### Abstract

*Large diffusion models have become mainstream generative models in both academic studies and industrial AIGC applications. Recently, a number of works further explored how to employ the power of large diffusion models as zero-shot classifiers. While recent zero-shot diffusion-based classifiers have made performance advancement on benchmark datasets, they still suffered badly from extremely slow classification speed (e.g.,* ∼*1000 seconds per classifying single image on ImageNet). The extremely slow classification speed strongly prohibits existing zero-shot diffusion-based classifiers from practical applications. In this paper, we propose an embarrassingly simple and efficient zero-shot Gaussian Diffusion Classifiers (GDC) via pretrained text-to-image diffusion models and DINOv2. The proposed GDC can not only significantly surpass previous zero-shot diffusion-based classifiers by over 10 points* (61.40%  $\rightarrow$  71.44%*)* on ImageNet, *but also accelerate more than 30000 times (*1000  $\rightarrow$  0.03 *seconds) classifying a single image on ImageNet. Additionally, it provides probability interpretation of the results. Our extensive experiments further demonstrate that GDC can achieve highly competitive zero-shot classification performance over various datasets and can promisingly selfimprove with stronger diffusion models. To the best of our knowledge, the proposed GDC is the first zero-shot diffusionbased classifier that exhibits both competitive accuracy and practical efficiency.*

### <span id="page-0-0"></span>1. Introduction

Diffusion models, as the representative of generative models, have achieved tremendous success and attracted great attention due to their impressive performance [\[14\]](#page-8-0). Diffusion models have been proposed with similar ideas, including Diffusion Probabilistic Models [\[61\]](#page-10-0), Noise-conditioned

Score-based Generative Models [\[62\]](#page-10-1), and Denoising Diffusion Probabilistic Models [\[20\]](#page-8-1). Diffusion models serve as backbone algorithms of various AIGC applications, including image generation [\[37,](#page-9-0) [48,](#page-9-1) [50,](#page-9-2) [55,](#page-10-2) [56\]](#page-10-3), video generation [\[3,](#page-8-2) [21\]](#page-8-3), 3D generation [\[30,](#page-9-3) [46,](#page-9-4) [69\]](#page-10-4), and speech generation [\[24,](#page-8-4) [49,](#page-9-5) [70\]](#page-10-5).

Diffusion models have been continually improving with increasingly more model parameters, training data, and computational resources [\[44,](#page-9-6) [45\]](#page-9-7). We particularly note that modern large generative models usually have cost much more computational resources and training data than modern discriminative models. With such strong generative ability and large resources/data, large generative models should be very powerful foundation models for more applications. A generative classifier is a type of classification model that is based on the principles of generative models. This line of research, often called *zero-shot generative classifiers*, has suggested promising potential and advantages, especially in the era of large generative models. Recent advancements in large diffusion models [\[45,](#page-9-7) [48,](#page-9-1) [57,](#page-10-6) [71\]](#page-10-7) make powerful zero-shot generative classifiers become more possible.

Only a few pioneering works have explored *zero-shot diffusion-based classifiers*. Li et al. [\[28\]](#page-9-8) and Clark and Jaini [\[10\]](#page-8-5) similarly employed the denoising loss of each class via large Stable Diffusion (SD) models to achieve state-of-theart zero-shot classification performance on ImageNet [\[13\]](#page-8-6). Jaini et al. [\[22\]](#page-8-7) studied intriguing properties of zero-shot diffusion-based classifiers and argued that they approximate human object recognition data surprisingly well. Emerging zero-shot diffusion-based classifiers are mainly loss-based diffusion-based classifiers. While we have seen progress in recent works, zero-shot diffusion-based classifiers are still very naive and largely suffer from extremely slow classification speed. For example, it takes around 1133 seconds per classifying a single image from ImageNet [\[28\]](#page-9-8). The poor efficiency is exactly the main bottleneck of applying zero-shot diffusion-based classifiers widely in practice.

Contribution In this paper, we solve the efficiency problem of zero-shot diffusion-based classifiers and demonstrate

<sup>\*</sup>These authors contributed equally to this work.

<span id="page-1-2"></span>their promising performance. We made two contributions.

First, we introduce a simple yet useful baseline Diffusionbased zero-shot classifier, namely the Gaussian Diffusion Classifier (GDC), which can predict the class probability give a test image efficiently and accurately. We present its illustration in Figure [2](#page-3-0) and its pseudocode in Algorithm [1.](#page-2-0) It accelerates more than 30000 times (from 1133 seconds to 0.03 seconds), classifying a single image on ImageNet during evaluation. To the best of our knowledge, the proposed GDC is the first zero-shot diffusion classifier that exhibits both competitive accuracy and practical efficiency.

Second, our extensive experiments demonstrate that GDC can achieve impressive zero-shot classification performance over various datasets. For example, as Table [1](#page-5-0) shows, the proposed GDC can significantly surpass previous zero-shot diffusion-based classifiers by more than 10 points (from 61.40% to 71.44%) on ImageNet, the most popular image classification benchmark. Interestingly, when provided with one single training images, GDC can outperform CLIP. We also show that GDC can promisingly self-improve its performance with stronger diffusion models, which will naturally appear in the future.

