#### Abstract

*We propose to synthesize high-quality and synchronized audio, given video and optional text conditions, using a novel multimodal joint training framework (MMAudio). In contrast to single-modality training conditioned on (limited) video data only, MMAudio is jointly trained with largerscale, readily available text-audio data to learn to generate semantically aligned high-quality audio samples. Additionally, we improve audio-visual synchrony with a conditional synchronization module that aligns video conditions with audio latents at the frame level. Trained with a flow matching objective, MMAudio achieves new video-to-audio stateof-the-art among public models in terms of audio quality, semantic alignment, and audio-visual synchronization, while having a low inference time (1.23s to generate an 8s clip) and just 157M parameters. MMAudio also achieves surprisingly competitive performance in text-to-audio generation, showing that joint training does not hinder singlemodality performance. Code and demo are available at:* [hkchengrex.github.io/MMAudio](https://hkchengrex.github.io/MMAudio)*.*

## <span id="page-0-3"></span>1. Introduction

We are interested in *Foley*, *i.e*., for a given video we want to synthesize ambient sound (*e.g*., rain, river flow) and sound effects induced by visible events (*e.g*., a dog barks, a racket hits a tennis ball). Note, Foley does not focus on synthesizing background music or human speech, which is often added in post-processing. Importantly, Foley requires to synthesize convincing high-quality audio that is 1) semantically and 2) temporally aligned to an input video. For semantic alignment, methods need to understand scene contexts and their association with audio – the visual concept of rain should be associated with the sound of splashing raindrops. For temporal alignment, methods need to understand audio-visual synchrony as humans can perceive audio-visual misalignment as slight as 25 ms [\[47\]](#page-9-0). Inspired by the efficacy of training data

<span id="page-0-1"></span>

Figure 1. In addition to training on audio-visual-(text) datasets, we perform multimodal joint training with high-quality, abundant audio-text data which enables effective data scaling. At inference, MMAudio generates conditions-aligned audio with video and/or text guidance.

scaling demonstrated by recent works [\[7,](#page-8-0) [19,](#page-8-1) [49\]](#page-9-1), we pursue a data-driven approach to synthesize high-quality audio that respects these two types of alignment.

Current state-of-the-art video-to-audio methods either train only on audio-visual data [\[1\]](#page-8-2) from scratch [\[63\]](#page-9-2) or train new "control modules" [\[18,](#page-8-3) [62,](#page-9-3) [65,](#page-9-4) [69\]](#page-10-0) for pretrained textto-audio models on audio-visual data. The former is limited by the amount of available training data: the most commonly used dataset VGGSound [\[1\]](#page-8-2) contains only around 550 hours of videos. Audio-visual data are expensive to curate at a large scale, as in-the-wild videos from the Internet 1) mostly contain music and speech<sup>[1](#page-0-0)</sup>, which has limited utility for training a general Foley model, and 2) contain non-diegetic [\[54\]](#page-9-5) sounds such as background music or sound effects added in post-processing that are not suited for a Foley model. The latter, *i.e*., finetuning pretrained text-to-audio models (with some new adapter layers) on audio-visual data, enables to benefit from audio-generation knowledge obtained from larger-scale audio-text data (*e.g*., WavCaps [\[43\]](#page-9-6) at 7,600 hours). However, adding control modules to pretrained textto-audio models complicates the network architecture and

<sup>\*</sup>Work done during an internship at Sony AI.

<span id="page-0-0"></span><sup>&</sup>lt;sup>1</sup>In AudioSet [\[8\]](#page-8-4) (collected from YouTube), 82.48% of videos contain either human speech or music according to the provided audio labels.

<span id="page-1-0"></span>limits the design space. It is also unclear whether pretrained text-to-audio models have sufficient degrees of freedom to support all video-to-audio scenarios, compared to training from scratch.

To avoid these limitations, we propose a *multimodal joint training* paradigm (Figure [1\)](#page-0-1) that jointly considers video, audio, *and* text in a single transformer network and masks away missing modalities during training. This allows us to train from scratch on both audio-visual and audio-text datasets with a simple end-to-end framework. Jointly training on large multimodal datasets enables a unified semantic space and exposes the model to more data for learning the distribution of natural audio. Empirically, with joint training, we observe a significant relative improvement in audio quality (10% lower Fréchet Distance [\[21\]](#page-8-5) and 15% higher Inception Score [\[52\]](#page-9-7)), semantic alignment (4% higher ImageBind [\[10\]](#page-8-6) score), and temporal alignment (14% better synchronization score).

To further improve temporal alignment, we note that using attention layers only is ineffective at indicating precise timings in audio/visual signals. To tackle this issue, instead, we introduce a conditional synchronization module that uses high frame-rate visual features (extracted from a self-supervised audio-visual desynchronization detector [\[17\]](#page-8-7)) and operates in the space of scales and biases of adaptive layer normalization (adaLN) layers [\[46\]](#page-9-8), leading to accurate frame-level synchronization (50% relative improvement in synchronization score).

In summary, we first propose MMAudio, a multimodal joint training paradigm for video-to-audio. It enables accessible data scaling and cross-modal understanding, significantly improving audio quality and semantic alignment. We also propose a conditional synchronization module which enables more precise audio-visual synchrony. We train MMAudio on openly accessible datasets and scale it to two audio sampling rates (16kHz and 44.1kHz) and three model sizes (157M, 621M, 1.03B), with the smallest model already achieving new state-of-the-art performance in videoto-audio synthesis among public models. Surprisingly, our multimodal approach also achieves competitive performance in text-to-audio generation compared to dedicated text-toaudio methods, showing that joint training does not hinder single-modality performance. Our code and models will be released publicly.

## <span id="page-1-1"></span>2. Related Works

Semantic alignment. Semantic alignment between audio and video is obtained by training on paired audio-visual data with a generation objective [\[2,](#page-8-8) [5,](#page-8-9) [16,](#page-8-10) [42,](#page-9-9) [45,](#page-9-10) [56,](#page-9-11) [62,](#page-9-3) [67\]](#page-10-1) or a contrastive objective [\[40\]](#page-9-12). To further understand the semantics of audio, we additionally train on paired audiotext data. We argue that the semantic understanding learned from audio-text pairs can be transferred to video-text pairs, as joint training leads to a shared semantic space (similar to ImageBind [\[10\]](#page-8-6) and LanguageBind [\[70\]](#page-10-2)) and enables the network to learn richer semantics from more diverse data.

Temporal alignment. Besides learning temporal alignment directly from audio-visual pairs, some recent works first learn from videos a separate model to predict handcrafted proxy features such as onsets [\[50,](#page-9-13) [69\]](#page-10-0), energy [\[15,](#page-8-11) [18\]](#page-8-3), and root-mean-square (RMS) of waveforms [\[3,](#page-8-12) [32\]](#page-8-13). We deviate from these explicit handcrafted proxy features and directly learn alignment from the deep feature embeddings of a pre-trained self-supervised de-synchronization detector Synchformer [\[17\]](#page-8-7), allowing a more nuanced interpretation of the input signal. A concurrent work V-AURA [\[61\]](#page-9-14) also uses Synchformer [\[17\]](#page-8-7) for synchronization in an autoregressive framework. However, V-AURA [\[61\]](#page-9-14) does not perform multimodal training on text and has a short context window (2.56s) while we produce longer-term (8-10s) temporally consistent generation.

