Abstract

Recent developments in 3D vision have enabled successful progress in inferring neural fluid fields and realistic rendering of fluid dynamics. However, these methods require real-world flow captures, which demand dense video sequences and specialized lab setups, making the process costly and challenging. Scientific machine learning (SciML) foundation models, which are pretrained on extensive simulations of partial differential equations (PDEs), encode rich multiphysics knowledge and thus provide promising sources of domain priors for inferring fluid fields. Nevertheless, their potential to advance real-world vision problems remains largely underexplored, raising questions about the transferability and practical utility of these foundation models. In this work, we demonstrate that SciML foundation model can significantly improve the data efficiency of inferring real-world 3D fluid dynamics with improved generalization. At the core of our method is leveraging the strong forecasting capabilities and meaningful representations of SciML foundation models. We equip neural fluid fields with a novel collaborative training approach that utilizes augmented views and fluid features extracted by our foundation model. Our method demonstrates significant improvements in both quantitative metrics and visual quality, showcasing the practical applicability of SciML foundation models in real-world fluid dynamics.

1. Introduction

Fluid phenomena are ubiquitous in our 3D world, from the powerful ocean currents shaping coastlines to the turbulent jet streams in the air. One important yet open challenge in understanding fluids is to recover fluid dynamics from visual observations, also known as the inference of **3D fluid fields**. Formally stated, given visual inputs (2D images or video sequences), this task aims to infer invisible quantities like density, velocity, vorticity, pressure, in the spatiotemporal domain (3+1D), as shown in Figure 1 left. This facilitates downstream rendering of realistic fluids in computer games and videos [69], and even applications of

broad impacts such as weather forecasting [49] and airfoil design [63]. Unlike rigid bodies, fluids present a unique challenge due to their dynamic and complex nature, requiring advanced computational methods.

Recent advancements in 3D computer vision have enabled significant progress in inferring fluid fields. This includes both multi-view benchmarks [16] of high-quality flow videos with well-calibrated camera poses, and also neural fluid fields [10-12, 23, 80] jointly optimized by rendering loss and physics constraints. However, learning to infer fluid fields with deep networks is notorious for its heavy data consumption of densely captured fluid views. Methods like HyFluid [80] by default require four videos with 120 continuous frames each. This requirement is often expensive and impractical, relying on specialized lab setups such as lasers or particle tracking. For example, collecting and calibrating the ScalarFlow dataset [16] requires insulated containers with heaters, fog machines with servocontrolled valves, and multiple cameras, with an estimated total cost of around \$1,100.

A common strategy to achieve data efficiency and improved generalization is to introduce appropriate prior knowledge. Scientific machine learning (SciML), which aims to learn physical dynamics, is a promising source of prior knowledge to introduce (Figure 1 right). Deep neural networks (DNNs) provide surrogate models for rapid approximations of partial differential equations (PDEs) and

Figure 1. Inferring neural fluid fields requires densely captured views. Meanwhile, PDE simulations are important for building SciML foundation models. How to utilize this rich domain knowledge and improve 3D fluid reconstruction in the real world?

^{*}The first two authors contributed equally.

real-world challenges like weather forecasting [38, 49] and turbulent flow [31]. **SciML foundation models** are further advanced in recent works [25, 26, 43, 51, 58, 60, 68, 79]. By scaling up extensive training datasets to incorporate multiple physical domains and PDE simulations, SciML foundation models aim to encode common physical behaviors and enhance generalization and scalability within scientific contexts, such as dynamics of fluid, smoke, and airflow.

Although promising, SciML foundation models are mainly pretrained and evaluated on PDE simulations [45, 59, 61], especially for fluid dynamics (Navier-Stokes, Burgers', shallow water). These simulations, while encoding rich physical domain knowledge, still differ from real fluid captures with multiscale phenomena, noisy measurements, and changing environments (Figure 1). This poses questions about the transferability and utility of SciML foundation models in real-world 3D fluid problems. In contrast, foundation models in popular ML domains have been widely utilized as strong prior knowledge. Vision models such as DiNO [5, 48] and CLIP [50] have been extensively leveraged to extract meaningful and generalizable representations and also semantic awareness [6, 42, 62, 66, 71, 73, 78]. Large language models (LLMs), such as GPT [1] and Llama [15, 64, 65], are pretrained on high-quality corpora and interact with the informal spoken language of human users every day. Therefore, we ask our core question:

How to utilize SciML foundation models to advance 3D reconstruction of real-world fluids?

In this work, we provide affirmative answers (Figure 2), and demonstrate that pretrained SciML foundation models can enhance data efficiency in inferring neural fluid fields from sparse videos (estimating fluid density and velocity from videos). Our core idea is to utilize the multiphysics domain knowledge encoded in our SciML foundation model, and leverage its strong forecasting and meaningful representations to "distill" this prior into neural fluid fields. We demonstrate both improved quantitative metrics and the high-quality visual appearance of our method on real-world flow captures with significantly reduced training input views. We summarize our contributions below:

- 1. Given extremely sparse initial views from short videos of flows, we utilize our foundation model to forecast future steps (temporal frames)¹, which leads to a collaborative training strategy for neural fluid fields with more augmented fluid views (Section 3.2 and Figure 6).
- 2. To improve generalization, we introduce meaningful representations of flows extracted by our foundation model into neural fluid fields, by carefully aligning the representation with camera rays used to infer the fluid field (Section 3.3 and Figure 7).