Structure of the paper In Section [2,](#page-1-0) we review related work and highlights distinctions from zero-shot diffusionbased classifiers. In Section [3,](#page-1-1) we clearly explain our motivation for using Gaussian-based classifier. In Section [4,](#page-2-1) we formally introduce our GDC method details. In Section [5,](#page-4-0) we present comprehensive experimental results, demonstrating both the empirical success and unique properties of our zero-shot diffusion-based classifiers. In Section [7](#page-6-0) we provide case analyses and discusses the main limitations, while in Section [8](#page-7-0) we conclude our work.

### <span id="page-1-0"></span>2. Related Work

In this section, we review related work and discuss how they differ from the studies of zero-shot diffusion-based classifiers.

Text-to-Image Diffusion Models Since generative diffusion models have been proposed, pioneering works have shown impressive image generation improvements over previous mainstream GAN-based methods [\[14,](#page-8-0) [53\]](#page-10-8). GLIDE [\[38\]](#page-9-9) is the pioneering work on text-to-image generation, which explored classifier-free guidance for the sample photorealism and caption similarity. Imagen [\[56\]](#page-10-3) further adopted a pretrained and frozen large language model as the text encoder. Latent Diffusion is a milestone of text-to-image diffusion models. SD [\[55\]](#page-10-2) made significant progress towards diffusion in low-dimensional latent space. Dall-E 2 [\[54\]](#page-10-9) further explored multimodal latent space. We recommend Yang et al. [\[71\]](#page-10-7) for a comprehensive survey on diffusion models. However, this line of research only focused on generative tasks and failed to explore the promising potential of diffusion models in discriminative tasks.

Generative classifiers Discriminative models directly learn to model the decision boundary of the underlying classification task, while generative models learn to model the (conditioned) distribution of the data. A large body of works [\[29,](#page-9-10) [36,](#page-9-11) [58,](#page-10-10) [63,](#page-10-11) [73\]](#page-10-12) studied generative classifiers from a Bayesian perspective. A number of works [\[12,](#page-8-8) [27,](#page-9-12) [34,](#page-9-13) [75\]](#page-10-13) reported that generative classifiers may naturally accomplish relatively good robustness for classification. Chen [\[8\]](#page-8-9) highlights the generative classifiers with pre-trained diffusion models have potential for adversarial robustness compared with the commonly studied discriminative classifiers. Several seminal works [\[5–](#page-8-10)[7,](#page-8-11) [18,](#page-8-12) [19\]](#page-8-13) studied efficient representations of generative models, which are later used for downstream tasks. However, directly employing generative models for classification in a zero-shot way is still underexplored. Most of these works required training data and did not touch zero-shot generative classification. Zero-shot generative classifiers require essentially different methods and exhibit novel intriguing properties [\[22\]](#page-8-7) beyond conventional generative classifiers that require training data.

Zero-Shot Classification Common machine-learning methods focus on classifying instances whose classes have already been seen in training, which is sometimes not possible in practice. Zero-shot learning is a powerful and promising learning paradigm where, at test time, a learner observes samples from classes that were not observed during training and needs to predict the class that they belong to [\[65\]](#page-10-14). Some works have explored zero-shot classification with various techniques, such as co-occurrences of visual concepts for knowledge transfer [\[35\]](#page-9-14), learning latent embeddings [\[23,](#page-8-14) [68,](#page-10-15) [72\]](#page-10-16), and generating visual representations [\[6\]](#page-8-15). Recently, it has become well known that large vision-language models, such as CLIP, are robust and strong unsupervised multitask learners [\[51,](#page-9-15) [67\]](#page-10-17). Further, fine-tuned large language models are also reported to be powerful zero-shot learners for many downstream tasks [\[66\]](#page-10-18).

This naturally leads to an open question: are large diffusion models also efficient and powerful zero-shot classifiers? Moreover, if large diffusion models are capable, how to enable the model output the classification results and further endow the results with a probabilistic interpretation? Large diffusion models must require essentially different zero-shot methodology beyond the previous zero-shot methodology of Large Language Models. As we mentioned in Section [1,](#page-0-0) this line of research only contains a few pioneering works and is still largely under-explored.

### <span id="page-1-1"></span>3. Motivation

We use DINOv2 [\[41\]](#page-9-16) to extract image features from two wellknown classification datasets, CIFAR100 and ImageNet, and analyze the resulting feature distributions. We examine the distribution of random 30 components from PCA. As shown in Figure [1,](#page-2-2) the feature values approximate a Gaussian distri-

Figure 1. We visualize the distribution of image features for random 60 PCA components from a randomly picked class on CIFAR-10. The red curves representing fitted Gaussian distributions. The results indicate that the feature values approximate a Gaussian distribution, motivating our method.

bution. We assess the Gaussianity of image features of each class in ImageNet by the Shapiro-Wilk normality test [\[60\]](#page-10-19). The statistical test results show that, for the 1,000 classes in ImageNet, more than 60% principal components' p-value are higher than 0.05, which indicate that these components can be approximately Gaussian. Moreover, some components' p-values are even higher than 0.99. Appendix C and D show more visual and statistical results. The visualization and

statics results motivate our natural use of a Gaussian Mixture Model (GMM) to represent each class's feature distribution. In this framework, each Gaussian component captures the mean and variability of the embeddings for a specific class and predict the modeling probability of a given image embedding. By modeling class distributions probabilistically, the GMM not only improves classification accuracy but also 194 enables a probabilistic interpretation, facilitating uncertainty quantification and enhanced interpretability of the results.

