## Abstract

Accurate uncertainty estimation is crucial for deploying neural networks in risk-sensitive applications such as medical diagnosis. Monte Carlo Dropout is a widely used technique for approximating predictive uncertainty by performing stochastic forward passes with dropout during inference. However, using static dropout rates across all layers and inputs can lead to sub-optimal uncertainty estimates, as it fails to adapt to the varying characteristics of individual inputs and network layers. Existing approaches optimize dropout rates during training using labeled data, resulting in fixed inference-time parameters that cannot adjust to new data distributions, compromising uncertainty estimates in Monte Carlo simulations.

In this paper, we propose **Rate-In**, an algorithm that dynamically adjusts dropout rates during inference by quantifying the information loss induced by dropout in each layer’s feature maps. By treating dropout as controlled noise injection and leveraging information-theoretic principles, Rate-In adapts dropout rates per layer and per input instance without requiring ground truth labels. By quantifying the functional information loss in feature maps, we adaptively tune dropout rates to maintain perceptual quality across diverse medical imaging tasks and architectural configurations. Our extensive empirical study on synthetic data and real-world medical imaging tasks demonstrates that Rate-In improves calibration and sharpens uncertainty estimates compared to fixed or heuristic dropout rates without compromising predictive performance. Rate-In offers a practical, unsupervised, inference-time approach to optimizing dropout for more reliable predictive uncertainty estimation in critical applications.

## 1 Introduction

Deep neural networks have achieved remarkable success in a wide range of applications, from image recognition to natural language processing. However, their deployment in risk-sensitive domains such as medical diagnosis, autonomous driving, and financial forecasting requires not only accurate predictions but also reliable estimates of predictive uncertainty [1]. Accurate uncertainty estimation enables models to express confidence in their predictions, allowing practitioners to make

informed decisions and to identify cases where the model may be less reliable.

Monte Carlo Dropout [2] is a popular and practical technique for approximating predictive uncertainty in neural networks. By performing stochastic forward passes with dropout activated during inference, Monte Carlo Dropout samples from an approximate posterior distribution over the network’s weights, enabling the estimation of both the mean prediction and the associated uncertainty. This method offers a balance between computational efficiency and uncertainty estimation quality, making it suitable for large-scale applications.

A common limitation of Monte Carlo Dropout is the use of fixed dropout rates during inference, typically the same rates used during training. These static dropout rates are applied uniformly across all layers and inputs, regardless of the varying characteristics of individual inputs and the differing sensitivities of network layers. This rigidity can lead to suboptimal uncertainty estimates [3]: fixed dropout rates may either inject excessive noise, degrading the model’s predictive performance, or fail to introduce sufficient variability to capture the true predictive uncertainty.

As illustrated in Figure 1, the way we estimate this uncertainty can dramatically affect our ability to identify truly challenging regions in tasks such as medical image segmentation. Traditional uncertainty estimation methods often produce overly diffuse uncertainty patterns that fail to distinguish between genuinely difficult decisions and simpler ones. This limitation becomes particularly critical in medical applications, where highlighting truly uncertain regions can guide clinical attention to areas requiring additional scrutiny.

Existing approaches have explored optimizing dropout rates during training [4, 5, 6], often relying on labeled data to learn optimal dropout parameters. However, these methods result in fixed dropout rates that remain static during inference, unable to adapt to new or diverse input distributions encountered after deployment. Moreover, in many practical scenarios, especially in medical applications, ground truth labels may not be available during inference, necessitating methods that can adapt without supervision.

To address these limitations, we propose leveraging information theory to dynamically adjust dropout rates during inference. By viewing dropout as controlled noise injection and each layer as a noisy communication channel [7], we can quan-

<sup>†</sup>These authors contributed equally to this work.

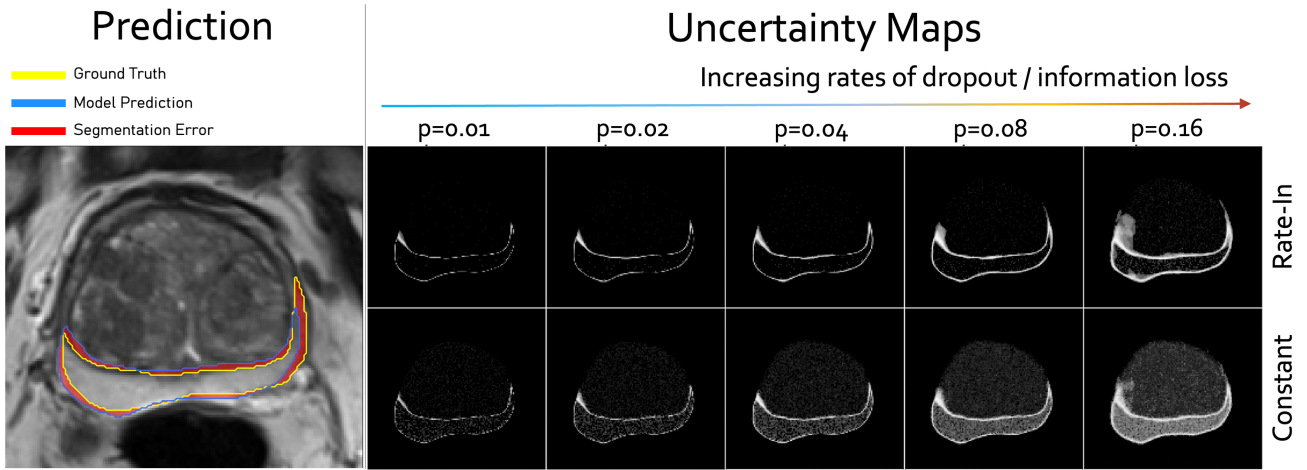

Figure 1: **Rate-In maintains anatomically meaningful uncertainty estimates at high dropout rates, while standard methods degrade into noise.** Left: Prostate MRI segmentation showing ground truth (yellow), model predictions (blue), and errors (red). Right: Uncertainty maps (brighter regions indicate higher uncertainty) at increasing dropout rates (1%-16%). While constant dropout produces diffuse uncertainty that obscures anatomical details, Rate-In precisely highlights challenging regions, particularly along tissue boundaries, preserving clinical utility of the uncertainty estimates.

tify the information loss induced by dropout in each layer’s feature maps. This perspective allows us to adjust dropout rates per layer and per input instance, aiming to maintain a desired level of information retention while introducing sufficient variability for uncertainty estimation.

In this paper, we introduce **Rate-In**, an algorithm that dynamically adjusts dropout rates during inference by quantifying the functional information loss in feature maps induced by dropout. Rate-In operates without requiring ground truth labels, making it suitable for deployment in real-world applications where labeled data is unavailable or scarce. By treating each layer’s dropout-induced information loss as a controllable parameter, Rate-In adaptively tunes dropout rates to maintain perceptual quality across diverse tasks and architectures.

Our main contributions are:

- We introduce an information-theoretic framework for adjusting dropout rates during inference, interpreting dropout as controlled noise injection and quantifying its impact on information flow within the network.
- We propose **Rate-In**, an algorithm that dynamically adjusts dropout rates per layer and per input instance by controlling the information loss induced by dropout, without requiring ground truth labels.
- We demonstrate the effectiveness of Rate-In through extensive empirical evaluations on synthetic data and real-world medical imaging tasks, showing that it improves uncertainty estimation and calibration compared to fixed or heuristic dropout rates, without compromising predictive performance.

The rest of the paper is organized as follows: In Section 2, we provide background on uncertainty estimation in neural networks, discuss dropout and its limitations, and explore the application of information theory to deep learning. In Section 3, we detail the Rate-In algorithm and its implementation. Section 4 presents experimental results demonstrating the benefits of Rate-In in uncertainty estimation tasks. Finally, in Section 5, we discuss the implications of our findings and potential directions for future work.

