point if $0 \in \partial f(x)$.

The well known Fermat's rule remains unchanged; that is if $x \in \mathbb{R}^n$ is a local minimizer of f then $0 \in \partial f(x)$ (see Theorem 10.1 in [\[36\]](#page-25-26)).

If $f : \mathbb{R}^n \to (-\infty, \infty]$ is a proper and convex function, as particular case we obtain the definition of subdifferential for a convex function (see $[6]$ and Proposition 8.12 in $[36]$); i.e. for any $x \in \text{dom } f$

$$
\partial f(x) = \{ u \in \mathbb{R}^n : f(y) \ge f(x) + u^\top (y - x), \forall y \} = \widehat{\partial} f(x).
$$

When f is also differential at $x, u \in \partial f(x)$ coincides with $\nabla f(x)$.

Now, we recall the essentials issues about the Kurdyka– Lojasiewicz (KL) property (see [\[2\]](#page-24-12) for more details) playing a crucial role in the nonconvex optimization theory. These property guarantees the global convergence of the whole sequence generated by a nonconvex algorithms to a critical point (see, e.g, [\[2\]](#page-24-12), [\[8\]](#page-24-4) and [\[29\]](#page-25-15)).

Let $\Phi_n, \eta \in (0, +\infty]$, be the class of concave and continuous functions $\varphi : [0, \eta) \to \mathbb{R}_+$ such that the following conditions fulfill: 1) $\varphi(0) = 0$; 2) $\varphi \in C^1((0, \eta))$ and φ is continuous in 0; 3) $\varphi'(s) > 0$ for all $s \in (0, \eta)$.

Definition 3 (Kurdyka–Lojasiewicz property; see [\[2\]](#page-24-12)). Let $f : \mathbb{R}^n \to (-\infty, \infty]$ be a proper lower semicontinuous function. Then f is said to have the KL property if for any $\bar{u} \in dom \; \partial f := \{u \in \mathbb{R}^n : \partial f(u) \neq \emptyset\}$ there exists $\eta \in (0, +\infty]$, a neighborhood U of \bar{u} and a function $\varphi \in \Phi_{\eta}$ such that for all $u \in U \cap \{u \in \mathbb{R}^n : f(\bar{u}) < f(u) < f(\bar{u} + \eta)\}\$ the following inequality holds

$$
\varphi'(f(u) - f(\bar{u}))\text{dist}(0, \partial f(u)) \ge 1.
$$

The KL property is not so restrictive. Several functions appearing in the optimization problems, such as semi-algebraic functions are KL functions (see [\[2\]](#page-24-12) and [\[8\]](#page-24-4) for a formal definition of semi-algebraic function and its property). Typical semi-algebraic functions include real polynomial functions, finite sums/product and compositions of semi-algebraic functions, $||x||_0$, $||x||_p$, with $p > 0$ and rational.