Multimodal conditioning. The most common way to support multimodal conditioned generation is to add "control modules" to a pretrained text-to-audio network that injects visual and temporal features into the pretrained network [\[15,](#page-8-11) [18,](#page-8-3) [32,](#page-8-13) [44,](#page-9-15) [50,](#page-9-13) [69\]](#page-10-0). However, this usually further increases the number of parameters (the base text-to-audio network plus the control modules). Besides, as the text modality is fixed during video-to-audio training, it becomes more challenging to learn a joint semantic space – the video modality needs to bind to the semantics of text instead of both modalities learning to cooperate. In contrast, we train all modalities simultaneously in our multimodal training formulation to learn joint semantics and enable omnidirectional feature sharing among modalities. Alternatively, to align different modalities without training, Seeing-and-Hearing [\[65\]](#page-9-4) uses a pretrained text-to-audio model and performs gradient ascent on an alignment score (*e.g*., ImageBind [\[10\]](#page-8-6)) at test-time. We note that test time optimization is typically slower and sometimes results in low-quality and temporally misaligned output. Indeed, our model is faster at test time and is more consistent in producing synchronized audio. A concurrent work VATT [\[38\]](#page-9-16) uses both video and text to generate audio and trains a captioning model to label unlabeled videos. However, they always require video condition inputs during training which limits the amount of training data. In contrast, our multimodal formulation allows us to train on audio-text datasets.

Multimodal generation. Related to multimodal conditioning, multimodal generation models generate samples composed of multiple modalities (*e.g*., video and audio at the same time). We note that multimodal generation is a more challenging problem and existing approaches [\[23,](#page-8-14) [51,](#page-9-17) [57,](#page-9-18) [58\]](#page-9-19) are not yet competitive with dedicated video-to-audio models. In this work, we focus on single-modal audio generation with multimodal conditions. We believe our multimodal

<span id="page-2-2"></span>formulation and architecture can serve as a foundation for future works in multimodal generation.

#### <span id="page-2-3"></span>3. MMAudio

### <span id="page-2-1"></span>3.1. Preliminaries

Conditional flow matching. We use the conditional flow matching objective [\[35,](#page-9-20) [59\]](#page-9-21) for generative modeling and refer readers to [\[59\]](#page-9-21) for details. In short, at test time, to generate a sample, we randomly draw noise  $x_0$  from the standard normal distribution and use an ODE solver to numerically integrate from time  $t = 0$  to time  $t = 1$  following a learned time-dependent conditional velocity vector field  $v_{\theta}(t, \mathbf{C}, x) : [0, 1] \times \mathbb{R}^C \times \mathbb{R}^d \to \mathbb{R}^d$ , where t is the timestep, C is the condition  $(e.g.,$  video and text), and x is a point in the vector field. We represent the velocity vector field via a deep net parameterized by  $\theta$ .

At training time, we find  $\theta$  by considering the conditional flow matching objective

<span id="page-2-0"></span>
$$
\mathbb{E}_{t,q(x_0),q(x_1,\mathbf{C})}||v_{\theta}(t,\mathbf{C},x_t)-u(x_t|x_0,x_1)||^2, \quad (1)
$$

where  $t \in [0, 1]$ ,  $q(x_0)$  is the standard normal distribution, and  $q(x_1, C)$  samples from the training data. Further,

$$
x_t = tx_1 + (1 - t)x_0 \tag{2}
$$

defines a linear interpolation path between noise and data, and

$$
u(x_t|x_0, x_1) = x_1 - x_0 \tag{3}
$$

denotes its corresponding flow velocity at  $x_t$ .

Audio encoding. For computational efficiency, we model the generative process in a latent space, following the common practice [\[36,](#page-9-22) [63\]](#page-9-2). For this, we first transform audio waveforms with the short-time Fourier transform (STFT) and extract the magnitude component as mel spectrograms [\[53\]](#page-9-23). The spectrograms are then encoded by a pretrained varia-tional autoencoder (VAE) [\[25\]](#page-8-15) into latents  $x_1$ . During testing, the generated latents are decoded by the VAE into spectrograms which are then vocoded by a pretrained vocoder [\[33\]](#page-8-16) into audio waveforms.

#### <span id="page-2-4"></span>3.2. Overview

Following conditional flow matching, at test time, we numerically integrate noise  $x_0$  from  $t = 0$  to  $t = 1$  following a flow  $v_{\theta}$ , which was learned at training time by optimizing Eq. [\(1\)](#page-2-0). Numerical integration at test time arrives at a latent  $x_1$  that is decoded to audio preferably of high-quality and preferably semantically and temporally aligned to the video and text conditions.

To estimate a flow  $v_{\theta}$  for the current latent x, MMAudio operates on the video/text conditions and the flow timestep t. Figure [2](#page-3-0) illustrates our network architecture. To combine inputs from different modalities, MMAudio consists of a

series of  $(N_1)$  multimodal transformer blocks [\[7\]](#page-8-0) with visual/text/audio branches, followed by a series of  $(N_2)$  audioonly transformer blocks [\[30\]](#page-8-17). Additionally, for audio-visual synchrony, we devise a conditional synchronization module that extracts and integrates into the generation process a high frame rate (24 frames per second (fps)) visual feature for temporal alignment. Next, we describe both components in detail.

#### <span id="page-2-5"></span>3.3. Multimodal Transformer

Core to our approach is the desire to model the interactions between video, audio, and text modalities. For this purpose, we largely adopt the MM-DiT block design from SD3 [\[7\]](#page-8-0) and introduce two new components for temporal alignment: aligned RoPE positional embeddings for aligning sequences of different frame rates and 1D convolutional MLPs (ConvMLPs) for capturing local temporal structure. Figure [2](#page-3-0) (right) illustrates our block design. Note, we also include a sequence of audio-only single-modality blocks following FLUX [\[30\]](#page-8-17), implemented by simply removing the streams of the two other modalities (joint attention becomes selfattention). Compared to considering all modalities at every layer, this design allows us to build a deeper network with the same parameter count and compute without sacrificing multimodality. This multimodal architecture allows the model to selectively attend to and focus on different modalities depending on the inputs, thus enabling effective joint training on both audio-visual and audio-text data. Next, we describe the feature representation in our network and then the core components of our block design.