### <span id="page-2-1"></span>4. Methodology

In this section, we present our Gaussian Diffusion Classifiers (GDC) and show why it can solve the efficiency problem of zero-shot diffusion-based classifiers.

Notations Suppose we try to classify samples from a dataset D which contain k categories,  $\{y_i\}_{i=1}^k$ , and m samples,  $\{x_j\}_{j=1}^m$ . A diffusion model M, which models the text-conditioned distribution  $p(x|c)$ , can generate images conditioned on a given class caption c.

Previous zero-shot diffusion-based classifiers [\[10,](#page-8-5) [28\]](#page-9-8) are loss-based methods. When performing classification, they must spend expensive costs doing diffusion reverse inference thousands of times per classifying a single image to estimate some diffusion-based loss of the image  $x$  and each class. If a diffusion model produces a relatively low loss of the pair of the image  $x$  and the class caption  $c$ , it suggests that the class caption  $y$  may describe the image  $x$  better than the other candidate class caption. This strategy is natural but extremely slow, especially when the number of classes is large. For example, this strategy must repeat  $k = 100$  times and  $k = 1000$  times per classifying a single image from CIFAR100 and ImageNet, respectively.

To solve the efficiency problem of zero-shot diffusionbased classifiers, we must avoid repeating diffusion backward processes  $k$  times per classifying a single image. The basic idea of our method is very simple but effective. We present the pseudocode of GDC in Algorithm [1.](#page-2-0) Our GDC method consists of two phases.

1) Preparation Phase. This phase includes reference image generation and GMM construction. Before classifying any images, we use diffusion models to generate  $n$  (e.g., 240) reference images per class. To increase the diversity of these reference images, we apply a prompt augmentation strategy [\[42\]](#page-9-17). This approach allows us to generate only  $N \times k$  images to classify arbitrarily large image sets, including over one million images from ImageNet. We then use DINOv2  $[41]$  to extract d-dimensional embeddings for all reference images. This results in  $k$  clusters, each containing  $N$  data points in the embedding space, which we use to construct a Gaussian Mixture Model (GMM) with  $k$  components. For each Gaussian component, we calculate the cluster mean vector  $\mu$  and the cluster covariance matrices  $\Sigma$ . For the GMM, we combine the mean vec-

<span id="page-3-1"></span><span id="page-3-0"></span>

Figure 2. The overview of our Gaussian Diffusion Classifiers (GDC), which consists of two phases: 1) Preparation Phase and 2) Gaussianbased Classification Phase. GDC not only can output the classification result but also the probability. For conciseness, we present only three reference images, while the influence of varying numbers of reference images is discussed in Section [5.](#page-4-0) Algorithm [1](#page-2-0) shows more details.

tors as  $[\mu_1, \mu_2, \dots, \mu_k] \in \mathcal{R}^{k \times d}$  and covariance matrices as  $[\Sigma_1, \Sigma_2, \ldots, \Sigma_k] \in \mathcal{R}^{k \times d \times d}$ . We calculate the cholesky decomposition of the precision matrixes, the inverse of covariance matrix for the GMM.

$$
\text{cholesky}([\hat{\Sigma}_0, \hat{\Sigma}_1, \dots \hat{\Sigma}_k]^{-1}) = \mathbf{LL}^*,\tag{1}
$$

where **L** is a lower triangular matrix with real and positive diagonal entries, and  $L^*$  denotes the conjugate transpose of L. Appendix C presents the calculate method for L. The matrix  $\hat{\Sigma}_i$  is defined as  $\Sigma_i + \epsilon I$ , and its inverse,  $\hat{\Sigma}_i^{-1}$ , is referred to as the precision matrix. Here, I represents identity matrices with the same shape as  $\Sigma$ . The regular term,  $\epsilon$ , should be a small positive value (e.g.  $10^{-8}$ ), under the premise of ensuring the positive certainty of the precision matrix. Appendix B presents the relevant experimental results for regularization value selection. It is note that storing the precision matrices instead of the covariance matrices makes it more efficient to compute the log-likelihood of new samples at test time.

2) Gaussian-based Classification Phase. Given a set of cluster data includes  $k$  classes, the task of a classifier is to assign a sample  $x$  to one of the k classes. According to Bayes rule,  $p(y_i|x)$  can be calculated by using the class-conditional probability  $p(x|y_i)$  and the class prior probability of the class  $p(y_i)$ :  $p(y_i|x) = \frac{p(x|y_i)p(y_i)}{p(x)}$ . Thus, the main idea of a classifier based on Bayes decision theory can be written as flowing:

$$
x \in y_i, \iff y_i = \argmax_{y_i} p(x|y_i) p(y_i). \tag{2}
$$

The class prior probability  $p(y_i)$  is commonly known in advance or can be calculated/estimated using some approaches [\[15,](#page-8-16) [26\]](#page-8-17). Thus, when we do zero-shot classification on an image  $x$ , we only need to use GMM to compute the class-condition probability  $p(x|y_i)$  of x and then assign x to the class with the highest probability. Noticed, we firstly use the DINO to extract the features  $e$  of  $x$  and the input it to each Gaussian Model to calculate the probabilities. Thus, ther are  $p(x|y_i) \iff p(e|y_i)$  and  $p(y_i|x) \iff p(y_i|e)$ .