## 2 Background

In this section, we provide the necessary background to understand our proposed method. We begin by discussing the importance of uncertainty estimation in neural networks and the existing approaches to achieve it. We then go over the Monte Carlo Dropout as a practical method for uncertainty estimation, highlighting its limitations due to fixed dropout rates during inference. Finally, we introduce the application of information theory in deep learning, particularly how it can inform the adaptive adjustment of dropout rates to improve uncertainty estimation.

### 2.1 Uncertainty Estimation in Neural Networks

Deep neural networks have revolutionized numerous fields due to their remarkable predictive capabilities. However, their deterministic nature often prevents them from expressing uncertainty about their predictions [8]. In risk-sensitive applications such as medical diagnosis, autonomous driving, and financial forecasting, understanding the confidence of a model’s predictions is as crucial as the predictions themselves [1]. Reliable uncertainty estimation allows practitioners to make informed decisions, identify cases where the model may be less reliable, and potentially defer to human experts when necessary.

Uncertainty in neural networks can be broadly categorized into two types [9]:

- **Aleatoric Uncertainty:** Arises from inherent data noise and represents the uncertainty due to the stochastic nature of the data generation process. It is irreducible and cannot be eliminated even with more data.
- **Epistemic Uncertainty:** Stems from model uncertainty, often due to limited data or model capacity, and can be reduced with more data or better modeling.

Accurately estimating both types of uncertainty is essential for building reliable models. Various methods have been proposed for uncertainty estimation in neural networks:

- **Bayesian Neural Networks (BNNs):** Introduce probability distributions over network weights [10], allowing the model to capture uncertainty through posterior distributions. However, BNNs are often computationally expensive and challenging to scale.
- **Ensemble Methods:** Train multiple models and aggregate their predictions [11]. Ensembles can capture both types of uncertainty but require significant computational resources.
- **Monte Carlo Dropout:** Applies dropout at inference time to approximate Bayesian inference [2], providing a practical and computationally efficient method for uncertainty estimation.

## 2.2 Monte Carlo Dropout for Uncertainty Estimation

Monte Carlo (MC) Dropout leverages the dropout regularization technique [12] for uncertainty estimation by performing multiple stochastic forward passes through the network with dropout activated during inference [2]. This approach approximates a Bayesian posterior over the model parameters, allowing for the estimation of predictive uncertainty.

Given an input  $\mathbf{x}$  and a neural network with parameters  $\mathbf{W}$ , the predictive distribution is approximated by averaging the predictions over  $T$  stochastic forward passes:

$$p(\mathbf{y}|\mathbf{x}) \approx \frac{1}{T} \sum_{t=1}^T p(\mathbf{y}|\mathbf{x}, \mathbf{W}_t) \quad (1)$$

where  $\mathbf{W}_t$  represents the parameters of the network after applying dropout at iteration  $t$ . The variability in the predictions reflects the model's uncertainty.

## 2.3 Limitations of Fixed Dropout Rates

While MC Dropout is a practical method for uncertainty estimation, it commonly uses fixed dropout rates across all layers and inputs during inference [2]. This approach has limitations:

- **Suboptimal Uncertainty Estimation:** Fixed dropout rates may not adequately capture the predictive variance needed for accurate uncertainty estimation [3]. Some inputs may require higher dropout rates to reflect uncertainty, while others may suffer from excessive noise.
- **Potential Performance Degradation:** Applying the same dropout rate uniformly can introduce unnecessary noise in some layers, potentially affecting model performance [12]. Critical features may be disrupted, adversely impacting prediction accuracy.
- **Lack of Adaptability:** Fixed rates do not account for the varying complexity of different inputs or the differing sensitivities of layers within the network. This rigidity limits the model's ability to adapt to new or diverse data distributions.

These limitations highlight the need for methods that can adapt dropout rates dynamically during inference to improve uncertainty estimation without compromising performance.

## 2.4 Information Theory in Deep Learning

Information theory provides a powerful framework for quantifying the amount of information transmitted through a system [7]. In the context of deep learning, information-theoretic concepts have been used to understand and improve neural networks in several ways:

- **Information Bottleneck Principle:** Proposes that layers in a neural network aim to compress input data while preserving relevant information for the output [13]. This principle has been used to analyze learning dynamics and generalization.
- **Mutual Information Analysis:** Estimating mutual information between inputs, hidden layers, and outputs helps in understanding how information is processed and transformed within the network [14, 15].
- **Regularization Techniques:** Information-theoretic regularization methods, such as information dropout [16], have been introduced to improve robustness and generalization by controlling the flow of information during training.

However, most of these applications focus on the training phase of neural networks, using information theory to guide learning and improve representations. The potential of information theory to inform adaptive mechanisms during inference, particularly for uncertainty estimation, remains under-explored.

## 2.5 Applying Information Theory to Dropout

Interpreting dropout through the lens of information theory allows us to view it as introducing controlled noise into the network, effectively treating each layer as a *noisy communication channel* [7]. This perspective provides valuable insights into how dropout affects information flow within the network:

- **Dropout as Noise Injection:** Dropout reduces mutual information between a layer's input and output by introducing random perturbations [12, 16]. The noise can prevent overfitting by discouraging the network from relying too heavily on any single neuron.
- **Information Loss Quantification:** The amount of information lost due to dropout can be quantified using measures like entropy and mutual information [17]. This quantification enables us to assess the impact of dropout on the network's representations.
- **Layer Sensitivity:** Different layers may exhibit varying sensitivities to information loss induced by dropout, depending on their role and the nature of their activations. Early layers may be more robust to noise, while later layers may be more sensitive.

These insights suggest that by controlling the information loss induced by dropout, we can adaptively adjust dropout rates to balance the trade-off between introducing variability for uncertainty estimation and maintaining sufficient information for accurate predictions.

### 3 Rate-In: Adaptive Dropout at Inference

In this section, we present **Rate-In**, an algorithm that dynamically adjusts dropout rates during inference by quantifying the information loss induced in each layer’s feature maps. By viewing dropout as controlled noise injection and leveraging information-theoretic principles, Rate-In adapts dropout rates per layer and per input instance, enhancing uncertainty estimation without compromising predictive performance.

#### 3.1 Reinterpreting Dropout as Noise Injection

Traditionally, dropout serves as a regularization technique that randomly drops units or connections during training [12, 18]. In the context of uncertainty estimation during inference, we reinterpret dropout as a form of noise injection into the neural signal. This perspective allows us to analyze dropout’s impact on information flow within the network.

By considering each layer as a communication channel [7], applying dropout introduces noise into this channel, reducing the mutual information between the layer’s input and output. The extent of information loss depends on the dropout rate and the characteristics of the activations in that layer.

#### 3.2 Quantifying Information Loss

To adjust dropout rates dynamically, we need to quantify the information loss induced by dropout in each layer. We employ the concept of *mutual information* (MI), which measures the shared information between two random variables [7].

Given a layer with input activations  $\mathbf{h}_{in}$  and output activations  $\mathbf{h}_{out}$ , the mutual information  $I(\mathbf{h}_{in}; \mathbf{h}_{out})$  quantifies how much information about  $\mathbf{h}_{in}$  is preserved in  $\mathbf{h}_{out}$ . Dropout reduces this mutual information due to the introduced randomness.

Directly computing MI in high-dimensional spaces is challenging. To address this, we use efficient estimation methods, such as the *adaptive binning estimator* [17], which approximates MI using entropy estimations with adaptive data binning.

#### 3.3 The Rate-In Algorithm

Rate-In adjusts the dropout rate for each layer during inference by maintaining the information loss below a predefined threshold. The algorithm operates sequentially during the forward pass, adjusting dropout rates per layer and per input instance (Figure 2 and Algorithm 1).

Figure 2: **Rate-In dynamically optimizes dropout rates through an information-theoretic feedback loop:** (i) apply a dropout mask to the feature map; (ii) assess information integrity; (iii) calculate the difference from the target information level; (iv) update the dropout rate accordingly.