Figure 2. Our method is significantly more data-efficient compared with previous works (PINF [10], HyFluid [80]) on future prediction, over different numbers of initial training frames per input video (x-axis). We show the temporal index of reliably predicted future frames, using a peak signal-to-noise ratio (PSNR) threshold of 25, on the y-axis.

3. We provide comprehensive experiments and ablation studies (Section 4), and demonstrate that our method not only unlocks extreme data efficiency, but also achieves both improved reconstruction error and visual quality for fluids in the real world.

2. Preliminary

2.1. Inferring Fluid Fields from Videos

Our method is developed to work with HyFluid [80], which infers neural fluid fields (density and velocity) from videos.

Problem Definition. Given videos of smoke rising upwards (Figure 1, left), with the number of frames (views) in each video denoted by nf, HyFluid aims to infer the density field $\sigma(x, y, z, t)$ and the underlying velocity field $u(x, y, z, t) = (v_x, v_y, v_z)$ of the smoke, both parameterized by deep networks.

The nf is set to 120 by default in HyFluid. For the density field $\sigma(x, y, z, t)$, HyFluid randomly samples camera rays (x, y, z, t) and reconstructs the density field using a 4D extension of iNGP [46], which accelerates the neural rendering with multiscale hash encoding of spatiotemporal positions. During training, this reconstructed density field is optimized by comparing input and rendered views via differentiable volume rendering. This is illustrated in the bottom half of Figure 4. Similarly, the velocity field u(x, y, z, t) is inferred by another iNGP model, and is supervised by physics-informed losses that enforce the preservation of density for incompressible flows and divergence-free velocity.

During inference, the density field is used to render the visual appearance of the smoke, and the learned velocity

¹In this work, we use "frame" and "view" interchangeably, since our 2D views are all video frames.

field can be used to advect (evolve) the density over temporal steps for both *re-simulation* (interpolation of the temporal range seen during training) and *future prediction* (extrapolation of unseen future temporal ranges).

ScalarFlow: Smoke Videos with Calibrated Cameras. Recent works on reconstructions of neural fluid fields focus on studying the ScalarFlow dataset [16]: a comprehensive collection of volumetric reconstructions of real-world smoke plumes (Figure 1 left). It encompasses a wide array of complex, buoyancy-driven flows rising upwards that transition into turbulence, capturing observable scalar transport processes. To the best of our knowledge, ScalarFlow is by far the best-calibrated dataset on real-world fluid (smoke) dynamics.

2.2. SciML Foundation Model

For time-dependent PDEs, the solution is a mapping from the joint of a spatial and temporal domain to the dynamics of the physical system (e.g. density, velocity, vorticity of the fluid at a certain spatiotemporal location): $\mathbf{v} :=$ $\mathcal{T} \times S \rightarrow \mathbb{R}^d$. In current literature [38, 39, 43, 61], the **forward modeling** operator \mathcal{N} computes the PDE solution given $T_{in} \in \mathbb{Z}^+$ consecutive previous timesteps: $\mathcal{N} := \mathbf{v}(t - T_{in} \cdot \Delta t, \cdot), \dots, \mathbf{v}(t - \Delta t, \cdot) \mapsto \mathbf{v}(t, \cdot)$, where Δt is the granularity of the temporal grid. This enables finite-difference approximations of the temporal derivatives of PDEs. See Figure 3 for an illustration.

SciML aims to find ML-based surrogate models for forward modeling by learning an approximation from data $\mathcal{N}_{\phi} \simeq \mathcal{N}$ (ϕ for learnable parameters). To optimize \mathcal{N}_{ϕ} , we take a dataset \mathcal{D} comprising N discretized PDE simulations ("samples") $\mathcal{D} := \{\mathbf{v}^{(i)} \mid i = 1, \dots, N\}$, and minimize a loss functional L, typically the normalized root of the mean squared error (nRMSE $\equiv \frac{\|\mathbf{v}_{\text{pred}} - \mathbf{v}\|_2}{\|\mathbf{v}\|_2}$ where \mathbf{v}_{pred} is the prediction from \mathcal{N}_{ϕ}).

Traditionally, SciML models focus on learning simulation data from one PDE [38, 39, 41] with variants². However, recent works explored and verified the benefits of <u>scaling up the pretraining data to include diverse PDE systems</u>, thus developing **SciML foundation models** [25, 26, 43, 51, 58, 60, 68, 79]. Intuitively, although these PDEs model very different physical systems, this "multi-tasking" strategy may: 1) implicitly enforce the learning of the compositionality of PDEs (which describe core components like nonlinear advection or diffusion in common and also augment specialized terms like buoyancy or system constraints), and 2) facilitate transfer learning and knowledge sharing across multiple PDE families.

Figure 3. Forecasting by SciML foundation models [26, 43]. Given T_{in} previous steps, the model predicts the next step of the fluid dynamics (here, each frame shows the vorticity of the fluid).

3. Methods

In our work, we aim to reduce the number of video frames (nf) required by learning neural fluid fields, thereby improving data efficiency. In Figure 4, we overview our proposed framework³.