Representations. We represent all the features as onedimensional tokens. Note, we deliberately do not use any absolute position encoding which allows us to generalize to different durations at test time. Thus, we specify the sequences in terms of frame rates to determine the number of tokens for a given duration. The visual features  $F_v$  (one token per frame, at 8 fps) and text features  $F_t$  (77 tokens) are extracted from CLIP [\[49\]](#page-9-1) as 1024d features. The audio latents  $x$  are in the VAE latent space (Section [3.1\)](#page-2-1), at 31.25 fps as 20d latents by default. The synchronization features  $F_{syn}$  are extracted from Synchformer [\[17\]](#page-8-7) at 24 fps as 768d features, which we will detail in Section [3.4.](#page-3-1) Note, except for the text tokens, all other tokens follow the same temporal ordering, albeit at different frame rates. After the initial ConvMLP/MLP layers, all features will be projected to the hidden dimension h.

Joint attention. These tokens from different modalities communicate via joint attention (Figure [2,](#page-3-0) right). Following [\[7\]](#page-8-0), we concatenate the query, key, and value representations from the three different modalities and apply a joint attention operation [\[60\]](#page-9-24). The output is split into three modalities, following the input partition. We refer readers to [\[7\]](#page-8-0) for details. We note that joint attention alone does not capture

<span id="page-3-3"></span><span id="page-3-0"></span>

Figure 2. Overview of the MMAudio flow-prediction network. Video conditions, text conditions, and audio latents jointly interact in the multimodal transformer network. A synchronization model (Section [3.4\)](#page-3-1) injects frame-aligned synchronization features for precise audio-visual synchrony.

temporal alignment which we will address next.

Aligned RoPE position embedding. For audio-visual synchrony, precise temporal alignment is crucial. As typical in transformers [\[60\]](#page-9-24), we adopt positional embeddings to inform the attention layers of time. Specifically, we apply the RoPE [\[55\]](#page-9-25) embeddings on the queries and keys in the visual and audio streams before joint attention (Figure [2\)](#page-3-0). Note that we do not apply it to the text stream since it does not follow the temporal order of video or audio. Further, since the frame rates do not align (8 fps for the visual stream, 31.25 fps for the audio stream), we scale the frequencies of the positional embeddings in the visual stream proportionally, *i.e*., by 31.25/8. We visualize the default (non-aligned) RoPE and our proposed aligned RoPE in Figure [A5.](#page-17-0) We note that these aligned embeddings are beneficial yet insufficient for good synchrony. Therefore, we introduce an additional synchronization module, which we discuss in Section [3.4.](#page-3-1)

ConvMLP. To better capture local temporal structure, we use ConvMLPs rather than MLPs in the visual and audio streams. Concretely, our ConvMLP uses 1D convolutions (kernel size  $= 3$  and padding  $= 1$ ) rather than linear layers. Again, this change is not made to the text stream since it does not follow the temporal order of video or audio.

Global conditioning. Global conditioning injects global features into the network through scales and biases in adaptive layer normalization layers (adaLN) [\[46\]](#page-9-8). First, we compute a global conditioning vector  $c_g \in \mathbb{R}^{1 \times h}$  shared across all transformer blocks from the Fourier encoding [\[60\]](#page-9-24) of the flow timestep, the average-pooled visual features, and the average-pooled text features (Figure [2\)](#page-3-0). Then, each adaLN layer modulates its input  $y \in \mathbb{R}^{L \times h}$  (*L* is the sequence length) with the global condition  $c<sub>q</sub>$  as follows:

<span id="page-3-2"></span>
$$
adalN_g(y, c_g) = LayerNorm(y) \cdot 1 \mathbf{W}_{\gamma}(c_g) + 1 \mathbf{W}_{\beta}(c_g).
$$
\n(4)

<span id="page-3-1"></span>Here,  $\mathbf{W}_{\gamma}$ ,  $\mathbf{W}_{\beta}$  are MLPs, and 1 is a  $L \times 1$  all-ones matrix, which "broadcasts" the scales and biases to match the sequence length  $L$  – such that the same condition is applied to all tokens in the sequence (hence global). Next, we describe how we design position-dependent conditions for precise audio-visual synchronization.

#### <span id="page-4-0"></span>3.4. Conditional Synchronization Module

We develop a token-level conditioning to further improve audio-visual synchrony. While the visual and audio streams already communicate via cross-modality attention layers, these layers aggregate features via a soft distribution, which we found to hamper precision. To address this issue, we first extract high frame rate (24 fps) features ( $F_{syn}$ ) from the input video using the visual encoder of Synchformer [\[17\]](#page-8-7). We use Synchformer because it is trained in a self-supervised manner to detect temporal misalignment between video and audio data, which we hypothesize will yield visual features relevant to audio events and hence benefit synchronization.We find the frame-aligned conditioning  $c_f \in \mathbb{R}^{L \times h}$  via

$$
c_f = \text{Upsample}(\text{ConvMLP}(F_{syn})) + \mathbf{1}c_g. \tag{5}
$$

The upsample operation uses nearest neighbor interpolation and matches the frame rate of the synchronization features  $F_{syn}$  with that of the audio latent x. This frame-aligned conditioning  $c_f$  is injected via the adaLN layers in the audio stream for precise feature modulation. Similar to Eq. [\(4\)](#page-3-2), we apply  $c_f$  via

adaLN<sub>f</sub> (x, c<sub>f</sub>) = LayerNorm(x) ·  $\mathbf{A}_{\gamma}(c_f) + \mathbf{A}_{\beta}(c_f)$ , (6)

where  $\mathbf{A}_{\gamma}, \mathbf{A}_{\beta} \in \mathbb{R}^{h \times h}$  are MLPs. Different from Eq. [\(4\)](#page-3-2), the scales and biases are applied per token without broadcasting, providing fine-grained control.

## <span id="page-4-1"></span>3.5. Training and Inference

#### <span id="page-4-2"></span>3.5.1. Multimodal Datasets

VGGSound. We train on VGGSound [\[1\]](#page-8-2) as the only audiovisual dataset. It offers around 500 hours of footage. Additionally, VGGSound contains a class label (310 classes in total) for each video and we use the class names as input following ReWaS [\[18\]](#page-8-3) and VATT [\[38\]](#page-9-16). We set aside 2K videos from the training set for validation, resulting in a training set of around 180K 10s videos. We truncate the videos to 8s from the end for training.

Audio-text datasets. We use AudioCaps [\[22\]](#page-8-18) (around 128 hours, manually captioned) and WavCaps [\[43\]](#page-9-6) (around 7,600 hours, automatically captioned from metadata) as audio-text datasets for training. Since they do not contain the visual modality, we set all the visual features and synchronization features corresponding to these samples as learnable empty tokens  $\varnothing_v$  and  $\varnothing_{syn}$  respectively. For short audios (<16s), we truncate them to 8s from the end for training as in VGGSound. For longer audios, we take at most five non-overlapping crops of 8s from each audio. This results in a total of 951K audio clip-text pairs.