---

#### Algorithm 1 Rate-In Algorithm

---

**Require:** Trained neural network  $\mathcal{F}$  with  $L$  layers, input  $\mathbf{x}$ , initial dropout rates  $p^{(0)}$ , information loss threshold  $\epsilon$ , maximum iterations  $N_{\max}$

**Ensure:** Adjusted dropout rates  $p$ , output prediction  $\hat{\mathbf{y}}$

```

1: Initialize  $p \leftarrow p^{(0)}$ 
2: for  $l = 1$  to  $L$  do
3:    $n \leftarrow 0$ 
4:   repeat
5:     Apply dropout with rate  $p_l$  to layer  $l$ 
6:     Compute activations  $\mathbf{h}^{(l)}_{in}$  and  $\mathbf{h}^{(l)}_{out}$ 
7:     Estimate mutual information  $I(\mathbf{h}^{(l)}_{in}; \mathbf{h}^{(l)}_{out})$ 
8:     Compute information loss  $\Delta I_l = I^{(l)}_{full} - I(\mathbf{h}^{(l)}_{in}; \mathbf{h}^{(l)}_{out})$ 
9:     if  $\Delta I_l > \epsilon$  then
10:      Decrease  $p_l$ 
11:    else
12:      Increase  $p_l$ 
13:    end if
14:     $n \leftarrow n + 1$ 
15:  until  $|\Delta I_l - \epsilon| < \delta$  or  $n \geq N_{\max}$ 
16: end for
17: Perform forward pass with adjusted dropout to obtain  $\hat{\mathbf{y}}$ 
18: return  $p, \hat{\mathbf{y}}$ 

```

---

#### 3.3.1 Algorithm Details

**Initialization** We start with initial dropout rates  $p^{(0)}$ , which can be uniform across layers or based on prior knowledge. We define an information loss threshold  $\epsilon$  specifying the maximum allowable mutual information loss per layer.

**Layer-wise Adjustment** For each layer  $l$ , we perform the following steps:

1. **Apply Dropout:** Apply dropout with the current rate  $p_l$  to the activations in layer  $l$ .
2. **Compute Activations:** Obtain the input and output activations  $\mathbf{h}_{in}^{(l)}$  and  $\mathbf{h}_{out}^{(l)}$  for layer  $l$ .
3. **Estimate Mutual Information:** Estimate the mutual information  $I(\mathbf{h}_{in}^{(l)}; \mathbf{h}_{out}^{(l)})$  using an appropriate estimator.
4. **Compute Information Loss:** Calculate the information loss  $\Delta I_l = I_{full}^{(l)} - I(\mathbf{h}_{in}^{(l)}; \mathbf{h}_{out}^{(l)})$ , where  $I_{full}^{(l)}$  is the mutual information without dropout.
5. **Adjust Dropout Rate:** If  $\Delta I_l > \epsilon$ , decrease  $p_l$  to reduce information loss; otherwise, increase  $p_l$  to introduce more variability.
6. **Convergence Check:** Repeat the adjustment until the information loss is within an acceptable range or the maximum number of iterations is reached.

**Forward Pass** After adjusting dropout rates, perform a final forward pass with the adjusted rates to obtain  $\hat{\mathbf{y}}$ .

#### 3.3.2 Implementation Considerations

**Estimating Mutual Information** To make MI estimation tractable in high-dimensional spaces, we can:

- Use **dimensionality reduction** to project activations to lower dimensions.
- Employ **non-parametric estimators** like k-nearest neighbors or kernel density estimators.
- Approximate MI using **simpler metrics** such as correlation or variance when appropriate.

**Optimization Strategy** Adjusting dropout rates can be formulated as an optimization problem. Simple strategies like gradient descent or rule-based adjustments (e.g., fixed step sizes) can be used to reach the desired information loss threshold.

**Computational Overhead** To mitigate the additional computations:

- Limit the number of iterations per layer ( $N_{\max}$ ).
- Share computations across similar inputs or batches.
- Precompute or approximate certain quantities.

### 3.4 Discussion of the Rate-In Approach

The Rate-In algorithm offers several advantages:

- **Adaptive Dropout Rates:** By adjusting dropout rates per layer and per input instance, Rate-In accommodates the varying sensitivities of layers and the complexities of different inputs.
- **Improved Uncertainty Estimation:** By controlling the information loss, Rate-In ensures that sufficient variability is introduced for uncertainty estimation without degrading the predictive performance.
- **No Need for Ground Truth Labels:** Rate-In operates during inference without requiring labeled data, making it applicable in deployment scenarios where labels are unavailable.

However, there are also challenges:

- **Computational Complexity:** The need to estimate mutual information and adjust dropout rates can increase inference time.
- **Estimation Accuracy:** Accurate estimation of mutual information is non-trivial, especially in high-dimensional spaces.
- **Hyperparameter Selection:** Choosing appropriate values for the information loss threshold  $\epsilon$  and other hyperparameters requires careful consideration.

In the next section, we present experimental results demonstrating Rate-In’s effectiveness across various tasks and architectures.

## 4 Experiments

In this section, we evaluate the effectiveness of the proposed **Rate-In** algorithm for predictive uncertainty estimation through MC simulations. We conduct experiments on both synthetic data and real-world medical imaging tasks, utilizing state-of-the-art pre-trained neural network architectures. Our evaluation focuses on three main objectives:

- (i) **Effectiveness of Rate-In:** Assess Rate-In’s ability to improve uncertainty estimation and calibration compared to fixed or heuristic dropout rates.
- (ii) **Impact on Predictive Performance:** Determine whether dynamically adjusting dropout rates at inference time affects predictive accuracy.
- (iii) **Adaptability across Tasks and Architectures:** Demonstrate the applicability of Rate-In across different tasks and neural network architectures.

### 4.1 Experimental Setup

We evaluate our method on three categories of tasks:

**Synthetic Regression** To validate our method in a controlled setting, we generate a one-dimensional regression dataset with varying levels of noise. The target variable is defined as  $y = \sin(x) + \epsilon$ , where  $x$  is uniformly sampled from  $[-3, 3]$  and  $\epsilon \sim \mathcal{N}(0, \sigma^2)$ . We create datasets with five different noise levels by setting  $\sigma \in 0.1, 0.2, 0.3, 0.4, 0.5$ . Each dataset contains 100 training and test instances.

**Medical Image Classification** For real-world classification tasks, we utilize three datasets from the MedMNIST v2 repository [19]:

- **PathMNIST:** 107,180 histopathology images for colorectal cancer tissue classification (9 classes).
- **BloodMNIST:** 17,092 blood cell microscope images for peripheral blood cell classification (8 classes).
- **TissueMNIST:** 236,386 kidney cortex microscope images for kidney cortex cell type classification (8 classes).

**Medical Image Segmentation** We select two segmentation tasks involving different imaging modalities:

- **Prostate MRI Segmentation**[20]: Segmenting the peripheral and transitional zones in prostate MRI scans.
- **Liver Tumor CT Segmentation**[20]: Segmenting liver and tumor regions in CT scans.

**Baselines Methods** We compare Rate-In with the following methods:

- **Fixed Dropout**[12]: Applying a constant dropout rate across all layers during MC iterations.
- **Scheduled Dropout**[21]: Linearly decreasing the dropout rate over MC iterations.
- **Activation-Based Dropout:** Adjusting dropout rates based on the coefficient of variation (CoV) of layer activations, inspired by adaptive dropout methods [4].

#### 4.1.1 Implementation Details

To directly compare Rate-In with classical dropout approaches, we set the information loss threshold  $\epsilon$  equal to the fixed dropout rate  $p^{(0)}$ .  $\delta$  was set to 0.01 based on preliminary experiments. The maximum number of iterations per layer was set to  $N_{\max} = 30$ .