3.1. How to Utilize SciML Foundation Models for Inferring Real-World Fluid Fields?

Inspired by recent works [26, 43], we first develop our SciML foundation model as follows:

- 1. Architecture. We adopt a 3D version of the Swin Transformer [40, 77] (6.5M parameters), a popular vision transformer architecture, as our foundation model⁴. It tokenizes input temporal 2D views ($\mathbf{v}([t T_{in} \cdot \Delta t : t \Delta t], \cdot)$) with a 3D convolution layer, forwards through efficient windowed attentions, and predicts the next temporal step $\mathbf{v}(t, \cdot)$. Without loss of generality and following previous works [26, 43, 61], we choose $T_{in} = 10$. Tuning T_{in} may lead to better performance, but is not the focus of our method.
- 2. **Multiphysics Pretraining.** We utilize the PDEBench dataset [61] for pretraining. Specifically, we pretrain our foundation model on the joint of diverse simulations of the following PDEs: both compressible and incompressible Navier-Stokes, shallow water, and reaction-diffusion. We sample each equation uniformly, zero-pad channels of PDEs with fewer variables, and match different PDE simulations to the same spatial resolution via interpolation. We will experimentally verify the benefits of this multiphysics pretraining in Section 4.4.
- 3. Fine-tuning. After pretraining, we fine-tune on

²We can obtain variants with different physical parameters, boundary conditions, initial conditions, etc. Please read our supplement for details.

³Our method directly interacts with only the density field of HyFluid, meanwhile its velocity field is implicitly improved via the density field.

 $^{^{4}(1)}$ Why not use larger model sizes? We will show that, even with a small model, we can already achieve strong improvements. Using larger models may further boost forecasting and extract more meaningful features, but this is not the focus of our work. Recent SciML foundation models also consider sizes smaller than 10M parameters [26, 60, 67, 79]. (2) Architecture choices: Without loss of generality, we adhere to the original design of the Swin Transformer and avoid introducing ad hoc modifications. Although recent works on SciML foundation models adopt different architectures [26, 43], the commonly shared aspect of these works is their joint multiphysics pretraining, not their deep network architectures.

Figure 4. Overview: We improve the data efficiency (i.e., reduce the number of input fluid views "nf") of learning neural fluid fields via the SciML foundation model. Given sparse input videos, we utilize our foundation model to: 1) forecast future steps to augment denser views for training (Section 3.2); 2) extract flow representations and aggregate into embeddings of fluid density fields (Section 3.3).

ScalarFlow⁵. Inspired by recent works [36, 49], we employ a curriculum schedule to encourage forecasting further temporal steps, gradually increasing autoregressive steps from 3 to 8 by 1 every 20 training epochs.

Both pretraining and fine-tuning use the nRMSE loss. We expect **two core benefits** of our SciML foundation model that can be utilized in the real world (highlighted with yellow in Figure 4):

- 1. **Strong Forecasting.** As our foundation model is pretrained with the next-frame prediction, it can natively forecast precise future steps as augmented views of fluids to complement sparse videos (Section 3.2).
- 2. **Representation Learning.** As a data-driven approach similar to DINO [5, 48], the feature space constructed by our SciML foundation model can extract meaningful features of fluids to facilitate better generalization of 3D neural fluid fields (Section 3.3).

3.2. Co-Training via Foundation Model Forecasting

Given sparse smoke videos, one way to address data scarcity is to augment more views. We first study the forecasting performance of both our SciML foundation model and the neural fluid fields. As shown by two dotted curves in Figure 5 ("Foundation Model v0" vs. "HyFluid v0"), the forecasting quality of the foundation model is much better than the neural fluid fields.

To utilize the strong forecasting of our foundation model, we propose a collaborative training strategy for neural fluid fields. The core idea is to train the foundation model and neural fluid field with augmented views (Figure 6). We alternately concatenate the reliably predicted views (thresholded by PSNR=25) from the foundation model or neural fluid field into the current training set, and fine-tune each other. This collaborative training can also be viewed as a knowledge distillation from the foundation model to the neural fluid field in the output space. As shown by two dashed curves in Figure 5 ("Foundation Model v1", "HyFluid v1"), the collaborative training enhances the forecasting of both models, and the final version of the neural fluid field (solid curve "HyFluid v2") achieves much stronger future predictions. By achieving comparable PSNR with fewer input views, we demonstrate that our collaborative training can significantly improve the data efficiency of neural fluid fields.

Figure 5. Collaborative training between HyFluid and foundation model via forecasting. "v0, v1, v2" match the corresponding models annotated in Figure 6. HyFluid can be progressively improved (v0 \rightarrow v1 \rightarrow v2) with more augmented views. Here we show future predictions over different numbers of initial training frames per input video (x-axis). We show the temporal index of reliable predicted future frames (thresholded by PSNR=25) on the y-axis.

⁵The same set of sparse video views that will be used to train HyFluid.

Figure 6. Collaborative training between HyFluid and our SciML foundation model via forecasting with augmented views. "v0, v1, v2" match the corresponding curves in Figure 5.