<span id="page-4-3"></span>**Overlaps.** We notice a minor  $\left(\frac{1}{6}$  of the test sets) train/test data contamination among these datasets. For a fair comparison, we have removed the test sets of VGGSound and AudioCaps from all training data. We provide more details in Appendix [C.](#page-13-0)

#### 3.5.2. Implementation Details

Model variants. Our default model generates 16kHz audio encoded as 20-dimensional, 31.25fps latents (following Frieren [\[63\]](#page-9-2)), with  $N_1 = 4, N_2 = 8, h = 448$ . We refer to this default model as 'S-16kHz'. We additionally train larger models and models with higher audio sampling rates: 'S-44.1kHz', 'M-44.1kHz', and 'L-44.1kHz', detailed in Appendix [E.1.](#page-15-0) The parameter counts and running time of these models are summarized in Table [1.](#page-5-0) We describe additional implementation details in Appendices [D](#page-14-0) to [F.](#page-16-0)

Classifier-free guidance. To enable classifier-free guidance [\[12\]](#page-8-19) in inference, we randomly mask away all visual tokens ( $F_v$  and  $F_{syn}$ ) or all the text with a 10% probability during training. The masked visual tokens are replaced with a learnable embedding ( $\varnothing_v$  and  $\varnothing_{sun}$ ), while any masked text is replaced with the empty string  $\varnothing_t$ .

Inference. By default, we use Euler's method for numerical integration with 25 steps, with a classifier-free guidance strength of 4.5. Both video and text conditions are optional during test-time – we replace the missing modalities with empty tokens  $\varnothing_v$ ,  $\varnothing_{syn}$ , or  $\varnothing_t$ . Recall, we deliberately do not use any absolute position encoding and thus can generalize to different durations at test time (*e.g*., 8s in VGGSound and 10s in AudioCaps in Section [4.2\)](#page-5-1).

## <span id="page-4-4"></span>4. Experiments

## <span id="page-4-5"></span>4.1. Metrics

We assess the generation quality in four different dimensions: distribution matching, audio quality, semantic alignment, and temporal alignment.

Distribution matching assesses the similarity in feature distribution between ground-truth audio and generated audio, under some embedding models. Following common practice [\[16,](#page-8-10) [63\]](#page-9-2), we compute Fréchet Distance (FD) and Kullback–Leibler (KL) distance. For FD, we adopt PaSST [\[28\]](#page-8-20)  $(FD_{PASST})$ , PANNs [\[27\]](#page-8-21) ( $FD_{PANNs}$ ), and VGGish [\[8\]](#page-8-4) ( $FD_{VGG}$ ) as embedding models. Note, PaSST operates at 32kHz, while both PANNs and VGGish operate at 16kHz. Moreover, both PaSST and PANNs produce global features, while VGGish processes non-overlapping 0.96s clips. For the KL distance, we adopt PANNs  $(KL_{PANNs})$  and PaSST  $(KL_{PASST})$  as classifiers. We follow the implementation of Liu et al. [\[36\]](#page-9-22).

Audio quality assesses the generation quality without comparing it to the ground truth using the inception score [\[52\]](#page-9-7). We adopt PANNs as the classifier following Wang et al. [\[63\]](#page-9-2). Semantic alignment assesses the semantic similarity between the input video and the generated audio. We use ImageBind [\[10\]](#page-8-6) following Viertola et al. [\[61\]](#page-9-14) to extract visual features from the input video and audio features from the generated audio and compute the average cosine similarity as "IB-score".

<span id="page-5-2"></span><span id="page-5-0"></span>

Table 1. Video-to-audio results on the VGGSound test set. Following the common practice [\[63\]](#page-9-2), the parameter counts exclude pretrained feature extractors (*e.g*., CLIP), latent space encoders/decoders, and vocoders. Time is the total running time using the official code to generate one sample with a batch size of one after warm-up and excludes any disk I/O operations on an H100 GPU. ∗: reproduced using official evaluation code.  $\dagger$ : evaluated using generation samples obtained directly from the authors.  $\diamond$ : does not use text input during testing. Note, Seeing&Hearing [\[65\]](#page-9-4) directly optimizes ImageBind score during test time, therefore attains the highest IB-score.

Temporal alignment assesses audio-visual synchrony with a synchronization score (DeSync). DeSync is predicted by Synchformer [\[17\]](#page-8-7) as the misalignment (in seconds) between the audio and video. Note that Viertola et al. [\[61\]](#page-9-14) also use the synchronization score but evaluate on audio (2.56s) that is shorter than the context window (4.8s) of Synchformer. Instead, we evaluate on longer (8s) audios by taking two crops (first 4.8s and last 4.8s) and averaging the results. Thus, the scores from Viertola et al. [\[61\]](#page-9-14) are not directly comparable with ours.

#### <span id="page-5-1"></span>4.2. Main Results

Video-to-audio. Table [1](#page-5-0) compares our main results on the VGGSound [\[1\]](#page-8-2) test set (15K videos) with existing state-ofthe-art models. We evaluate all generations at 8s following Wang et al. [\[63\]](#page-9-2) by truncating longer audio to 8 seconds. For V-AURA [\[61\]](#page-9-14), we use the official autoregression code to generate 8s audio. ReWaS [\[18\]](#page-8-3) only generates 5s audio thus we evaluate it as-is, by truncating the ground truth also to 5s – we indicate this discrepancy via the gray font in the table. Our smallest model (157M) demonstrates better distribution matching, audio quality, semantic alignment, and temporal alignment than prior methods, while being fast. A notable exception is the IB-score comparison with Seeingand-Hearing [\[65\]](#page-9-4). We note that Seeing-and-Hearing [\[65\]](#page-9-4) directly optimizes the IB score during test time, which we do not perform. Further, our larger models continue to improve in  $FD_{PASST}$  and IB-score, though we observe diminishing returns potentially limited by data quality and the amount of audio-visual data. Note, while our method uses more data for *multimodal joint training*, we *do not use more data overall* than some of the existing methods: FoleyCrafter [\[69\]](#page-10-0), V2A-Mapper [\[62\]](#page-9-3), ReWaS [\[18\]](#page-8-3), and Seeing-and-Hearing [\[65\]](#page-9-4) all finetune/incorporate a text-to-audio model that has been trained on audio-text data similar to the one we use. For a

fair evaluation, we use the precomputed samples provided by [\[38,](#page-9-16) [62,](#page-9-3) [63\]](#page-9-2), and reproduce the results using the official inference code for [\[18,](#page-8-3) [61,](#page-9-14) [65,](#page-9-4) [69\]](#page-10-0). Figure [3](#page-6-0) visualizes our results and compares them with prior works. We present the results of a user study and comparison with Movie Gen Audio [\[48\]](#page-9-26) in Appendices [A](#page-12-0) and [B.](#page-12-1)