Our GDC can give the probability interpretation for the results. The posterior probability can be calculated based on Bayes rule as flowing:

$$
p(y_i|x) \iff p(y_i|e) = \frac{p(e|y_i) p(y_i)}{p(e)} = \frac{p(e|y_i) p(y_i)}{\sum_{j=1}^k p(e|y_j) p(y_j)}.
$$
 (3)

The  $p(e|y_i) = \frac{1}{2\pi^{d/2}(|\Sigma_i|)^{1/2}} \exp\left(-\frac{1}{2}(e-u_i)^T \hat{\Sigma}_i^{-1}(e-u_i)\right)$ is the Gaussian density of the  $i_{th}$  component in ddimensional space, where  $\hat{\Sigma}_i^{-1}$  is the  $i_{th}$  precisions\_matrix. So  $\sum_{i=1}^{k} p(y_i|x) = 1$ . This can enable our GDC further analysis in uncertainty quantification, robustness evaluation, and risk assessment and also enhance the interpretability of the method.

The proposed GDC can classify an image very quickly during deployment, because the Gaussian-based Classification Phase only requires the forward process of the image encoder once and probability calculation. The expensive

<span id="page-4-1"></span>and slow diffusion reverse process only happens in the first Preparation Phase that generates clusters, which can be completed before deploying GDC. The first phase is prepared for the whole classification task rather than a single image. So our classification speed can be several orders of magnitudes faster than the conventional redundant diffusion reverse processes per classifying one image.

### <span id="page-4-0"></span>5. Empirical Analysis

In this section, we conduct extensive experiments and demonstrate the impressive efficiency and performance of GDC over the baseline methods.

Experimental Settings We use popular real-world classification datasets as benchmark datasets and open-source SD models as the backbone diffusion model of GDC. We hope to fairly compare our GDC with the previous state-of-theart baseline, namely loss-based diffusion-based classifiers [\[10,](#page-8-5) [28\]](#page-9-8). We use SDXL-turbo as the default diffusion model to generate 240 reference images with  $512 \times 512$  and DI-NOv2 [\[41\]](#page-9-16) as the default image encoder to output 1536-d vector for each reference image, unless we specify them otherwise. In this way, people can conveniently employ our GDC method in practice and reproduce our results for further research. The reference images are resized from  $512 \times 512$ to  $224 \times 224$  to align with the input dimensions of DINOv2. The default regularization value is  $1e^{-8}$ .

Dataset ImageNet [\[13\]](#page-8-6), CIFAR-10/100 [\[25\]](#page-8-18), Flower-102 [\[39\]](#page-9-18), Oxford Pet-37 [\[43\]](#page-9-19), Food-101 [\[4\]](#page-8-19), STL10 [\[11\]](#page-8-20), DTD [\[9\]](#page-8-21) and Caltech101 [\[16\]](#page-8-22). More experimental details can be found in Appendix A.1.

Prompt Argumentation In the default setting, we use SDXL-turbo to generate  $N = 240$  reference images for each class, employing eight different prompt templates to increase the diversity of the reference images, such as 'a photo of a  $\{\}$ ', 'an origami  $\{\}$ ', 'art of the  $\{\}$ ', 'a photo of the small  $\{\}$ ', and so on(see Appendix A.2). We replace the placeholder with the name of the category. We use each prompt template to generate 30 reference images averagely.

Zero-shot Generative Classification We empirically compare the proposed GDC with the previous state-of-theart baseline, Li's Diffusion Classifier(DC) [\[28\]](#page-9-8) and Clark's DC [\[10\]](#page-8-5) over various popular benchmark datasets.

We note that, due to the extremely poor efficiency, the original works that proposed diffusion classifiers [\[10,](#page-8-5) [28\]](#page-9-8) only used a subset (∼ 30000 images) of test sets for evaluation. We reproduce the compared DCs performance on CIFAR-100, which was not reported by Li et al. [\[28\]](#page-9-8) and directly use other numerical results of SD models in original papers [\[10,](#page-8-5) [28\]](#page-9-8), as compared DCs may not classify these whole datasets within a reasonable time. As code relase problem, we may not present the numerical results of Clark and Jaini [\[10\]](#page-8-5) on Flower-102. Also, due to the extensive testing time required by Li's DC [\[28\]](#page-9-8), we are unable to test it

on DTD and Caltech-101 within a reasonable time. Instead, we use the existing results to compute the mean values in Table [1.](#page-5-0)

The results in Table [1](#page-5-0) demonstrate our GDC significantly outperforms the baselines on benchmark datasets. The improvements on the three most popular datasets, including ImageNet, CIFAR-10/100, and Flowers-102, are especially significant. We believe it is because these three datasets contain rich classes and real-world natural objects, which are good for generating rich and representative reference clusters. We report that GDC can consistently outperform compared DCs over all datasets. And, the mean accuracy gains of CGC are also up to 4.9 points and 15.9 points compared with Li's DC [\[28\]](#page-9-8) and Clark's DC [\[10\]](#page-8-5), respectively, over the evaluated multiple datasets. Considering the efficiency advantage of GDC, the accuracy gains are very impressive.