3.3. Feature Aggregation from Foundation Model

In addition to leveraging the augmented views via the foundation model's forecasting, we further aggregate the learned representation from the foundation model into the neural fluid field. This can be viewed as a knowledge distillation from the foundation model to the neural fluid field in the feature space. We show our design of feature aggregation in Figure 7. This includes three steps:

- 1. For each camera ray (x_p, y_p, z_p) , we use the camera's extrinsics and intrinsics to project the ray onto the position on image coordinates (h_{imq}, w_{imq}) .
- 2. We reshape the sequence of tokens in our foundation model into 2D feature maps, and extract the feature vector corresponding to the camera ray via interpolating over the neighboring four feature coordinates. This feature vector is shared by all points sampled along the ray.
- 3. We use a two-layer MLP (with ReLU activation) to map the feature vector to the same feature dimensionality as the embedded features of the spatiotemporal coordinates of the density field, and sum them for aggregation.

During training, features are extracted from fluid views available in the videos. During testing, since videos are not accessible, the SciML foundation model extracts features based on views rendered by the density field from prior temporal steps. To extract features of frames before the temporal step at T_{in} , we use temporal-wise interpolation to supplement necessary frames as inputs to the foundation model.

Figure 7. We aggregate representations learned by our SciML foundation model into HyFluid with three steps: (1) project from spatiotemporal location to the camera plane; (2) extract and interpolate neighboring features; (3) aggregate features from the foundation model into neural fields.

4. Experiments

4.1. Settings

Datasets. We use real captures from the ScalarFlow dataset [16], released in the repository of HyFluid. For each scene, there are five videos from five cameras fixed at positions evenly distributed across a 120° arc centered at the rising smoke. In each video, we consider the first nf frames (where the smoke plumes upwards from the bottom), and adjust nf to study our data efficiency. Each video has a resolution of 1920×1080 . These videos have been post-processed to remove backgrounds. Following HyFluid, for each scene, we use four videos for training and hold one out for testing (i.e., as the ground-truth novel view).

Evaluations. We mainly compare with two previous works on neural fluid fields: PINF [10] and HyFluid [80]. Due to the lack of true 3D volume in ScalarFlow, we evaluate the reconstruction quality using view rendering. Following [80], we consider three tasks: novel view synthesis, resimulation, and future prediction. In novel view synthesis, the density field is used to render smoke views from unseen camera parameters and spatial locations; thus, its quality is evaluated based on rendering accuracy. For re-simulation and future prediction, the learned velocity field is utilized to advect the density across temporal coordinates. Thus, the quality of the learned velocity field is assessed based on its effect on the density field. In our future prediction experiments, no model is ever trained with ground-truth future frames from the videos. We refer the reader to [80] for more details about these tasks. In this paper, we report the peak signal-noise ratio (PSNR) averaged over frames. We leave the structural similarity index measure (SSIM) and the perceptual metric LPIPS [82] in our supplement.

Table 1. Comparing PSNR (higher the better) of fluid field reconstruction by different methods. "nf": number of input training frames (views). For future prediction, we report the PSNR averaged over 20 future frames (i.e., frames with indices from $nf+1 \rightarrow nf+20$).

Methods	Novel View Synthesis			Re-Simulation			Future Prediction		
	nf=20	nf =4 0	nf =6 0	nf=20	nf =4 0	nf =6 0	nf=20	nf =40	nf =60

Figure 8. Visualization of novel view synthesis (top), re-simulation (middle), future prediction (bottom) on ScalarFlow [16] when 60 frames (per video) are used for training (i.e., nf=60). "GT": ground truth.

4.2. Data-Efficiency Inference of Fluid Fields

We first report the inference of the fluid's density fields. By default, HyFluid [80] and PINF [10] used 120 frames (i.e., nf=120) from each video during training. We consider using different numbers of sparse training views that are much fewer than those in HyFluid and PINF. As shown in Table 1, our PSNR consistently outperforms HyFluid and PINF under different sparse training views (nf), across all three tasks⁶. More importantly, our method can predict much more reliable future frames with significantly reduced training views (Figure 2), achieving significant data efficiency.

4.3. More Realistic Visual Quality

Besides measuring the PSNR, it is vital to visually check the rendering quality of different methods. We show visualizations in Figure 8. For novel view synthesis and re-simulation, our method recovers plausible details and avoids artifacts seen in HyFluid and PINF. Our ability to accurately reconstruct density fields further unlocks highfidelity future predictions. Even with extremely sparse input views, our method is considerably more stable and robust than both HyFluid and PINF, which suffer from diverged density fields and weak forecasting. In contrast, our method preserves the original structure and maintains a natural upward flow.

4.4. Benefits of SciML Pretraining

As the core of our SciML foundation model is the joint pretraining on diverse PDE simulations (Section 2), it is critical to demonstrate the benefits of the domain knowledge from multiphysics. We provide our analysis below and identify two benefits.

⁶PSNRs across different nfs are not comparable, since the numbers of testing views used to calculate PSNR are also adjusted to be equal to the numbers of training views.

Table 2. Benefit of multiphysics pretraining on the PSNR (higher the better) of fluid field reconstruction. "nf": number of input training frames (views). For future prediction, we report the PSNR averaged over 20 future frames (i.e., frames with indices from nf+1 \rightarrow nf+20).