Text-to-audio. Our multimodal framework can be applied to *text-to-audio* synthesis without fine-tuning. Table [2](#page-6-1) compares our method with state-of-the-art text-to-audio models using the AudioCaps [\[22\]](#page-8-18) test set. For a fair comparison, we follow the evaluation protocol of GenAU [\[11\]](#page-8-22) to evaluate 10s samples in the AudioCaps [\[22\]](#page-8-18) test set without using CLAP re-ranking (used by AudioLDM [\[36\]](#page-9-22)). We transcribe the baselines directly from Haji-Ali et al. [\[11\]](#page-8-22), who have reproduced those results using officially released checkpoints under the same evaluation protocol. We assess  $FD<sub>PANNs</sub>$ ,  $FD<sub>VGG</sub>$ , IS, and CLAP [\[64\]](#page-9-27). CLAP measures the semantic alignment between the generated audio and the input caption. While our main focus is on video-to-audio synthesis, MMAudio attains state-of-the-art semantic alignment (CLAP) and audio quality (IS), due to a rich semantic feature space learned from multimodal joint training. We note that we attain a worse FD<sub>VGG</sub> score compared to recent works. We hypothesize that this is because VGGish processes local features (clips of 0.96s) while our strength lies in generating globally and semantically consistent audio.

## <span id="page-5-3"></span>4.3. Ablations

We base all ablations on the small-16kHz model and evaluate distribution matching ( $FD_{PaSST}$ ), audio quality (IS), semantic alignment (IB-score), and temporal alignment (DeSync) on the VGGSound [\[1\]](#page-8-2) test set. We highlight our default setting using a blue background.

<span id="page-6-2"></span><span id="page-6-0"></span>

Figure 3. We visualize the spectrograms of generated audio (by prior works and our method) and the ground-truth. Note our method generates the audio effects most closely aligned to the ground-truth, while other methods often generate sounds not explained by the visual input and not present in the ground-truth.

<span id="page-6-1"></span>

Method		Params $FD_{PANNs}$ $FD_{VGG}$		IS↑	CLAP <sub>1</sub>
AudioLDM $2-L$ [37]	712M	32.50	5.11	8.54	0.212
TANGO [9]	866M	26.13	1.87	8.23	0.185
<b>TANGO 2 [41]</b>	866M	19.77	2.74	8.45	0.264

MMAudio-L-44.1kHz	1.03B	15.04	4.03	12.08	0.348

Table 2. Text-to-audio results on the AudioCaps test set. For a fair comparison, we follow the evaluation protocol of [\[11\]](#page-8-22) and transcribe all baselines directly from [\[11\]](#page-8-22), who have reproduced those results using officially released checkpoints under the same evaluation protocol.

Cross-modal alignment. To elucidate the benefits of joint multimodal training, we mask away some modalities during training and observe the effects on the results. The results are summarized in Table [3.](#page-6-1) We denote the setting as (modalities used for audio-visual-text data + modalities used for audiotext data), where A: Audio, V: Video, T: Text. Our default setting (AVT+AT) means that we train on audio-visual-text data (VGGSound class labels as text input) and audio-text data. We make three observations:

1. Masking away the text modality from either the former

Training modalities $FD_{PaSST}\downarrow$ IS <sup><math>\uparrow</math></sup> IB-score $\uparrow$ DeSync $\downarrow$				
$AYT+AT$	70.19	14.44	29.13	0.483
$AV+AT$	72.77	12.88	28.10	0.502
$AYT+A$	71.01	14.30	28.72	0.496
<b>AVT</b>	77 38	12.53	27.98	0.562
AV	77.27	12.69	28.10	0.502

Table 3. Results when we vary the training modalities. A: Audio, V: Video, T: Text. In the second and third rows, we mask away the text token in either audio-visual data or audio-text data. In the last two rows, we do not use any audio-text data.

(AV+AT) or the latter (AVT+A) leads to worse results. This suggests that having a joint "text feature space" is beneficial for multimodality training.

- 2. Adding uncaptioned audio data improves results (AVT *vs*. AVT+A). This suggests that our network even benefits from training on unconditional generation data by learning the distribution of natural sounds.
- 3. When no audio-text data is used, using the simple class labels in VGGSound does not affect results significantly (AVT *vs*. AV). This suggests that training on large multi-

<span id="page-7-3"></span><span id="page-7-0"></span>

% audio-text data $FD_{\text{PasST}}$		$IS+$	IB-score $\uparrow$	DeSvnc.
$100\%$	70.19	14.44	29.13	0.483
50%	71.03	14.62	29.11	0.489
25%	71.67	14.41	28.75	0.505
10%	79.21	13.55	27.47	0.514
None	77.38	12.53	27.98	0.562

Table 4. Results when we vary the amount of multimodal training data. For the first four rows, we sample audio-visual and audio-text data at a 1:1 ratio during training. For the last row, only audiovisual data is used.

<span id="page-7-1"></span>

Variant	$FD_{\text{Passtr}}$	$IS^+$	IB-score↑ DeSync↓	
With sync module	70.19	14.44	29.13	0.483
Sum sync with visual	73.59	16.70	28.65	0.490
No sync features	69.33	15.05	29.31	0.973
Aligned RoPE	70.19	14.44	29.13	0.483
No RoPE	70.24	14.54	29.23	0.509
Non-aligned RoPE	70.25	14.54	29.25	0.496

Table 5. Results when we use synchronization features or RoPE embeddings differently.

modal datasets, rather than adding a transformer branch in the network or using the class labels, is key.

Multimodal data. Training on a large collection of multimodal data is crucial. Table [4](#page-7-0) shows our model's performance when we vary the amount of audio-text training data. Note, we always sample audio-visual data and audio-text data at a 1:1 ratio except when we use no audio-text data (then we only train on audio-visual data). When we do not use audio-text data, we observe overfitting and stop training early. When more multimodal data is used, distribution matching (FD<sub>PaSST</sub>), semantic alignment (IB-score), and temporal alignment (DeSync) improve with diminishing returns.

Conditional synchronization module. We compare several different methods for incorporating synchronization features: 1) our default of using the conditional synchronization module (Sec. [3.4\)](#page-3-1); 2) incorporating the synchronization features into the visual branch of the multimodal transformer. Concretely, we upsample (with nearest neighbor) the CLIP features to 24fps, and then sum the CLIP features and Sync features after linear projections as the final visual feature. We illustrate this architecture in Appendix  $E.5$ ; finally, 3) not using synchronization features. Table  $5$  (top) shows that our synchronization module attains the best temporal alignment. We note the "sum sync with visual" method achieves higher audio quality  $(IS)$  – we hypothesize that since upsampling CLIP features increased the number of tokens in the visual stream by three times, the model benefits from using the longer sequence for more fine-grained computations.