For information loss estimation, we use the adaptive binning estimator [17], which efficiently approximates mutual information in high-dimensional feature spaces. Additionally, we measured the information using structural similarity index measure (SSIM) [22] (See Appendix B for more information and results). Monte Carlo simulation involves 30 forward passes per input, with dropout rates dynamically adjusted according to the measured information loss. We employ the following neural network architectures:

- **Synthetic Regression:** A fully connected network with two hidden layers of 50 units each and ReLU activations.
- **Classification Tasks:** ResNet-18 [23] pre-trained on MedMNIST datasets, with dropout layers added after each residual block’s ReLU activation.
- **Segmentation Tasks:** nnU-Net [24], a U-Net-based architecture with dropout layers after each encoder and decoder block.

**Evaluation Metrics** For predictive performance, we use Mean Squared Error (MSE) for regression, Accuracy (ACC) for classification, and Dice Similarity Coefficient (DSC) for segmentation. To evaluate uncertainty estimation, we employ Expected Calibration Error (ECE)[25], Area Under the Accuracy-Rejection Curve (AUARC)[26], and Boundary Uncertainty Coverage (BUC) [27]. We also provide qualitative analyses through uncertainty maps and reliability diagrams.

Our code and complete implementation details are available in the supplementary material. The appendix includes full training protocols, hyperparameter settings, architectural details, and ablation studies.

## 4.2 Results

### 4.2.1 Synthetic Data Analysis

We first evaluate Rate-In on the synthetic regression task to validate our approach under controlled conditions. Figure 3a shows the efficiency of uncertainty estimation across increasing noise levels ( $\sigma \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$ ) with a fixed training set size ( $N = 100$ ). The efficiency is quantified using the ratio of interval width to empirical coverage; lower ratios indicate more precise uncertainty estimates without sacrificing reliability. Rate-In consistently maintains a lower ratio across all noise levels compared to baseline methods.

Figure 3b illustrates the impact of training set size under a fixed noise level ( $\sigma = 0.01$ ). Rate-In outperforms other methods across all training sample sizes, achieving more efficient uncertainty estimation. The results demonstrate Rate-In’s ability to adapt dropout rates based on local uncertainty characteristics, leading to more efficient and reliable uncertainty estimation compared to static dropout approaches. The method shows particular advantages in scenarios with heteroscedastic noise and limited training data.

### 4.3 Classification Tasks

Table 1 summarizes the performance metrics for each classification task and dropout policy. Rate-In consistently achieves higher accuracy and better uncertainty calibration compared to baseline methods. Specifically, for the PathMNIST dataset, Rate-In maintains high performance across different levels of information loss, as illustrated in Figure 4. At a 0.05 dropout

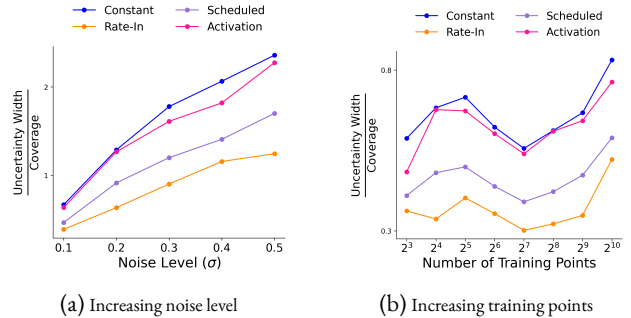

Figure 3: **Rate-In is more efficient in uncertainty estimation.** The ratio of uncertainty interval width to 95% coverage. Lower ratios indicate more efficient uncertainty estimation. (a) Varying noise levels; (b) Varying number of training points at fixed noise level ( $\sigma = 0.01$ ).

rate, Rate-In maintains full model accuracy for both TissueMNIST and PathMNIST datasets, while other methods show significant degradation.

The three medical datasets exhibit distinct patterns of robustness to dropout. BloodMNIST retains high performance even under significant dropout, while TissueMNIST shows greater sensitivity to information loss, and PathMNIST demonstrates intermediate resilience. These differences highlight the importance of adaptive dropout strategies across different medical imaging applications.

Table 1: **Rate-In maintains near-original model accuracy even at high dropout rates, while baseline methods show severe degradation.** Classification performance across three medical imaging datasets, reported as Accuracy (ACC) and AUARC. Results demonstrate that Rate-In consistently outperforms conventional dropout strategies, particularly at higher dropout rates. Higher AUARC values (in parentheses) indicate better uncertainty estimation quality.

Dataset	Method	ACC Full Model	Dropout Rate		
			0.05	0.10	0.20
TissueMNIST	Constant	.68	.53 (.67)	.31 (.37)	.09 (.25)
	Scheduled		.56 (.70)	.36 (.47)	.13 (.19)
	Activation		.54 (.67)	.32 (.40)	.10 (.24)
	<b>Rate-In</b>		<b>.68 (.84)</b>	<b>.64 (.80)</b>	<b>.48 (.59)</b>
PathMNIST	Constant	.90	.87 (.96)	.75 (.91)	.41 (.56)
	Scheduled		.88 (.97)	.78 (.93)	.47 (.65)
	Activation		.87 (.96)	.76 (.92)	.44 (.60)
	<b>Rate-In</b>		<b>.90 (.98)</b>	<b>.88 (.97)</b>	<b>.75 (.91)</b>
BloodMNIST	Constant	.97	.95 (.99)	.91 (.98)	.58 (.75)
	Scheduled		.95 (.99)	.92 (.98)	.75 (.86)
	Activation		.96 (.99)	.93 (.99)	.81 (.92)
	<b>Rate-In</b>		<b>.96 (.99)</b>	<b>.93 (.99)</b>	<b>.82 (.92)</b>

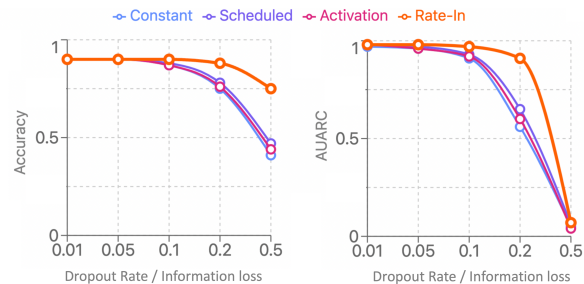

Figure 4: **Rate-In maintains high classification accuracy even at aggressive dropout rates where conventional methods degrade.** Classification accuracy on the PathMNIST dataset comparing dropout strategies across increasing rates. Traditional methods show sharp decline, while Rate-In preserves performance by adaptively adjusting dropout patterns based on local feature importance.

#### 4.4 Segmentation Tasks

Rate-In’s advantages are particularly evident in medical image segmentation, where accurate uncertainty estimation is crucial. As illustrated in Figure 1, Rate-In generates uncertainty maps that precisely highlight anatomically challenging regions, especially along tissue boundaries where expert radiologists often face ambiguity. In contrast, constant dropout produces diffuse uncertainty patterns at higher dropout rates, obscuring areas of genuine uncertainty.

Rate-In demonstrates several key advantages:

- **Anatomical Precision:** Rate-In accurately pinpoints ambiguous regions, particularly along tissue boundaries, enhancing clinical interpretability. Constant dropout yields diffuse patterns that obscure genuine concerns.
- **Dropout Rate Stability:** Rate-In maintains consistent, focused uncertainty estimates across varying dropout rates, unlike conventional methods that degrade with increased rates, ensuring reliable clinical performance.
- **Error Correlation:** Rate-In’s high-uncertainty regions strongly correlate with actual prediction errors, indicating better calibration and enhancing trust in the model’s predictions.
- **Clinical Interpretability:** Rate-In’s uncertainty maps align with anatomical structures and boundaries, making them more interpretable. It facilitates the integration of statistical uncertainty into clinical decision-making.

These qualitative observations are supported quantitatively by performance metrics across our test set. Table 2 summarizes the metrics for each segmentation task and dropout policy. Rate-In consistently outperforms benchmarks in uncertainty metrics such as ECE and BUC across most anatomical zones. For instance, in regions with inherent boundary ambiguity, Rate-In shows enhanced capability in quantifying uncertainty at region interfaces, evidenced by higher BUC scores in the Transitional zone. This improved boundary characterization is critical for clinical applications where precise delineation between overlapping anatomical zones impacts diagnostic accuracy.