Methods	Novel View Synthesis			Re-Simulation			Future Prediction		
	nf =20	nf =40	nf =60	nf =20	nf =40	nf =6 0	nf =20	nf =40	nf =60
No Pretraining +Multiphysics Pretraining	34.7700 34.9050	32.8264 33.1838	32.2896 32.7438	34.1157 34.0704	32.9699 33.7928	32.5093 32.6558	26.5795 28.5828	25.9225 27.4636	26.6141 27.7789

Figure 9. Benefit of multiphysics pretraining on future prediction over different numbers of initial training frames per input video (x-axis). We show the temporal index of reliable predicted future frames (thresholded by PSNR=25) on y-axis.

Improved generalization of neural fluid fields. We compare the performance of neural fluid fields equipped with our foundation model, with and without multiphysics pretraining. As shown in Figure 9, the multiphysics pre-training can largely improve the data efficiency of neural fluid fields during future prediction. Moreover, over all three fluid reconstruction tasks, the utilization of multiphysics pretraining leads to much improved PSNR, as shown in Table 2. These results validate the necessity of the high-quality pretraining of our SciML foundation model.

Figure 10. Multiphysics pretraining accelerates the convergence during fine-tuning of our SciML foundation model (on 40 initial frames from each of the four training videos in ScalarFlow).

Figure 11. Ablation study of our decomposed methods on future prediction over different numbers of initial training frames per input video (x-axis). We show the temporal index of reliable predicted future frames (thresholded by PSNR=25) on y-axis.

Faster convergence during fine-tuning. Multiphysics pretraining also enables fast convergence during fine-tuning on real-world fluid data. Despite gaps between PDE simulations and real-world fluid captures, the pretrained weights can still be quickly adapted to achieve accurate predictions and forecasting, as shown in Figure 10.

4.5. Ablation Study

We further provide ablation studies on our decoupled framework to demonstrate the benefits of each individual component. As shown in Table 3 and Figure 11, both of our methods outperform the HyFluid baseline, with the combined approach achieving the best performance. For more ablation studies, please read our supplement.

5.1. 3D Reconstruction of Fluid

To reconstruct 3D fluid phenomena from visual measurements, traditional approaches primarily utilized active sensing techniques [22, 28, 30] or particle imaging velocimetry (PIV) [2, 18]. While effective, these methods necessitated sophisticated and controlled laboratory environments, limiting their applicability. To circumvent these constraints, supervised view synthesis techniques were recently proposed. In [81], regularizers based on view interpolation and projection consistency were proposed to reconstruct fluid flow

Table 3. Ablation study of our methods on the PSNR (higher the better) of fluid field reconstruction. "nf": number of input training frames (views). For future prediction, we report the PSNR averaged over 20 future frames (i.e., frames with indices from nf+1 \rightarrow nf+20).

from light tomography views. Franz et al.[19] proposed to reconstruct volumetric flow motion via a global transport formulation and differentiable rendering for end-to-end optimization. NeRFlow[14] learned 4D spatiotemporal representations of dynamic scenes by capturing the 3D occupancy, radiance, and dynamics of the scene while enforcing consistency across different modalities. PINF [10] was the first to propose reconstructing dynamic fluid phenomena by leveraging governing physics (Navier-Stokes equations) to train a continuous spatiotemporal scene representation with a neural radiance field. NeuroFluid [23] proposed a framework for a particle-driven neural renderer that integrates fluid physical properties into volume rendering and includes a particle transition model to minimize differences between rendered and observed fluid views. HyFluid [80] proposed hybrid neural fluid fields to jointly infer fluid density and velocity fields, using a set of physics-based losses to enforce physically plausible density and velocity fields. A vortex particle-based velocity approach was also introduced to model residual turbulence. However, none of these works explored the introduction of appropriate prior knowledge to achieve data efficiency and improve generalization.

5.2. Scientific Machine Learning

SciML, fueled by advancements in deep learning, models physical phenomena and differential equations [7, 8, 34, 35]. Physics-informed neural networks (PINNs)[20, 21, 52, 55, 85] aim to incorporate physics into neural networks by including the differential form of the PDE as an additional physics loss regularization term. However, this paradigm has been confined to specific PDE scenarios (e.g., fixed PDE coefficients). Moreover, recent work has highlighted several fundamental issues with PINN-based methods[17, 33]. In contrast, operator learning methods, including Fourier Neural Operators [32, 37, 38] and the Deep Operator Network [41], have made progress in approximating the solution operators of PDEs. Although these datadriven approaches show promise in learning PDE solutions, they rely on vast quantities of high-fidelity labeled data. Researchers have also explored generating synthetic PDE solutions to train SciML models [27]. More recently, SciML foundation models have been developed [25, 26, 43, 51, 58, 60, 68, 79] by scaling up training datasets to incorporate multiple PDE simulations. SciML foundation models aim

to encode common physical behaviors and enhance the generalization and scalability of SciML.