RoPE embeddings. We compare our aligned RoPE formulation with 1) not using RoPE embeddings and 2) non-

<span id="page-7-2"></span>

Variant	$FD_{\text{PAST}}$	IS↑	IB-score $\uparrow$	$Desvec \downarrow$
ConvMLP	70.19	14.44	29.13	0.483
MLP	73.84	13.01	28.99	0.533
$N_1 = 4, N_2 = 8$	70.19	14.44	29.13	0.483
$N_1 = 6, N_2 = 3$	72.53	13.75	29.06	0.509
$N_1 = 2, N_2 = 13$	70.33	15.18	29.39	0.487

Table 6. Results when we vary the MLP architecture or the ratio between multi-/single-modality transformer blocks.

aligned RoPE embeddings, *i.e*., no frequency scaling in the visual branch. Table [5](#page-7-1) (bottom) shows that using aligned RoPE embeddings [\[55\]](#page-9-25) improves audio-visual synchrony.

ConvMLP. Table [6](#page-7-2) (top) summarizes the performance difference of using MLP *vs*. ConvMLP. For the MLP model, we increase h from  $448 \rightarrow 512$ ,  $N_1$  from  $4 \rightarrow 6$ , and  $N_2$ from  $8 \rightarrow 10$  to roughly match the number of parameters in the ConvMLP model. The ConvMLP model is better at capturing local temporal structure and thus has a better performance, especially in synchronization.

**Ratio between**  $N_1$  and  $N_2$ . Table [6](#page-7-2) (bottom) compares different assignments of the number of multimodal  $(N_1)$ and single-modal  $(N_2)$  transformer blocks with roughly the same parameter budget. We note our default assignment  $(N_1 = 4, N_2 = 8)$  performs similarly as using more singlemodal blocks  $(N_1 = 2, N_2 = 13)$  and better than using fewer single-modal blocks ( $N_1 = 6, N_2 = 3$ ). We think this is because using single-modal blocks allows us to build a deeper network with the same parameter count.

## <span id="page-7-4"></span>4.4. Limitations

Our model generates unintelligible mumbles when prompted to generate human speech (from seeing a human talk or from text input). We believe human speech is inherently more complex (*e.g*., with languages, tones, and grammars) and our model aimed at general audio effects (Foley) fails to adequately accommodate.

#### <span id="page-7-5"></span>5. Conclusion

We propose MMAudio, the first multimodal training pipeline that jointly considers audio, video, and text modalities, resulting in effective data scaling and cross-modal semantic alignment. Combined with a conditional synchronization module, our method achieves a new state-of-the-art performance among public models and comparable performance with Movie Gen Audio. We believe a multimodal formulation is key for the synthesis of data in any modality and MMAudio lays the foundation in the audio-video-text space.

# Table of Contents

#### <span id="page-12-2"></span><span id="page-12-0"></span>A. User Study

In addition to the objective metrics presented in Table [1,](#page-5-0) we have also performed a user study for subjective evaluation on the VGGSound [\[1\]](#page-8-2) test set. For comparisons, we have selected our best model (MMAudio-L-44.1kHz) and four best baselines:

- 1. Seeing and Hearing [\[65\]](#page-9-4), as it has the highest ImageBind (*i.e*., best semantic alignment with videos) score, besides ours.
- 2. V-AURA [\[61\]](#page-9-14), as it has the lowest DeSync (*i.e*., best temporal alignment) with videos, besides ours.
- 3. VATT [\[38\]](#page-9-16), as it has the lowest Kullback–Leibler divergence (*i.e*., KLPANNs and KLPaSST), besides ours.
- 4. V2A-Mapper [\[62\]](#page-9-3), as it has the lowest Fréchet distances (*i.e.*, FD<sub>PaSST</sub>, FD<sub>PANNs</sub>, and FD<sub>VGG</sub>), besides ours.

We sample eight videos from the VGGSound [\[1\]](#page-8-2) test set, after excluding videos that are of low-resolution (below 360p) or that contain human speech. In total, each participant evaluates 40 videos (8 videos  $\times$  5 methods). We group the samples for the same video, and randomly shuffle the ordering in each group to avoid bias. We ask each participant to rate the generation in three aspects using the Likert scale [\[34\]](#page-9-30) (1-5; strongly disagree, disagree, neutral, agree, strongly agree) providing the following instructions:

(a) The audio is of high quality.

*Explanation*: An audio is low-quality if it is noisy, unclear, or muffled. In this aspect, ignore visual information and focus on the audio.

- (b) The audio is semantically aligned with the video. *Explanation*: An audio is semantically misaligned with the video if the audio effects are unlikely to occur in the scenario depicted by the video, *e.g*., the sound of an explosion in a library.
- (c) The audio is temporally aligned with the video.

*Explanation*: An audio is temporally misaligned with the video if the audio sounds delayed/advanced compared to the video, or when audio events happen at the wrong time (*e.g*., in the video, the drummer hits the drum twice and stops; but in the audio, the sound of the drum keeps occurring).

<span id="page-12-3"></span>In total, we have collected 920 responses in each of these aspects from 23 participants. Table [A1](#page-12-3) summarizes the results from the user study. MMAudio receives significantly higher ratings in all three aspects from the users, which aligns with the objective metrics presented in Table [1](#page-5-0) of the main paper.

Table A1. Average ratings for each method from the user study. We show mean±std in each aspect.

#### <span id="page-12-1"></span>B. Comparisons with Movie Gen Audio

Recently, Movie Gen Audio [\[48\]](#page-9-26) has been introduced for generating sound effects and music for input videos. While Movie Gen Audio's technical details are sparse, it represents the industry's current state-of-the-art video-to-audio synthesis algorithm. Its 13-billion parameters model has been trained on non-publicly accessible data that is  $> 100 \times$  larger than ours. Nevertheless, we compare MMAudio to Movie Gen Audio [\[48\]](#page-9-26) to benchmark the differences between public and private models.

At the time of writing, the only accessible outputs from Movie Gen Audio are  $527<sup>2</sup>$  $527<sup>2</sup>$  $527<sup>2</sup>$  generations in the "Movie Gen Audio Bench" dataset. All the videos from Movie Gen Audio Bench are generated by MovieGen [\[48\]](#page-9-26), which we note is different from the distribution of real-world videos (*e.g*., over-smoothed textures, slow motions). Since these are synthetic videos, there is no corresponding ground-truth audio. We run our best model MMAudio-L-44.1kHz on these videos and the corresponding audio prompts (which Movie Gen Audio also uses) and compare our generations with Movie Gen Audio.

Since there is no ground truth audio, among the standard metrics that we have used in the main paper, we can only evaluate Inception Score (IS, audio quality), IB-score (ImageBind [\[10\]](#page-8-6) similarly, semantic alignment between video and audio), DeSync (misalignment predicted by SynchFormer [\[17\]](#page-8-7) between video and audio), and CLAP [\[6,](#page-8-26) [64\]](#page-9-27) (alignment between text and audio). Additionally, we have conducted a user study following the protocol of Appendix [A,](#page-12-0) and have excluded audios with

<span id="page-12-4"></span><sup>&</sup>lt;sup>2</sup>While the MovieGen technical report mentioned 538 samples, only 527 were released at the time of writing.