Computational Efficiency Since poor efficiency is the main bottleneck of employing zero-shot diffusion-based classifiers, it is essentially important to analyze the computational efficiency. In Table [2,](#page-5-1) we carefully evaluate the computational efficiency of GDC and Li's DC on ImageNet and CIFAR-100. We particularly focus on single-image classification time, because this metric reflects the efficiency of employing diffusion-based classifiers in the real world. If the single-image classification time is short enough, zero-shot diffusion-based classifiers with good classification performance will truly start to compete with common discriminative models on classification tasks. We also present the total time of performing zero-shot classification on the benchmark datasets, because the time of classifying a dataset provides simple and fair efficiency comparisons. Fortunately, we find that the proposed GDC is several orders of magnitude faster than Li's DC in both efficiency metrics.

One-shot Classification Results Table [1](#page-5-0) presents the zero-shot performance across various benchmarks, while Table [3](#page-5-2) demonstrates the accuracy on ImageNet, CIFAR10 and CIFAR100 under one-shot setting. We randomly replace one reference image with a real image. We employ pre-trained OpenCLIP(ViT-H-14 [\[52\]](#page-9-20)) on these dataset to calculate the similarity score between the visual features and text features.The text prompt is 'a photo of a {}', with the {} replaced by the class name. The test image is assigned to the class with the highest similarity score. From the results, we observe that even with only one single real data, the performance of GDC surpasses CLIP over 1.0, 1.2 and 4.2 receptively on ImageNet, CIFAR10 and CIFAR100. Incorporating real data enables the estimated Gaussian model to more accurately capture the distribution of the test data.

### 6. Ablation Analysis

In this section, we analysis the key factors affecting GDC performance.

Choices of the hyperparameter  $N$ .  $N$  as Algorithm

<span id="page-5-4"></span><span id="page-5-0"></span>

Method								ImageNet CIFAR-10 CIFAR-100 STL-10 Pet-37 Food-101 Flower-102 Caltech-101 DTD Mean		
Li's DC $[28]$ 61.4		88.5	67.6	95.4	87.3	77.7	66.3	$  77.7$

Table 3. One-shot generative classification accuracy of GDC. We randomly replace the generated reference images with one single training image.

Table 4. Zero-shot generative classification accuracy of GDC with vs. without the prompt augmentation strategy for reference images on ImageNet, CIFAR10 and CIFAR100 datasets.

[1](#page-2-0) shows, we need to specify the choices of the hyperparameter *n* (the number of reference images per class). We first conduct the experiment of GDC with  $N \in$ {5, 10, 30, 60, 120, 240} in Figure [3.](#page-6-1) With more reference images, we can obtain more statistically stable clusters for zero-shot classification, which often leads to higher classification accuracy. While we use  $N = 240$  as the default setting, we notice that GDC with 100 reference images can perform similarly well and cost only half preparation time while trying to maintain performance as much as possible. The results in the figure suggest that GDC is pretty robust to the choice of  $N$ . Of course, the choice of  $N$  almost does not affect single-image classification time, because the embedding extraction of the image encoder costs most single-image classification time.

Without Prompt Augmentation To evaluate the importance of the diversity of reference image, we compare the results of eights prompts and one single prompt, 'a photo of a {}' on three representative datasets: ImageNet, CIFAR10 and CIFAR100.

Table [4](#page-5-3) clearly shows that the results with reference images generated using diversity prompts have significant advantage across all three representative datasets. The diversity prompts mitigate the concentration of the generated reference image distribution, thereby enhancing its alignment with the Gaussian distribution of the test category.

Stronger Diffusion, Stronger Classification We further evaluate the zero-shot classification performance of various diffusion models. In terms of text-to-image generation quality, the models rank as SD-turbo  $>$  SD 1.5  $>$  SD 1.3 > SD 1.1. Due to experimental time constraints, the number of reference images in this evaluation is set to 30. The results are shown in Figure [4.](#page-6-1) As depicted, diffusion models with superior generation performance also demonstrate significantly better classification performance. This finding underscores a key advantage of our method: stronger diffusion models lead to better classification results. Diffusion models can be improved through various approaches such as increasing data and adjusting the structure [\[31,](#page-9-21) [55\]](#page-10-2), obtaining better initial noise [\[17,](#page-8-23) [50,](#page-9-2) [74\]](#page-10-20), optimizing the sampling strategy [\[1,](#page-8-24) [32,](#page-9-22) [33,](#page-9-23) [59\]](#page-10-21), and enhancing alignment capabilities [\[31,](#page-9-21) [47,](#page-9-24) [64\]](#page-10-22). Such advancements not only boost generative performance but also naturally enhance zero-shot classification capabilities.

<span id="page-6-3"></span><span id="page-6-1"></span>

Figure 3. The test accuracy of GDC with various choices of  $N$  on CIFAR10, CIFAR100 and ImageNet. The performance of GDC is pretty robust to the choice of N, when  $N \ge 100$ . Even if we have only one reference image per class, GDC performs still better than conventional Li's DC.

Figure 4. The classification accuracy of GDC monotonically increases with stronger diffusion models on ImageNet. Generation Performance: SDXL-turbo > SD 1.5 > SD 1.3 > SD 1.1.

### <span id="page-6-0"></span>7. Discussion

In this section, we discuss case study, error analysis, limitations, and potential directions.

Case Study Through good and bad case analysis, we may highlight some success or failure modes of GDC. Recent studies analyzed label errors in ImageNet and pointed out that most label errors come from ambiguous instances and the resulting human uncertainty [\[40\]](#page-9-25). We particularly evaluate GDC on the instances difficult for human annotators and surprisingly observe that GDC is able to correctly classify many instances that human annotators cannot correctly classify. In Figure [5,](#page-6-2) we randomly present some instances in which ImageNet incorrectly annotates given by Cleanlab [\[40\]](#page-9-25). Fortunately, GDC yields reasonably good semantic labels for the shown cases.