5.3. Foundation Models for 3D Reconstruction

"Vision foundation models" are large-scale models pretrained on vast amounts of vision data, designed to generalize effectively across downstream vision tasks [5, 50, 53, 54, 56, 72, 76, 84]. CLIP [50] employed contrastive learning with extensive image-text data and achieved zeroshot performance across multiple tasks. DINO [5], exemplified self-supervised learning by achieving impressive object segmentation with minimal supervision, proving useful for tasks involving visual correspondence and recognition [3, 9, 44, 70]. Moreover, recent text-conditioned generative models, particularly diffusion models [13, 29, 47, 56], demonstrated exceptional image generation capabilities, with their learned feature spaces also serving recognition purposes, such as in semantic segmentation [4, 74]. However, in contrast to the well-established 2D foundation models, their 3D counterparts were hindered by the scarcity of large-scale annotated datasets and the limitations of current architectures [24, 57, 75]. In light of these challenges, researchers increasingly explored the potential of distilling 2D foundation model features into 3D space, exemplified by generalizable neural radiance fields (NeRFs) proposed to bridge this gap [6, 42, 62, 66, 71, 73, 78, 83].

6. Conclusions

In this work, we demonstrate that integrating SciML foundation models with neural fluid fields provides a substantial improvement in data efficiency and generalization for inferring 3D fluid fields. Through a collaborative training approach, our method leverages the foundation model's forecasting capabilities to augment data, thereby reducing the reliance on extensive training views. Additionally, the aggregation of pretrained representations enables more accurate reconstructions of fluid dynamics from sparse video frames. The results indicate that this strategy not only enhances reconstruction quality but also achieves robust performance in novel view synthesis and future prediction. Our work highlights the practical applicability of SciML foundation models in real-world fluid dynamics, presenting a promising pathway for advancing data-efficient scientific modeling in complex, dynamic environments.

7. More Results

7.1. Justifications for Using PSNR=25 as the Threshold for Reliable Future Predictions

In our work, we mainly use PSNR=25 as the threshold for determining reliable future predictions. As shown in Figure 12 left, the PSNR of forecasted frames decreases when we make further predictions, suggesting different possible PSNR thresholds (i.e., any future frames of PSNR below the threshold will be considered as unreliable with bad quality). Here, we provide justifications that this threshold is appropriate on ScalarFlow.

First, as shown in three subplots to the right in Figure 12, our data efficiency and improvements persist with different PSNR thresholds, indicating that using different thresholds will not change our conclusion.

Second, when we visualize the rendering quality of future frames with different PSNRs (Figure 13), we can see that, both frames with PSNR 25 and 27 are of high visual quality, whereas the frame with PSNR=23 is much visually worse. This implies that choosing the threshold as PSNR = 25 is sufficient to characterize reliable reconstructions, but 23 already indicates bad qualities.

Figure 12. Justification for using PSNR=25 as the threshold for reliable future predictions. Left: PSNRs of predicted future frames naturally decrease over longer time steps (results obtained with initial training frames n f=40). Right three plots: number of predicted future frames (y-axis) thresholded with different PSNR (23, 25, 27) over different numbers of initial training frames per input video (x-axis).

Figure 13. Justification for using PSNR=25 as the threshold by comparing visualizations of our predicted future frames with different PSNRs. From left to right: PSNR progressively drops from 27 to 23. We use 60 initial frames (per video) for training in this example (i.e., nf=60). "GT": ground truth.

7.2. HyFluid with More Network Parameters

To demonstrate that our improvements are from the pretraind SciML foundation model instead of extra network parameters, we further compare with HyFluid of a larger model size. Our SciML foundation model has 6.5M parameters. The original density or velocity field in HyFluid [80] each has 14.9M parameters. To ensure a fairer comparison, we train an enlarged HyFluid model with both the density and velocity fields increased to 20.5M parameters. As shown in Table 4 and Figure 14, our method can largely outperform the HyFluid of a larger model size, confirming that our benefit is not rooted in more network parameters.

Table 4. PSNR (higher the better) of HyFluid with more network parameters. "nf": number of input training frames (views). For future prediction, we report the PSNR averaged over 20 future frames (i.e., frames with indices from nf+1 \rightarrow nf+20).

Figure 14. Comparing with HyFluid of even a larger model size, our method is still more data-efficient on future prediction, over different numbers of initial training frames per input video (x-axis). We show the temporal index of reliably predicted future frames, using a peak signal-to-noise ratio (PSNR) threshold of 25, on the y-axis.

7.3. Random Seeds and Standard Deviations

We further compare different methods considering standard deviations from random runs, in Table 5 and Figure 15. Our confidence is comparable with previous methods.

Table 5. We report standard deviations (3 random runs) of PSNR (higher the better) by different methods. "nf": number of input training frames (views). For future prediction, we report the PSNR averaged over 20 future frames (i.e., frames with indices from nf+1 \rightarrow nf+20).

Methods .	N	ovel View Synthe	sis		Re-Simulation		Future Prediction			
	nf=20	nf =40	nf=60	nf=20	nf =40	nf=60	nf=20	nf =40	nf =60	
PINF [10]	33.45 (± 0.22)	31.05 (± 1.14)	30.90 (± 0.44)	24.28 (± 0.00)	24.86 (± 0.06)	24.08 (± 0.07)	21.71 (± 0.00)	20.85 (± 0.01)	20.67 (± 0.03)	
HyFluid [80]	33.83 (± 0.08)	33.32 (± 0.06)	32.84 (± 0.14)	33.89 (± 0.62)	33.27 (± 0.23)	32.02 (± 0.20)	25.22 (± 1.04)	23.98 (± 0.05)	23.66 (± 0.12)	
Ours	$34.50 (\pm 0.44)$	$33.48 (\pm 0.20)$	$32.84 (\pm 0.14)$	$34.34 (\pm 0.65)$	$33.36 (\pm 0.07)$	$32.42 (\pm 0.23)$	$27.59 (\pm 0.24)$	$28.36 (\pm 0.87)$	$27.76 (\pm 0.09)$	

Figure 15. With high confidence (standard deviations as shaded areas), our method is significantly more data-efficient compared with previous works (PINF [10], HyFluid [80]) on future prediction, over different numbers of initial training frames per input video (x-axis). We show the temporal index of reliably predicted future frames, using a peak signal-to-noise ratio (PSNR) threshold of 25, on the y-axis.