The results demonstrate that Rate-In’s information-theoretic approach to adjusting dropout rates produces uncertainty estimates that are both more accurate and more

clinically meaningful. The method’s ability to maintain focused uncertainty patterns while preserving anatomical detail makes it particularly valuable for medical imaging applications where precision and reliability are paramount.

Figure 5 illustrates the impact of dropout rates on information loss across network layers. In the pre-trained U-Net model, the decoder layers experience a significant decline in information, with a reduction of approximately 40% as dropout rates increase from 5% to 20%. In contrast, the encoder layers are less affected, showing smaller changes in structural similarity with varying dropout rates. This suggests that Rate-In effectively allocates dropout rates to minimize information loss where it is most critical.

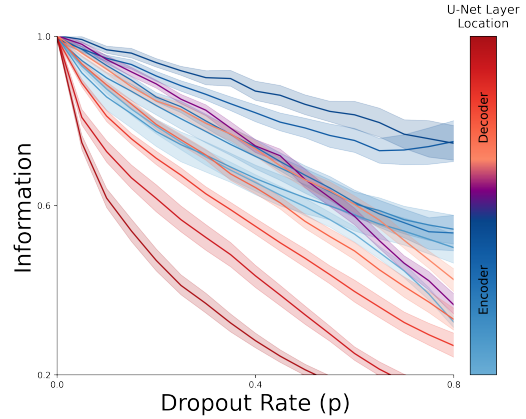

Figure 5: **Decoder layers are more sensitive to information loss from dropout than encoder layers, demonstrating the need for layer-specific dropout rates.** Analysis of information retention across U-Net layers as dropout rates increase. Decoder layers show significant information loss, while encoder layers maintain higher information. This asymmetric behavior validates Rate-In’s layer-adaptive approach, which can allocate lower dropout rates to sensitive decoder layers while maintaining higher rates in more robust encoder layers for efficient uncertainty estimation.

## 5 Summary

We introduced **Rate-In**, a novel algorithm that dynamically adjusts dropout rates during inference to enhance predictive uncertainty estimation in neural networks. Traditional methods like Monte Carlo Dropout use fixed dropout rates, which fail to adapt to individual inputs and network layers, leading to

Table 2: **Rate-In achieves superior uncertainty estimation across all anatomical zones while preserving or improving segmentation accuracy compared to best benchmarks.** Comprehensive evaluation across different anatomical regions in MRI and CT modalities, showing DSC, ECE, and BUC at varying dropout rates. Rate-In demonstrates consistent improvements in uncertainty metrics (lower ECE, higher BUC) while maintaining competitive DSC scores, with particularly strong performance in challenging regions like the transitional zone and tumor boundaries.

suboptimal uncertainty estimates. By treating dropout as controlled noise injection and leveraging information-theoretic principles, Rate-In quantifies the information loss in each layer and adjusts dropout rates accordingly, without requiring additional training or labels.

Our extensive experiments on synthetic data and real-world medical imaging tasks demonstrate that Rate-In consistently improves uncertainty calibration and sharpens uncertainty estimates compared to fixed or heuristic dropout rates, all while maintaining predictive performance. In segmentation tasks, Rate-In produced uncertainty maps that accurately highlighted anatomically challenging regions, enhancing clinical interpretability. By effectively minimizing critical information loss, Rate-In offers a practical, unsupervised inference-time solution for optimizing dropout, making it particularly valuable for risk-sensitive applications where accurate uncertainty estimation is essential.

## 6 Appendix A: Reproducibility

### 6.1 Reproducibility Statement

The Rate-In algorithm code and implementation examples are available in the [GitHub repository](#)<sup>1</sup>.

- **Environment and Data:** Dependencies are listed in requirements.txt. Datasets (PathMNIST, BloodMNIST, TissueMNIST) are from MedMNIST-V2 [19], while Liver CT and Prostate MRI datasets are from the Medical Segmentation Decathlon [20]. Download and preprocessing instructions are included in the original repositories.
- **Training and Evaluation:** Hyperparameters and training schedules are in supplement section 6.2.2. Pre-trained models for classification [19] and segmentation [24] are publicly available. Dropout baseline and evaluation metric scripts and formulations are in the repository and supplement section 6.2.3 and 6.2.4, respectively.
- **Hardware and Software:** Experiments used Python 3.9.12 and PyTorch 2.3.0 on an NVIDIA GeForce RTX 2080 Ti GPU. The code is hardware-agnostic but runtimes may vary on different setups.

### 6.2 Experiment Setting Supplement

#### 6.2.1 Rate-In Configuration

To enable direct comparison with standard dropout baseline approaches, we initialized Rate-In’s parameters as follows: The initial dropout rate  $p_0$  was set equal to the dropout rate  $p$  used in the constant dropout benchmark approach. The objective information loss threshold  $\epsilon$  was set to  $p$ , representing similar proportion of information to be preserved. For example, with a constant dropout rate of  $p = 0.2$ , we set  $p^{(0)} = 0.2$  and  $\epsilon = 0.2$ , targeting 80% information preservation. We set  $\delta$  to 0.01.

We defined information loss at layer ( $l$ ) as the relative change in mutual information (MI) between input and post-dropout feature maps. Let  $I_{\text{drop}}^{(l)}$  and  $I_{\text{full}}^{(l)}$  represent MI in dropout and full models at layer  $l$ :

$$I_{\text{drop}}^{(l)} = \text{MI}(\mathbf{h}^{(0)}_{\text{in}}, \mathbf{h}^{(l)}_{\text{drop out}})$$

$$I_{\text{full}}^{(l)} = \text{MI}(\mathbf{h}^{(0)}_{\text{in}}, \mathbf{h}^{(l)}_{\text{full out}})$$

The information loss at layer  $l$  is:

$$\Delta I_l = \frac{I_{\text{drop}}^{(l)} - I_{\text{full}}^{(l)}}{I_{\text{full}}^{(l)}}$$

**Network Architectures and MI Calculation:** For synthetic data, we used fully connected networks and calculated mutual information (MI) in two steps: first, computing batch-level MI between the input and each normalized hidden unit using 2D histograms, then averaging these values across all units. For real-world data using CNNs, we first resampled all feature maps to a uniform spatial resolution to maintain spatial consistency. We then calculated MI using adaptive estimators with entropy-equal bins [17].

#### 6.2.2 Architectures of Neural Networks Used

**Synthetic Data:** The network was implemented in PyTorch with an architecture consisting of three linear layers ( $[1 \rightarrow 50 \rightarrow 50 \rightarrow 1]$ ) with ReLU activations between hidden layers. Training utilized Adam optimizer ( $\text{lr}=0.01$ ) and mean squared error (MSE) loss over 1000 epochs, processing the entire dataset ( $N=100$ ) in each iteration. For reproducibility, NumPy and PyTorch random seeds were set to 123. Dropout layers were placed after each hidden layer post-training (Figure 6).

Figure 6: Basic layout of the regression network with dropout layers shown in blue.

**Classification:** ResNet-18 networks were employed using dataset-specific pre-trained weights and pre-processing protocols from MedMNIST-V2 [19]. The TissueMNIST, PathMNIST, and BloodMNIST datasets were provided as 28x28 voxel inputs. Dropout layers were placed after after each residual block in the pre-trained network (Figure 7).

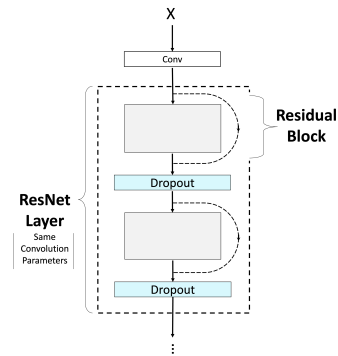

Figure 7: A single ResNet layer with dropout layers shown in blue. The ResNet-18 architecture comprises four such layers.