<span id="page-6-2"></span>

Figure 5. GDC can correct some common label errors in ImageNet. We provide examples illustrating instances where the ImageNet dataset assigns incorrect labels but GDC can annotate correctly. Cleanlab [\[40\]](#page-9-25), which focuses on correcting incorrect labels, can be accessed from this [URL.](https://github.com/cleanlab/cleanlab) The results demonstrate that GDC yields equivalent correct results as Cleanlab for these hard cases and excels in distinguishing visually similar instances.

Visual Comparision In Figure [6,](#page-7-1) we illustrate visual examples where Li's DC misclassifies, but our GDC successfully classifies them. Our method shows exceptional performance in challenging scenarios, such as when the *subject's texture is similar to the background* (e.g., hammerhead shark), *the subject appears small* (e.g., macaw), or *the subject is partially occluded* (e.g., goldfish and Whippet). These improvements can be credited to the diverse reference samples generated by SD, the critical features extracted by DINO, and the robust modeling power of GMM. These results inspire further research into Gaussian-based diffusion classification approaches.

Error Analysis We first show multiple examples of correctly/incorrectly classified instances from ImageNet in Figure [7](#page-7-2) and summarize three kinds of typical errors that may help us better understand and improve GDC. We try to understand when and why GDC fails. First, a class of erroneous cases fools GDC because the object is well hidden in the environment and is visually difficult for object recognition. For example, the misclassified water snake in the Figure [7](#page-7-2) belong to this class of erroneous cases. In these cases, GDC may be misled by the environment but not the main semantic object. Second, another class of erroneous cases fool GDC because multiple semantic objects co-exist in the images. For example, the misclassified trench coat in the Figure [7](#page-7-2) appears with a man riding a bicycle. In these cases, even human annotators may not exactly identify which is the main semantic label. We do not have a single ground-truth

<span id="page-7-1"></span>

classified by our GDC.

label for co-existent semantic objects. So, it actually makes sense that GDC predicts the semantic label of one of the coexistent semantic objects. Third, some erroneous cases fool GDC because the camera views are unusual. For example, the misclassified prison house in the Figure [7](#page-7-2) is shown from the inside angle with a man standing outside of the prison **a Prison house**  $\rightarrow$  Worm fence **…** cell. As for these cases, diffusion models rarely generate unusual camera views without specific prompts. To mitigate the typical errors, we believe improving the generation diversity and focusing on the main objects can be valuable. For example, we may design more strategies to improve the diversity of 1) background, 2) co-existent semantic objects, and 3) camera views.

Limitations (1) While our method achieves impressive Edimentations (1) while our method definitives impressive results for some typical cases. We do not completely know about the scope of these erroneous cases. This may limit the application scope of GDC for some settings. (2) We use image features with full dimensions to construct GMM. There may be redundancies and outliers here. Projecting the features into a low-dimensional space may a useful way to further analyze and enhance GDC.

Future Directions (1) The framework of Gaussian-based generative classification be easily generalized to other learning tasks beyond standard classification, including novel class discovery and anomaly detection, particularly when obtaining training data is difficult. (2) It is also interesting to employ GDC-based methods to solve various domain tasks, such as medical image analysis and remote sensing, which may leverage the power of large diffusion models. (3) According to our observation that stronger diffusion models lead to stronger classifiers, zero-shot classification accuracy on ImageNet can naturally become a useful performance

<span id="page-7-2"></span>

Figure 7. Correct Cases and Erroneous Cases. We show examples of correctly and incorrectly classified instances from ImageNet. The large images are the test images, while the small images are the generated reference images corresponding to the category assigned by GDC.

First Compression included to the compression in the method in the method cases. This may limit to deeply analysis how generative abilities associate with the measure for text-to-image generation. It will be interesting generated image embeddings.

## <span id="page-7-0"></span>8. Conclusion

In this paper, we aim at solving the efficiency bottleneck of zero-shot diffusion-based classifiers while maintaining good accuracy. Leveraging the powerful generative abilities of pretrained diffusion models without requiring any training data, the proposed GDC not only well solved the extremely poor efficiency problem but also achieved very competitive classification performance on popular benchmark datasets. For example, on ImageNet, the most popular classification dataset, GDC accelerates single-image classification by 30000 times and outperforms previous diffusion-based classifiers by 10 points. As the first zero-shot diffusion-based classifier that exhibits both competitive accuracy and practical efficiency, our work makes zero-shot diffusion-based classifiers get much closer to real-world applications. With stronger diffusion models that will appear in future, GDC can even naturally self-improve these advantages. While some limitations still exist, it will be very promising to further understanding and improve this approach.

# Supplementary Material

### A. Experimental Settings of Main Experiments

Computational environment. The experiments are conducted on a computing cluster with GPUs of NVIDIA® Tesla<sup>™</sup> V100, and Intel(R) Xeon(R) Platinum 8352V CPU @ 2.10GHz.

#### A.1. Datasets and Data Preprocessing

For a comprehensive comparison, we conduct experiments across seven benchmark classification datasets as follows:

**ImageNet-1K** [\[13\]](#page-8-6) is a large-scale visual database designed for visual object recognition research. It encompasses 1,000 distinct categories, with each category featuring 50 images in the validation subdataset. The challenges posed by this dataset for image classification include some categories with similar appearances and variations in resolutions across the dataset.