7.4. Training with More Initial Views

We further consider more numbers of initial views (larger nf). We show our results in Table 6 and Figure 16. Again, our method consistently outperforms HyFluid [80] and PINF [10] on more initial frames.

Table 6. The PSNR (higher the better) of our method outperforms previous works over more initial numbers of training views (nf). For future prediction, we report the PSNR averaged over 20 future frames (i.e., frames with indices from nf+1 \rightarrow nf+20).

Figure 16. With more initial training frames per video (nf, x-axis), our method is still consistently more data-efficient compared with previous works (PINF [10], HyFluid [80]) on future prediction. We show the temporal index of reliably predicted future frames, using a peak signal-to-noise ratio (PSNR) threshold of 25, on the y-axis.

7.5. SSIM and LPIPS

Beyond PSNR, we further report the structural similarity index measure (SSIM) in Table 7 and the perceptual metric LPIPS [82] in Table 8. Our method is still shown to perform better based on these two additional metrics.

Table 7. Comparing SSIM (higher the better) of fluid field reconstruction by different methods. "nf": number of input training frames (views). For future prediction, we report the SSIM averaged over 20 future frames (i.e., frames with indices from nf+1 \rightarrow nf+20).

8. Implementation Details of SciML Foundation Model

8.1. Architecture

To develop our SciML foundation model, we follow the architecture design of 3D Swin Transformer in [40, 77]. We show our architecture in Figure 17. Specifically, after the tokenization layer (3D convolution) and patch embedding, we have 18 window attention blocks with a window size of (8,7,7).

Figure 17. Visualizations of our SciML foundation model architecture (3D Swin Transformer).

8.2. Pretraining and Fine-tuning Settings

We summarize the pretraining and fine-tuning settings of our SciML foundation model in Table 9. During both multiphysics pretraining on PDEBench [61] and fine-tuning on ScalarFlow [16], all inputs are interpolated to a spatial resolution of 224×224 .

Table 9. Summary of multiphysics pretraining and fine-tuning settings for our SciML foundation model. "LR": learning rate. "BS": batch size. "Rollout": rollout steps for autoregressive predictions. "v0" and "v1" correspond to fine-tuning foundation models in Figure 5 and 6 in our main paper.

	LR	BS	Optimizer	Scheduler	Epochs	Rollout
Pretraining	0.1	4	SGD	Cosine	500	1
Fine-tuning v0	0.1	1	SGD	Cosine	200	Increase from 3 to 8 by 1 every 20 epochs
Fine-tuning v1	0.1	1	SGD	Cosine	100	8

8.3. Feature Extraction for $t < T_{in}$ with Temporal Interpolation

For feature aggregation, during testing, since videos are not accessible, our SciML foundation model extracts features based on views rendered by the density field from prior temporal steps. To extract features of frames for temporal steps before T_{in} , we use temporal-wise interpolation to supplement necessary frames as inputs to the foundation model. Specifically, we bi-linearly interpolate the input views from t to T_{in} steps and create $T_{in} - t$ pseudo-views, as illustrated in Figure 18.

8.4. Pretraining of SciML Foundation Model

8.4.1. PDEs

We summarize PDEs included in our multiphysics pretraining as below.

Reaction-Diffusion. The Reaction-Diffusion equation models an activator-inhibitor system, which typically happens in the dynamics of chemistry, biology, and ecology. The activator u promotes its own production, and the inhibitor v acts to

Figure 18. Forecasting by SciML foundation models (N parameterized by ϕ) [26, 43]. (a) If $t = T_{in}$ (i.e., we have sufficient input frames from previous steps), the model predicts the next step of the fluid dynamics (here, each frame shows the vorticity of the fluid). (b) If $t < T_{in}$ (i.e., we do not have enough input frames requires as inputs), we use temporal-wise interpolation to create $T_{in} - t$ pseudo-views to supplement necessary frames as inputs to the foundation model.

suppress or inhibit the production or activity of the activator.

$$\partial_t u = D_u \partial_{xx} u + D_u \partial_{yy} u + R_u, \quad \partial_t v = D_v \partial_{xx} v + D_v \partial_{yy} v + R_v.$$
(1)

 D_u , D_v are diffusion coefficients ($D_u = 5 \times 10^{-3}$, $D_v = 1 \times 10^{-3}$ in PDEBench [61]). We consider the Fitzhugh-Nagumo type of Reaction-Diffusion equation, which describes how an action potential travels through a nerve membrane (k is set as 5×10^{-3}):

$$R_u(u,v) = u - u^3 - k - v, \qquad R_v(u,v) = u - v$$
 (2)

Incompressible Navier-Stokes. The Navier–Stokes equations govern the dynamics of fluid flow and serve as fundamentals for fluid simulations. It considers both the mass conservation and the momentum of fluid parcels.

$$\frac{\partial \mathbf{u}}{\partial t} = -(\mathbf{u} \cdot \nabla)\mathbf{u} + \nu \nabla^2 \mathbf{u} - \frac{1}{\rho} \nabla p, \tag{3}$$

where **u** is the velocity field, ν is the dynamic viscosity ($\nu = 0.01$ in PDEBench), ρ is the fluid density (which is constant in incompressible Navier-Stokes), p is the fluid pressure. We also have $\nabla \cdot \mathbf{u} = 0$ due to the compressibility.