**Segmentation:** The segmentation pipeline employs nnU-Net, using task-specific pre-trained weights from the top-performing models in the Medical Segmentation Decathlon [28]. Each model utilizes a self-configuring segmentation pipeline based on the U-Net architecture with 2D convolutional layers [24]. Dropout layers were placed after each encoding and decoding step in the pre-trained network, except for the output step (Figure 8).

Figure 8: Basic layout of the U-Net network with dropout layers shown in blue.

### 6.2.3 Baseline Dropout Strategies

In the absence of widely established inference-time dropout strategies, we drew inspiration from training-time dropout approaches, adapting them for inference-time uncertainty estimation.

- **Constant Dropout** [12]: Dropout rates are fixed across all layers and MC iterations, represented as:

$$p_t^{(l)} = p \quad \forall l, t$$

where  $l$  represents the layer and  $t$  the MC iteration.

- **Scheduled (Annealing) Dropout** [21]: Dropout rates are constant across layers but decrease linearly over MC iterations, starting with  $p_0 = p$  and gradually reducing until dropout is fully disabled. This is given by:

$$p_t^{(l)} = p \cdot \left(1 - \frac{t-1}{T-1}\right) \quad \forall l, t$$

where  $T$  is the total number of MC iterations.

- **Activation-Based Dropout**: Dropout rates vary across layers based on the activation diversity, measured by the coefficient of variation (CoV) of feature map values, while remaining constant across MC iterations. For each layer  $l$  and iteration  $t$ , the dropout rate  $p_t^{(l)}$  is set as:

$$p_t^{(l)} = p \cdot \frac{\text{CoV}(X^{(l)})}{\max_j \text{CoV}(X^{(j)})} \quad \forall l, t$$

where  $X^{(l)}$  is the feature map for layer  $l$  in the full no-dropout model, and  $p$  is the maximum dropout rate applied to the layer with the highest CoV. To handle both positive and negative values in feature maps, CoV is calculated using the mean of absolute values for stability. Our Activation-Based Dropout method is inspired by training-time dropout approaches that adjust dropout rates based on activation patterns during training, as seen in variational dropout [6] and adaptive dropout [4].

### 6.2.4 Evaluation Metrics

**Predictive Power:** Diluting neural network models can impact their performance. We assessed the deviation from the full (no-dropout) model’s prediction performance using the same evaluation metrics as those provided in the original public repository where the dataset was published.

- **Mean Squared Error (MSE):** For regression, MSE measures the average squared difference between predicted values and ground truth values, quantifying the error magnitude. The MSE is defined as:

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$$

where  $y_i$  represents the ground truth value,  $\hat{y}_i$  is the predicted value, and  $n$  is the total number of data points. MSE provides a cohort-level evaluation by averaging the squared errors across all data instances.

In this study, we used the implementation from `torchmetrics.MeanSquaredError`, with its default parameters.

- **Dice Similarity Coefficient (DSC):** For segmentation, DSC measures pixel-wise overlap between predicted binary mask and ground truth regions. The DSC is defined as:

$$\text{DSC} = \frac{2|P \cap G|}{|P| + |G|}$$

where  $P$  is the set of predicted pixels,  $G$  is the set of ground truth pixels, and  $|\cdot|$  denotes the cardinality of the set. DSC was calculated at the pixel level and averaged across all data instances to provide a cohort-level evaluation.

In this study, we used the implementation from `torchmetrics.classification.Dice`, with its default parameters.

- **Prediction Accuracy (ACC):** For classification, ACC measures the proportion of correctly classified instances over the total number of instances. The ACC is defined as:

$$\text{ACC} = \frac{\text{Number of Correct Predictions}}{\text{Total Number of Instances}}$$

In this study, we used the implementation from `sklearn.metrics.accuracy_score`.

**Predictive Uncertainty:** Uncertainty estimates were assessed as scores that classify model predictions into two outcomes: reject or do-not-reject, following [29, 30, 31]. To evaluate the alignment of uncertainty estimates with model prediction errors, we used:

- **Expected Calibration Error (ECE):** For segmentation uncertainty, ECE measures calibration by aligning uncertainty scores with actual model errors [32]. The ECE is defined as:

$$\text{ECE} = \sum_{m=1}^M \frac{|B_m|}{N} |\text{uncert}(B_m) - \text{err}(B_m)|$$

where  $M$  is the total number of bins,  $B_m$  is the set of pixels in bin  $m$ ,  $|B_m|$  is the number of pixels in  $B_m$ ,  $N$  is the total number of pixels,  $\text{uncert}(B_m)$  is the average predicted uncertainty score, and  $\text{err}(B_m)$  is the actual model error within the bin. ECE was calculated at the pixel level and averaged across all data to provide a cohort-level evaluation.

In this study, we used the implementation from `torchmetrics.CalibrationError` with parameters `CalibrationError(task='binary', norm='l1', n_bins=15)` and all other parameters set to their default values.

- **Area Under the Accuracy-Rejection Curve (AUARC):** For classification uncertainty, AUARC evaluates the trade-off between prediction accuracy and the fraction of predictions rejected based on uncertainty scores [26, 33]. The AUARC is defined as:

$$\text{AUARC} = \int_0^1 \text{ACC}(r) dr$$

where  $r$  is the rejection fraction, and  $\text{ACC}(r)$  is the accuracy of the retained predictions at rejection fraction  $r$ . Uncertainty scores corresponded to the highest predicted class was used. Accuracy was calculated for rejection thresholds corresponding to each uncertainty score percentile, and the area under the curve was computed using `sklearn.metrics.auc`. Higher AUARC values indicate that the model maintains high accuracy while effectively rejecting uncertain predictions.

- **Boundary Uncertainty Consistency (BUC):** Accurate estimation of uncertainty at organ boundaries is critical in medical imaging, as these regions often exhibit high uncertainty due to anatomical variability, image noise, and ambiguous structures [27, 34, 35, 36]. BUC quantifies the proportion of total uncertainty concentrated along boundaries compared to interior regions.

$$\text{BUC} = \frac{\text{Mean}(\text{uncert}_{\text{Boundary}})}{\text{Mean}(\text{uncert}_{\text{Boundary}}) + \text{Mean}(\text{uncert}_{\text{Interior}})},$$

where  $\text{Mean}(\text{uncert}_{\text{Boundary}})$  and  $\text{Mean}(\text{uncert}_{\text{Interior}})$  represent the average uncertainties in boundary and interior regions, respectively. The boundary region in our experiments was defined as a 5-pixel-wide band surrounding the edges of the segmented objects.

BUC highlights the model’s ability to assign higher uncertainty to critical boundary areas, ensuring robust uncertainty evaluation essential for clinical decision-making.

- **Interval Efficiency Ratio (IER):** Measures the trade-off between predictive interval width and its coverage probability (PICP), quantifying the efficiency of uncertainty estimation. The **interval width** represents the average range of the prediction intervals and is calculated as:

$$\text{Uncertainty Interval Width} = \frac{1}{N} \sum_{i=1}^N 2 \cdot Z \cdot \sigma_i$$

where  $Z$  represents the Z-score corresponding to the desired confidence level (e.g.,  $Z = 1.96$  for 95% confidence intervals), and  $\sigma_i$  denotes the predicted standard deviation, calculated as the standard deviation of the Monte Carlo (MC) predictions at each data point  $i$ .

The **PICP** quantifies the proportion of true values  $y_{\text{true}}$  that fall within the predicted intervals and is defined as:

$$\text{PICP} = \frac{1}{N} \sum_{i=1}^N \mathbb{I}[y_{\text{true},i} \in (\mu_i - Z \cdot \sigma_i, \mu_i + Z \cdot \sigma_i)]$$

where  $\mathbb{I}$  is the indicator function,  $\mu_i$  is the predicted mean, and  $N$  is the number of samples.