<span id="page-13-1"></span>very low volume (cannot be heard clearly at a normal volume) generated by Movie Gen Audio to prevent bias. We sampled a total of 5 videos and received 230 responses in each of the aspects from 23 participants.

Table [A2](#page-13-2) summarizes our results. In subjective metrics, MMAudio is comparable to Movie Gen Audio – slightly worse in semantic alignment and slightly better in temporal alignment. In objective metrics, we observe the same trend – MMAudio and Movie Gen Audio obtain the same audio quality (IS) score, Movie Gen Audio has a better semantic alignment (IB-score and CLAP), and MMAudio has a better video-audio synchrony (DeSync).

<span id="page-13-2"></span>

			Subjective metrics					Objective metrics	
Method	Param	Training data			Audio qual. $\uparrow$ Semantic align. $\uparrow$ Temporal align. $\uparrow$ IS $\uparrow$		IB-score† CLAP† DeSync↓		
Movie Gen Audio [48]	13B	$\mathcal{O}(1,000,000)$ h 3.93±0.92		$4.36 \pm 0.74$	$3.52 + 1.21$	8.40	36.26	0.4409	1.006
$MMAudio-L-44.1kHz$ 1.03B		$\sim 8.200h$	$3.93 + 0.89$	$4.26 + 0.71$	$3.62 + 1.03$	8.40	27.01	0.4324	0.771

Table A2. Comparisons between Movie Gen Audio and MMAudio in both subjective metrics (from user study) and objective metrics. For the subjective metrics, we show mean±std.

Further, in terms of IB-score, we find that MMAudio struggles more in some videos, while Movie Gen Audio delivers more consistent results. We plot the sorted IB-score comparing MMAudio and Movie Gen Audio in Figure [A1](#page-13-3) (left). Movie Gen Audio consistently performs better in the low-performance regime, but the gap narrows in the high-performance region. We believe this is due to our limited training data, which is unable to adequately cover the data in Movie Gen Audio Bench and thus falls short in unfamiliar video types. Note, our only video-audio dataset for training is VGGSound [\[1\]](#page-8-2) which contains videos for 310 classes. We hypothesize that collecting open-world data beyond these classes can effectively reduce this performance gap. The same phenomenon occurs at a much smaller scale for the CLAP score, which might be because we use more audio-text data. Figure [A2](#page-14-3) shows examples where we obtain a substantially higher/lower IB-score on videos with concepts well/not well covered by the training data.

<span id="page-13-3"></span>

Figure A1. Sorted MMAudio and Movie Gen Audio performance scores in Movie Gen Audio Bench.

### <span id="page-13-0"></span>C. Details on Data Overlaps

We note that there are training and testing data overlaps among commonly used datasets for video-to-audio generation. For example, AudioSet [\[8\]](#page-8-4) is commonly used to train VAE encoders/decoders but it contains test set data from VGGSound [\[1\]](#page-8-2) and AudioCaps [\[22\]](#page-8-18). Additionally, AudioCaps is often used to train text-to-audio models [\[66\]](#page-10-3), which is then used as the backbone for video-to-audio models which evaluate on VGGSound [\[1\]](#page-8-2) – however, part of the VGGSound test set overlaps with the AudioCaps training set. Moreover, AVSync15 [\[68\]](#page-10-4), which is sometimes used jointly with VGGSound for training/evaluating video-to-audio algorithms [\[69\]](#page-10-0), contains severe cross-contamination with VGGSound. This results in biased evaluations in both VGGSound and AVSync15. To our best knowledge, this data contamination is not yet addressed in the video-to-audio community. We thank Labb et al. [\[29\]](#page-8-27) for raising this issue in the audio captioning field, which has helped us identify this problem.

Table [A3](#page-14-4) summarizes the observed overlaps. The overlaps with WavCaps [\[43\]](#page-9-6) and Freesound [\[31\]](#page-8-28) have been included as part of their release, which we do not repeat in our table.

<span id="page-14-3"></span><span id="page-14-1"></span>

Audio prompt: rhythmic splashing and lapping of water IB-score (Movie Gen Audio): 42.74 IB-score (MMAudio, ours): 53.95

Audio prompt: creamy sound of mashed potatoes being scooped IB-score (Movie Gen Audio): 30.94 IB-score (MMAudio, ours): 10.52

Figure A2. Examples of videos in Movie Gen Audio Bench that are well/not well covered by our training data. Left: with a familiar concept in our training data (516 swimming videos in the VGGSound training set), MMAudio achieves a higher IB-score. Right: with an unfamiliar concept (there are no videos about mashed potatoes in VGGSound [\[1\]](#page-8-2), according to the provided labels), MMAudio attains a significantly lower IB-score.

<span id="page-14-4"></span>We have carefully removed from our training data (AudioSet [\[8\]](#page-8-4), AudioCaps [\[22\]](#page-8-18), Freesound [\[31\]](#page-8-28), WavCaps [\[43\]](#page-9-6), and VGGSound [\[1\]](#page-8-2)) anything that overlaps with any of the test sets (VGGSound and AudioCaps). Additionally, we have also removed from our training data the test set of Clotho [\[4\]](#page-8-29). Since most baselines have been trained on VGGSound, we elect not to evaluate on AVSync15.

Test sets (number of samples)	Training sets			
	AudioSet	<b>AudioCaps</b>	VGGSound	AVSync15
AudioCaps $(975)$	580 (59.5%)		$147(15.1\%)$	-
VGGSound (15,496)	$132(0.9\%)$	13 $(0.1\%)$	$\overline{\phantom{a}}$	59 (0.4%)
AVSync-15 (150)	-		144 (96.0%)	$\overline{\phantom{a}}$

Table A3. Overlaps between training and test sets of different datasets. The percentage denotes the proportion of overlapping data in the entire test set. "-" means that we did not compute this data (we do not train or test on AVSync15).

## <span id="page-14-0"></span>D. Details on the Audio Latents

As mentioned in the main paper, we obtain the audio latents by first transforming audio waveforms with the short-time Fourier transform (STFT) and extracting the magnitude component as mel spectrograms [\[53\]](#page-9-23). Then, spectrograms are encoded into latents by a pretrained variational autoencoder (VAE) [\[25\]](#page-8-15). During testing, the generated latents are decoded by the VAE into spectrograms, which are then vocoded by a pretrained vocoder [\[33\]](#page-8-16) into audio waveforms. Table [A4](#page-15-5) tabulates our STFT parameters and latent information.