CIFAR-10/CIFAR-100 [\[25\]](#page-8-18) includes 10/100 different categories, respectively, covering a range of common objects. Each dataset comprises 10,000 test images with dimensions of  $32 \times 32$  pixels. The low resolution poses a challenge for the classification task.

Flower-102 [\[39\]](#page-9-18) comprises 102 distinct flower categories, with each category containing between 40 and 258 images, all with resolutions exceeding  $500 \times 500$  pixels. The test subdataset includes over 6,000 images. The images exhibit variations in scale, poses, and lighting. Moreover, certain categories display significant intra-category variations, and some categories are remarkably similar. These factors contribute to the increased difficulty of classification tasks.

Oxford Pet-37 [\[43\]](#page-9-19) is a widely used pet classification dataset featuring 37 categories, each containing approximately 200 images. The test subdataset comprises over 3,600 images with varying resolutions.

Food-101 [\[4\]](#page-8-19) is a challenging food recognition dataset with 101 categories. Each class includes 250 manually reviewed test images, rescaled to a maximum side length of 512 pixels. The presence of noise in some test images adds a significant challenge to the classification task.

STL-10 [\[11\]](#page-8-20) The STL-10 dataset is an image recognition dataset for developing unsupervised feature learning, deep learning, self-taught learning algorithms. It includes 10 classes: airplane, bird, car, cat, deer, dog, horse, monkey, ship, truck. Each images is  $96 \times 96$  pixels, color. It contains 500 training images, 800 test images per class.

DTD [\[9\]](#page-8-21) DTD is a texture database, consisting of 5640 images, organized according to a list of 47 terms (categories) inspired from human perception. There are 120 images for each category. Image sizes range between  $300 \times 300$  and  $640 \times 640$ , and the images contain at least 90% of the surface representing the category attribute.

Caltech-101 [\[16\]](#page-8-22) Pictures of objects belonging to 101 categories. About 40 to 800 images per category. Most categories have about 50 images.

It is worth noting that, due to our ultra-high computational efficiency, we can rapidly process entire test data in a short time. In contrast, for large-scale datasets (e.g., ImageNet-1k), Li's DC and Clark's DC only select part of the data for validation. The impressive results from Table [1](#page-5-0) underscore the robustness of GDC in achieving effective zero-shot classification under various challenges.

### A.2. Prompt Templates

We use eight different prompt templates:'a photo of a {}', 'itap of a  $\{\}$ ', 'a bad photo of the  $\{\}$ ', 'a origami  $\{\}$ ', 'a photo of the large {}', 'a {} in a video game','art of the {}', 'a photo of the small {}', replacing the placeholder '{}' with class name. We use each prompt template to generate 30 reference images averagely.

## B. Ablation study on regularization values

We conduct ablation experiments of regularization value across various datasets, including ImageNet, CIFAR-10/100, Caltech-101, DTD and STL-10. The results are shown in Table [5.](#page-11-1)

<span id="page-11-1"></span>

Table 5. The influence of regularization value,  $\epsilon$ , on classification accuracy. The lower regularization value correlates with the higher accuracy. If the value is lower than  $1^{-10}$ , inversing  $\Sigma + \epsilon I$  is not stable.

### C. Supplementary Discussion

Normality Test of DINOv2 Features We assess the normality of DINOv2 feature representations for each class of generated images by performing Principal Component Analysis (PCA) followed by the Shapiro-Wilk normality test [\[60\]](#page-10-19). <span id="page-12-0"></span>We find that  $60.01\%$  of the components are approximately Gaussian according to the statistical tests for ImageNet.

Specifically, for each class, we first extract the DINOv2 feature representations e and compute their covariance matrix. Performing eigenvalue decomposition on this matrix yields the principal components, which are sorted by descending eigenvalues to prioritize the directions with the highest variance. We then project  $e$  onto these principal components. To evaluate normality along each component, we apply the Shapiro-Wilk test to each dimension in the projected space, yielding a p-value that reflects the likelihood that the distribution is Gaussian. A p-value above 0.05 suggests that normality cannot be rejected in that dimension. This approach allows us to analyze the normality characteristics across classes within the principal component space.

Shapiro–Wilk test To better understand the normality test, we present the calculation of the Shapiro–Wilk test. The Shapiro–Wilk test [\[60\]](#page-10-19) tests the null hypothesis that a sample  $x_1, \ldots, x_n$  came from a normally distributed population. The test statistic is:

$$
W = \frac{\left(\sum_{i=1}^{n} a_i x_{(i)}\right)^2}{\sum_{i=1}^{n} (x_i - \overline{x})^2},\tag{4}
$$

 $x(i)$  with parentheses enclosing the subscript index i is the  $i_{th}$  order statistic, i.e., the  $i_{th}$  -smallest number in the sample.  $\overline{x}$  is the sample mean. The coefficients  $a_i$  are given by:

$$
(a_1, ..., a_n) = \frac{m^T V^{-1}}{C}, \tag{5}
$$

where *C* is a vector norm:  $||V^{-1}m|| = (m^T V^{-1} V^{-1} m)$ , and the vector m  $(m_1, \ldots, m_n)^T$  is made of the expected values of the order statistics of independent and identically distributed random variables sampled from the standard normal distribution. The  $V$  is the covariance matrix of those normal order statistics.