The ratio of interval width to PICP evaluates the trade-off between the tightness of prediction intervals and the coverage of true values, with lower ratios indicating more efficient uncertainty estimation.

## 7 Appendix B: Additional Results

### 7.1 Synthetic Data

Figures 9 and 10 evaluate Rate-In dropout’s performance. Figure 9 compares uncertainty intervals from constant dropout ( $p = 0.10$ , red) and Rate-In dropout ( $\epsilon = 0.10$ , blue) across five noise levels ( $\sigma = 0.1 - 0.5$ ), showing Rate-In’s more precise and stable bounds under increasing noise.

Figure 9: Rate-In dropout yields narrower, more stable uncertainty intervals under increasing noise levels ( $\sigma = 0.1 - 0.5$ ), compared to constant dropout. Black: true function and training data; Red: constant dropout ( $p = 0.10$ ); Blue: Rate-In dropout ( $\epsilon = 0.10$ ).

Figure 10 examine performance at fixed noise levels ( $\sigma = 0.01, 0.10, 0.50$ ) across varying training set sizes, showing uncertainty interval efficiency ratios.

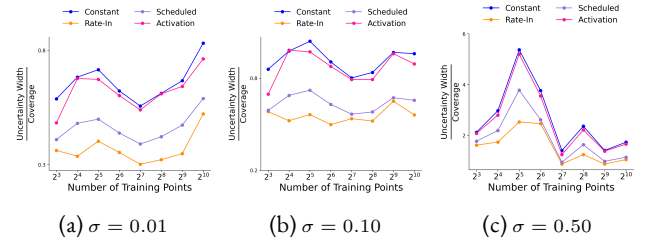

Figure 10: The ratio of uncertainty interval width to 95% coverage for varying number of training points at fixed noise levels. Lower ratios indicate more efficient uncertainty estimation. (a)  $\sigma = 0.01$ , (b)  $\sigma = 0.10$ , and (c)  $\sigma = 0.50$ .

Figure 11 analyzes the convergence behavior of Rate-In across varying initial dropout rates under different information loss thresholds ( $\epsilon = 0.10, 0.30, 0.50$ ), with  $N_{\text{max}} = 100$  and  $\sigma = 0.50$ . The results demonstrate that Rate-In converges to consistent dropout rates, independent of the initial dropout rate values.

Figure 11: Rate-In final dropout rate ( $y$ -axis) versus initial dropout rate ( $x$ -axis) for different information loss thresholds ( $\epsilon = 0.10, 0.30, 0.50$ ). Parameters:  $N_{\text{max}} = 100$ ,  $\sigma = 0.50$ .

### 7.2 Segmentation

Table 3 presents the comparison between Rate-In and all baseline dropout approaches across segmentation tasks.

### 7.3 Computational Complexity Analysis

The Rate-In algorithm may introduce an additional computational overhead during inference, resulting in increased latency from input availability to prediction. Section 3.3.2 outlines strategies to mitigate this inference-time overhead.

The pseudo-code in Listing 1 illustrates the AdaptiveInformationDropout class, which implements the optimization process for the Rate-In algorithm. The computational complexity of the dropout rate optimization is  $O(N_{\text{max}} \cdot (n + f))$ , where  $N_{\text{max}}$  is the maximum number of optimization iterations,  $n$  is the number of input instances, and  $f$  is the complexity of the information loss calculation, which may depend on  $n$ .

The optimization process dominates the complexity, iterating  $N_{\text{max}}$  times with  $O(n)$  dropout operations and  $O(f)$

Table 3: Comparison of Rate-In and baseline approaches for uncertainty estimation and segmentation accuracy across anatomical zones in MRI and CT modalities, evaluated using DSC, ECE, and BUC metrics at varying dropout rates.

calculations per iteration. The computational complexity of each dropout operation, while initially appearing as  $O(n)$ , further breaks down to  $O(d)$ , where  $d$  is the number of elements in each input instance. Thus, the true complexity of a single dropout operation is  $O(n \cdot d)$ .

Once the dropout rates are determined, they remain fixed during Monte Carlo inference and, therefore, do not introduce additional complexity compared to regular constant dropout approaches.

            post_dropout =
                self._apply_dropout(pre_dropout,
                    current_rate) # O(n)
            info_loss = self.calc_information_loss(...)
            # O(f)
            # Update dropout rate: O(1)
            ...

    def forward(self, x: torch.Tensor) -> torch.Tensor:
        if self.training:
            # O(N_max * (n + f) + n) = O(N_max * (n +
            # f))
            optimized_rate =
                self._optimize_dropout_rate(x) # O(m *
            # (n + f))
            return self._apply_dropout(x,
                optimized_rate) # O(n)
        return x # O(1) if not training