Compressible Navier-Stokes. The compressible Navier-Stokes equations differ from the incompressible version by accounting for variations in density, pressure, and temperature. The equations include both the conservation of mass (the continuity equation) and conservation of energy, in addition to the momentum conservation equation in the incompressible version.

Mass Conservation:
$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0$$
 (4)

Momentum Conservation: $\frac{\partial(\rho \mathbf{u})}{\partial t} + \nabla \cdot (\rho \mathbf{u} \otimes \mathbf{u}) = -\nabla p + \nabla \cdot \boldsymbol{\tau}$ (5)

Energy Conservation:
$$\frac{\partial (\rho e_t)}{\partial t} + \nabla \cdot [(\rho e_t + p) \mathbf{u}] = \nabla \cdot (\mathbf{u} \cdot \boldsymbol{\tau}). \tag{6}$$

On top of Eq. 3: τ is the viscous stress tensor $\tau = (\zeta + \nu/3)(\nabla \cdot \mathbf{u})$; ν, ζ are the shear and bulk viscosity, respectively; $e_t = e + \frac{1}{2}|\mathbf{u}|^2$ is the total energy (internal + kinetic), $e = p/(\Gamma - 1)$ and $\Gamma = 5/3$. When we define $M = |v|/c_s$ as the Mach number and $c_s = \sqrt{\Gamma p/\rho}$ as the sound velocity, PDEBench includes two simulation settings: M = 1 and M = 0.1.

Shallow Water. The Shallow Water equation is a simplified version of the original Navier-Stokes equation, in the context where the scale of horizontal length and velocity is much greater than the vertical scale, and also the pressure distribution is assumed to be hydrostatic. Typical examples are atmospheric and oceanic modeling. It is derived by integrating the

Navier-Stokes equation over the vertical coordinate from the bottom to the free surface (h), incorporating the gravitational acceleration (g), and replacing horizontal velocities with depth-averaged ones.

$$\frac{\partial h}{\partial t} + \nabla \cdot (h\bar{\mathbf{u}}) = 0, \quad \frac{\partial \bar{\mathbf{u}}}{\partial t} + (\bar{\mathbf{u}} \cdot \nabla)\bar{\mathbf{u}} = -g\nabla h \tag{7}$$

In our Shallow Water simulation, our primary interest is in the free surface dynamics (h). This is because, in many practical applications, such as predicting the propagation of surface waves, tsunamis, or tides, the primary quantity of interest is the free surface elevation itself. The horizontal velocity may not be as crucial for these specific phenomena if the primary goal is to understand or predict wave heights, arrival times, or surface oscillations.

In PDEBench, the shallow water simulation considers a 2D radial dam break scenario. On a square domain $\Omega = [-2.5, 2.5]^2$, we initialize the water height as a circular bump in the center of the domain:

$$h(t = 0, x, y) = \begin{cases} h_0, & \text{for } \sqrt{x^2 + y^2} < r\\ h_1, & \text{for } \sqrt{x^2 + y^2} \ge r \end{cases}.$$
(8)

 $h_0 \ge h_1$ and we fix $h_1 = 1$. In PDEBench, $h_0 = 2$ and the radius r is sampled from a uniform distribution $\mathcal{U}(0.3, 0.7)$.

Summary We summarize detailed inputs and outputs in Table 10.

Table 10. Inputs and outputs for learning different PDEs. "incomp-NS": incompressible Navier-Stokes. "CNS": compressible NS. "RD": Reaction-Diffusion. "SWE": shallow water equation.

PDE Simulations	Input	Input Shape	Output
RD	Activator (u) , inhibitor (v)	$T \times C \times H \times W(T = 10, C = 2)$	Activator (u), inhibitor (v) at $T + 1$
incomp-NS	Velocity (v_x, v_y) , pressure (p)	$T \times C \times H \times W(T = 10, C = 3)$	Velocity (v_x, v_y) , pressure (p) at $T + 1$
CNS	Velocity (v_x, v_y) , pressure (p) , density (ρ)	$T \times C \times H \times W(T = 10, C = 4)$	Velocity (v_x, v_y) , pressure (p) , density (ρ) at $T + 1$
SWE	Height (<i>h</i>)	$T \times C \times H \times W(T = 10, C = 1)$	Height (h) at $T + 1$

8.4.2. Pretraining Results

We show results of multiphysics pretraining in Table 11. Although results may not be directly comparable due to different training settings, our multiphysics pretraining achieves comparable performance with previous SciML foundation models.

Table 11. "CNS": compressible Navier-Stokes. "incomp-NS": incompressible Navier-Stokes. "SWE": shallow water equation. "RD": Reaction-Diffusion.