Cholesky decomposition We define the Cholesky decomposition [\[2\]](#page-8-25) of the precision matrix as the precision Cholesky term for the GMM. This decomposition represents a Hermitian, positive-definite matrix as the product of a lower triangular matrix and its conjugate transpose. It facilitates efficient numerical computations and is widely applied in solving systems of linear equations, linear least squares problems, nonlinear optimization, Monte Carlo simulations, matrix inversion, and more.

The Cholesky decomposition of a Hermitian positivedefinite matrix **A** is expressed as  $A = LL^*$ , where L is a lower triangular matrix with real and positive diagonal entries, and  $L^*$  denotes the conjugate transpose of  $L$ . This decomposition is unique for every Hermitian positive-definite matrix. When A is a real symmetric positive-definite matrix, the Cholesky decomposition can be written  $A = LL^{\mathsf{T}}$ , where L is a real lower triangular matrix with positive diagonal entries.

There are various approaches for calculating the Cholesky decomposition. We present two widely used approaches. The first one is the Cholesky algorithm, employed to compute the decomposition matrix L, is an modified variant of Gaussian elimination. The recursive algorithm starts with  $i := 1$  and

$$
\mathbf{A}^{(1)}:=\mathbf{A}.
$$

At step i, the matrix  $A^{(i)}$  has the following form:

$$
\mathbf{A}^{(i)} = \begin{pmatrix} \mathbf{I}_{i-1} & 0 & 0 \\ 0 & a_{i,i} & \mathbf{b}_i^* \\ 0 & \mathbf{b}_i & \mathbf{B}^{(i)} \end{pmatrix},
$$

where  $\mathbf{I}_{i-1}$  denotes the identity matrix of dimension  $i - 1$ . If the matrix  $\mathbf{L}_i$  is defined by

$$
\mathbf{L}_i := \begin{pmatrix} \mathbf{L}_{i-1} & 0 & 0 \\ 0 & \sqrt{a_{i,i}} & 0 \\ 0 & \frac{1}{\sqrt{a_{i,i}}} \mathbf{b}_i & \mathbf{I}_{n-i} \end{pmatrix},
$$

then  $A^{(i)}$  can be written as

$$
\mathbf{A}^{(i)} = \mathbf{L}_i \mathbf{A}^{(i+1)} \mathbf{L}_i^*,
$$

where

$$
\mathbf{A}^{(i+1)} = \begin{pmatrix} \mathbf{I}_{i-1} & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \mathbf{B}^{(i)} - \frac{1}{a_{i,i}} \mathbf{b}_i \mathbf{b}_i^* \end{pmatrix}.
$$

Note that  $\mathbf{b}_i \mathbf{b}_i^*$  is an outer product. This is repeated for i from 1 to *n*. After *n* steps,  $A^{(n+1)} = I$  is obtained, and hence, the lower triangular matrix L sought for is calculated as

$$
\mathbf{L} := \mathbf{L}_1 \mathbf{L}_2 \cdots \mathbf{L}_n.
$$

The second approaches is the Cholesky–Banachiewicz and Cholesky–Crout algorithms. If the equation

$$
\mathbf{A} = \mathbf{L}\mathbf{L}^T = \begin{pmatrix} L_{11} & 0 & 0 \\ L_{21} & L_{22} & 0 \\ L_{31} & L_{32} & L_{33} \end{pmatrix} \begin{pmatrix} L_{11} & L_{21} & L_{31} \\ 0 & L_{22} & L_{32} \\ 0 & 0 & L_{33} \end{pmatrix},
$$
  
= 
$$
\begin{pmatrix} L_{11}^2 & L_{21}L_{11} & L_{31}L_{11} \\ L_{21}L_{11} & L_{21}^2 + L_{22}^2 & L_{31}L_{21} + L_{32}L_{22} \\ L_{31}L_{11} & L_{31}L_{21} + L_{32}L_{22} & L_{31}^2 + L_{32}^2 + L_{33}^2 \end{pmatrix},
$$

is written out, the following is obtained:

$$
\mathbf{L} = \begin{pmatrix} \sqrt{A_{11}} & 0 & 0 \\ A_{21}/L_{11} & \sqrt{A_{22} - L_{21}^2} & 0 \\ A_{31}/L_{11} & (A_{32} - L_{31}L_{21})/L_{22} & \sqrt{A_{33} - L_{31}^2 - L_{32}^2} \end{pmatrix}.
$$

And therefore the following formulas for the entries of L:

$$
L_{j,j} = (\pm) \sqrt{A_{j,j} - \sum_{k=1}^{j-1} L_{j,k}^2},
$$

$$
L_{i,j} = \frac{1}{L_{j,j}} \left( A_{i,j} - \sum_{k=1}^{j-1} L_{i,k} L_{j,k} \right), \text{ for } i > j.
$$

For complex and real matrices, inconsequential arbitrary sign changes of diagonal and associated off-diagonal elements are allowed. The expression under the square root is always positive if A is real and positive-definite. So it now is possible to compute the  $(i, j)$  entry if the entries to the left and above are known.

More visual results We presents more visual results of feature distribution of CIFAR-10/100 and ImageNet.

Figure 8. We visualize the distribution of image features for random 30 PCA components from three randomly picked classes on CIFAR-10/100 and ImageNet.