# Overall forward pass complexity: O(N_max * (n + f))

```

**Synthetic Data:** Figures 12 illustrate the time (in seconds) required to apply Rate-In to the synthetic regression task described in Section 4.1. We analyzed how Rate-In execution time varies as a function of four parameters: initial dropout rate ( $p_0$ ), noise level ( $\sigma$ ), loss threshold ( $\epsilon$ ), and number of data instances. For each analysis, we varied one parameter while keeping the others fixed. The maximum number of Rate-In iterations ( $N_{max}$ ) was set to 30, with  $\delta = 0.001$  and a learning rate of 0.9 across all experiments.

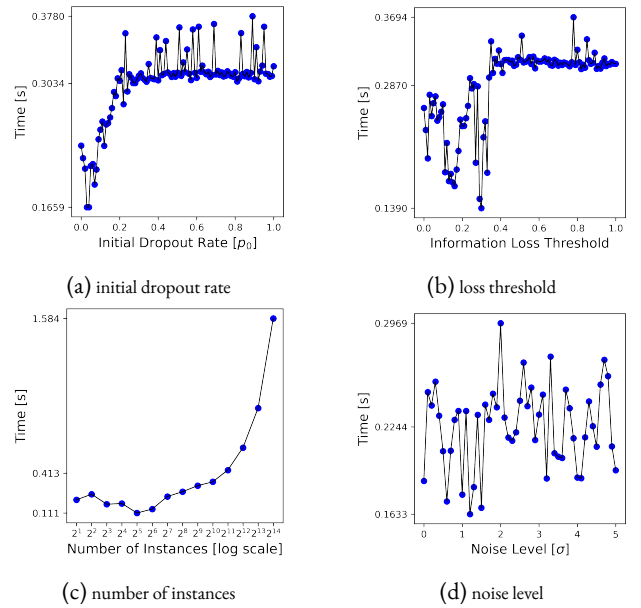

Figure 12: **Rate-In running time analysis for synthetic regression task.** Plots show optimization process duration (in seconds) as a function of: (a) initial dropout rate, (b) information loss threshold, (c) number of inference instances, and (d) noise level.

Rate-In running time plateaus with increased initial dropout rates and information loss probabilities, while scaling linearly with training examples (note log-scale x-axis). Noise levels show minimal impact on execution time. The optimization process occasionally failed to find valid dropout rates in deeper layers, particularly in the second hidden layer. This occurred when the cumulative information loss from

earlier layers made it mathematically impossible to achieve the target information loss threshold  $\epsilon$ , even with a dropout rate of zero. We defined convergence failure as the inability to reduce the objective function below the threshold  $\epsilon$  after  $N_{max}$  iterations, despite reaching the minimum possible dropout rate. Implementation of early stopping could mitigate computational costs.

**Natural Data:** Tables 4 and 5 report the mean duration (with standard deviation) in seconds for Rate-In processing of individual instances in real-world classification and segmentation tasks for different values of information loss objectives. Initial dropout rate was set to be equal to the information loss objectives ( $p_0 = \epsilon$ ), while all other parameters remained unchanged. The tables also include worst-case scenarios.

Table 4: Mean ( $\pm$  std) and worst-case processing times (in seconds) of MI-based Rate-In for classification tasks.

Dataset	Metric	Information Loss Objective ( $\epsilon$ )		
		0.05	0.10	0.20
TissueMNIST	Mean (Std)	0.42 (0.07)	0.43 (0.03)	0.39 (0.12)
	Worst-case	0.50	0.45	0.48
PathMNIST	Mean (Std)	0.65 (0.01)	0.67 (0.02)	0.56 (0.12)
	Worst-case	0.66	0.68	0.65
BloodMNIST	Mean (Std)	0.68 (0.01)	0.64 (0.01)	0.48 (0.12)
	Worst-case	0.70	0.65	0.57

Table 5: Mean ( $\pm$  std) and worst-case processing times (in seconds) of MI-based Rate-In for segmentation tasks.

Dataset	Metric	Information Loss Objective ( $\epsilon$ )		
		0.01	0.05	0.10
Prostate	Mean (Std)	15.48 (5.48)	22.48 (7.48)	28.8 (9.55)
	Worst-case	27.43	40.06	48.72
Liver	Mean (Std)	10.08 (9.59)	28.62 (16.62)	36.11 (18.74)
	Worst-case	56.89	77.4	95.76

## 7.4 Structural Similarity Index (SSIM)

The Rate-In algorithm enables domain-specific information loss measurements through user-defined metrics. While mutual information quantifies statistical dependencies affected by dropout noise, the Structural Similarity (SSIM) Index [37] can help evaluate spatial relationships in feature maps. This property makes SSIM relevant for CNNs, as it measures the preservation of local structures and patterns that these networks extract through their convolutional layers.

We used SSIM to measure information loss between pre- and post-dropout feature maps. This approach allows for simpler implementation as it only requires local comparisons within each layer, without needing access to the full model or input data. Based on earlier experiments showing non-negative SSIM values under dropout noise, the information loss at layer  $l$  is defined as:

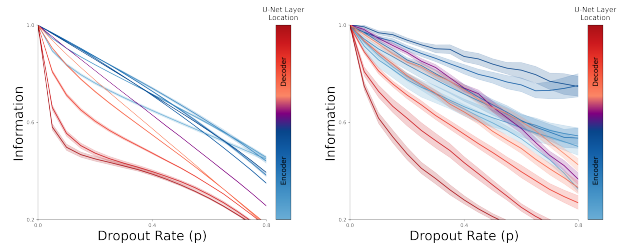

$$\Delta I_l = 1 - \text{SSIM}(\mathbf{h}_{\text{drop}}^{(l)}, \mathbf{h}_{\text{out}}^{(l)})$$

The performance comparison between SSIM-based and MI-based Rate-In across segmentation tasks is presented in Table 7, with corresponding processing times for the SSIM approach shown in Table 6. To ensure consistent SSIM computation across different network layers, we normalized all feature maps to the  $[0,1]$  range. We set `data_range=1` in the `torchmetrics` SSIM implementation to match this normalized range, allowing meaningful comparison of structural similarities regardless of the original feature map magnitudes. Figure 13 shows SSIM

(left) and MI (right) dropout-induced information loss across layers in the U-Net prostate segmentation network.

Table 6: Mean ( $\pm$  std) and worst-case processing times (in seconds) of SSIM-based Rate-In for segmentation tasks.

Dataset	Metric	Information Loss Objective ( $\epsilon$ )		
		0.01	0.05	0.10
Prostate	Mean (Std)	9.5 (1.53)	28.29 (4.59)	46.72 (7.23)
	Worst-case	13.86	44.07	71.9
Liver	Mean (Std)	11.39 (12.59)	13.08 (4.71)	17.13 (7.62)
	Worst-case	71.46	22.88	33.13

(a) SSIM vs. Dropout Rate

(b) MI vs. Dropout Rate

Figure 13: Dropout-induced information loss in the U-Net segmentation network as measured by SSIM (left) and MI (right) across different dropout rates and layers.

## 8 Appendix C: Further Discussion

**Dropout, beyond just graph manipulation.** Rather than viewing dropout as merely a tool for graph manipulation, Rate-In reinterprets it as a method for controlled noise injection. This perspective shift allows us to examine how dropout affects network representations in task-specific contexts. Rate-In effectively acts as a ‘noise translator’, converting random dropout noise into meaningful, task-specific variations in feature maps. Similar to how test-time augmentation adds meaningful noise to inputs, Rate-In dynamically manages noise levels in feature maps to achieve more accurate uncertainty estimates.

**Rate-In, enhancing dropout post-training.** Nearly a decade after its introduction, classical Bernoulli dropout is still among the most popular regularization techniques in deep learning, outlasting many newer alternatives. Rate-In builds upon this foundation by introducing dynamic rate adjustment without modifying the underlying dropout mechanism, making it easy for users to adopt Rate-In without altering their existing workflows.

**Similar dropout rates, different effects: layer position matters.** Our experiments revealed that dropout’s impact varies significantly across network layers, even when feature map dimensions are similar. In semantic segmentation tasks, we found that decoder layers showed higher sensitivity to dropout rate changes compared to encoder layers. This variation may be attributed to MRI image characteristics - uniform dark backgrounds in early layers mitigate dropout’s impact, while intensity variations in later layers amplify it. In addition, decoder layers have fewer opportunities to compensate for dropout noise, emphasizing the importance of layer-specific rate adjustment.

Table 7: Medical image segmentation performance of Rate-In across anatomical regions in MRI and CT: comparing segmentation accuracy (DSC) and uncertainty calibration (ECE, BUC) using MI and SSIM-based information metrics at varying dropout rates.

Zone	Modality	Method	Full Model DSC	DSC (Full Model, % change)			ECE $\times 10^{-3}$			BUC		
				p=0.01	p=0.05	p=0.10	p=0.01	p=0.05	p=0.10	p=0.01	p=0.05	p=0.10

		Rate-In (SSIM)		+1.32%	+1.29%	+1.29%	1.81	<b>1.76</b>	<b>1.74</b>	<b>0.64</b>	<b>0.60</b>	<b>0.55</b>

**Sequential dropout adjustments: preserving inter-layer rate dependency** The Rate-In algorithm operates sequentially during the forward pass of a pre-trained network. At each dropout layer, a feedback loop adjusts the dropout rate to align with the information loss objectives specific to that layer. After adjustment, the modified information propagates through the network to the next dropout layer, where the process repeats. This approach enables control over information loss across the entire network, establishing a dropout rate policy that maintains inter-layer dependency.

**Dropout does not cover all types of noise.** In convolutional layers, dropout adds noise only within small, localized regions defined by the convolution kernel. As a result, it may not capture broader noise patterns such as frequency artifacts, intensity shifts, or large-scale texture variations that span entire images. This limitation restricts dropout’s effectiveness in addressing global noise types that are more uniformly spread across feature maps.

**Additional complexity in inference, but can be handled offline.** Rate-In introduces additional computation at inference. While this can be challenging for some real-time applications, a few potential solutions can be considered. Rate-In can be applied offline to a dataset, such as the training or validation set, to establish population-level dropout rates that approximate individual case needs, assuming data distribution alignment. These rates can then serve as starting points for further tuning during inference or be sampled from the population rate distribution for each layer.

## 8.1 Limitations

**MI might not fully capture vision task nuances.** In our experiments, we used mutual information (MI) to quantify functional information loss from dropout. While MI is a common choice, it may not capture all aspects of information critical in computer vision tasks. Supplementing MI with metrics like the Structural Similarity Index (SSIM) could provide a more comprehensive assessment, covering different dimensions of information quality and enabling more precise dropout rate adjustments to address various types of potential information loss.

**Loss objectives may need empirical validation.** Rate-In’s feedback loop relies on an empirically defined information loss objective. Our experiments suggest that keeping information loss below 10% preserves functional information while retaining dropout’s benefits. Currently, each dropout layer applies a local loss function, resulting in distinct dropout rates per layer. The current implementation uses independent loss functions for each dropout layer, leading to layer-specific dropout rates. One potential modification would be to use a network-wide information loss constraint - a ‘dropout budget’ shared across layers.