For the VAE, we follow the 1D convolutional network design of Make-An-Audio 2 [\[13\]](#page-8-25) with a downsampling factor of 2 and trained with reconstruction, adversarial, and Kullback–Leibler divergence (KL) objectives. We note that the default setting leads to extreme values in the latent at the end of every sequence  $(\pm 10\sigma \text{ away})$ . To tackle this problem, we have applied the magnitude-preserving network design from EDM2  $[20]$ , by replacing the convolutional, normalization, addition, and concatenation layers with magnitude-preserving equivalents. While this change removes the extreme values, it leads to no significant empirical performance difference. We train the 16kHz model on AudioSet [\[8\]](#page-8-4), following Make-An-Audio 2 [\[13\]](#page-8-25). For the 44.1kHz model, we increase the hidden dimension from 384 to 512 and train it on AudioSet [\[8\]](#page-8-4) and Freesound [\[31\]](#page-8-28) to accommodate the increased reconstruction difficulty due to a higher sampling rate.

<span id="page-14-2"></span>For vocoders, we use the BigVGAN [\[33\]](#page-8-16) trained by Make-An-Audio 2 [\[13\]](#page-8-25) in our 16kHz model. For our 44.1kHz model, we use BigVGAN-v2 [\[33\]](#page-8-16) (the bigvgan\_v2\_44khz\_128band\_512x checkpoint).

<span id="page-15-5"></span><span id="page-15-1"></span>

Table A4. Short-time Fourier transform (STFT) parameters and latent information.

## E. Network Details

## <span id="page-15-0"></span>E.1. Model Variants

Our default model generates 16kHz audio encoded as 20-dimensional, 31.25fps latents (following Frieren [\[63\]](#page-9-2)), with  $N_1 = 4, N_2 = 8, h = 448$ . We refer to this default model as 'S-16kHz'. To faithfully capture higher frequencies, we also train a 44.1kHz model ('S-44.1kHz') that generates 40-dimensional, 43.07fps latents while all other settings are identical to the default. To scale up the high-frequency model, we first double the hidden dimension to match the doubled latent dimension, *i.e.*, we use  $N_1 = 4$ ,  $N_2 = 8$ ,  $h = 896$  and refer to this model using 'M-44.1kHz'. Finally, we scale the number of layers, *i.e.*,  $N_1 = 7, N_2 = 14, h = 896$  and refer to this model via 'L-44.1kHz'. These model variants are summarized in Table [A5.](#page-15-6)

<span id="page-15-6"></span>

Table A5. Summary for different MMAudio model variants. Time is the total running time to generate one sample with a batch size of one after warm-up and excludes any disk I/O operations on an H100 GPU.

#### <span id="page-15-2"></span>E.2. Projection Layers

We use projection layers to project input text, visual, and audio features to the hidden dimension  $h$  and for initial aggregation of the temporal context.

**Text feature projection.** We use a linear layer that projects to  $h$ , followed by an MLP.

**Clip feature projection.** We use a linear layer that projects to  $h$ , followed by a ConvMLP with a kernel size of 3 and a padding of 1.

**Sync feature projection.** We use a 1D convolutional layer with a kernel size of 7 and a padding of 3 that projects to h, an SELU [\[26\]](#page-8-31) activation layer, followed by a ConvMLP with a kernel size of 3 and a padding of 1.

Audio feature projection. We use a 1D convolutional layer with a kernel size of 7 and a padding of 3 that projects to  $h$ , an SELU [\[26\]](#page-8-31) activation layer, followed by a ConvMLP with a kernel size of 7 and a padding of 3.

#### <span id="page-15-3"></span>E.3. Gating

The gating layers are similar to the adaptive normalization layers (adaLN). Each global gating layer modulates its input  $y \in \mathbb{R}^{L \times h}$  (L is the sequence length) with the global condition  $c_g$  as follows:

<span id="page-15-7"></span>
$$
Gating_g(y, c_g) = y \cdot \mathbf{1} \mathbf{W}_g(c_g). \tag{A1}
$$

Here,  $\mathbf{W}_g \in \mathbb{R}^{h \times h}$  is an MLP, and 1 is a  $L \times 1$  all-ones matrix, which "broadcasts" the scales to match the sequence length  $L$ – such that the same condition is applied to all tokens in the sequence (hence global).

Similarly, for per-token gating layers, the frame-aligned conditioning  $c_f$  is injected into the audio stream for precise feature modulation via

$$
Gating_f(y, c_f) = y \cdot \mathbf{W}_f(c_f), \tag{A2}
$$

<span id="page-15-4"></span>where  $\mathbf{W}_f \in \mathbb{R}^{h \times h}$  is an MLP. Different from Equation [\(A1\)](#page-15-7), the scales are applied per token without broadcasting,

<span id="page-16-4"></span><span id="page-16-2"></span>

Figure A3. Synchformer feature extraction.

#### E.4. Details on Synchronization Features

We use the visual encoder of Synchformer [\[17\]](#page-8-7) to extract synchronization features. We use the pretrained audio-visual synchronization model trained on AudioSet, provided by Iashin et al. [\[17\]](#page-8-7). As input, we obtain frames at 25 fps. Synchformer partitions these frames into overlapping clips of 16 frames with stride 8 and produces features of length 8 for each clip. Thus, for a video of length  $T_{\text{sec}}$  seconds, the sequence length of the synchronization features is

$$
L_{\text{sync}} = 8\left(\left\lfloor \frac{25T_{\text{sec}} - 16}{8} \right\rfloor + 1\right). \tag{A3}
$$

The corresponding feature fps is

$$
FPSsync = \frac{L_{text}}{T_{sec}}.
$$
\n(A4)

In this paper, we experimented with  $T_{\text{sec}} = 8$  and  $T_{\text{sec}} = 10$ . In both cases, FPS<sub>sync</sub> is exactly 24. Additionally, we introduce a learnable positional embedding of length 8 (matching the number of features in each clip processed by Synchformer) that is added to the Synchformer features, as illustrated in Figure [A3.](#page-16-4)

# <span id="page-16-1"></span>E.5. Illustration of the "sum sync with visual" Ablation

Figure [A4](#page-17-2) illustrates the network architecture for the "sum sync with visual" ablation in the "conditional synchronization module" paragraph. The visual features are upsampled using the nearest neighbor to match the frame rate of the synchronization features. This architecture has a worse FD<sub>PaSST</sub>, IB-score, synchronization (DeSync) but a better inception score (IS), which we hypothesize is due to the increased number of visual tokens in the upsampling step, leading to finer-grained computations.

## <span id="page-16-3"></span>E.6. Visualization of Aligned RoPE

To visualize the effects of using aligned RoPE [\[55\]](#page-9-25), we compare the dot-product affinity of two sequences  $1^{250\times C}$  and  $1^{64\times C}$ when RoPE is applied. Here, 250 represents the audio sequence length (31.25 fps for 8 seconds), 64 represents the visual sequence length (8 fps for 8 seconds), and  $C = 64$  is the channel size. Concretely, we visualize

$$
RoPE_{default}(\mathbf{1}^{250 \times C}) \left( RoPE_{default}(\mathbf{1}^{64 \times C})\right)^{T}, \tag{A5}
$$

and,

$$
RoPE_{aligned}(\mathbf{1}^{250 \times C})\left(\text{RoPE}_{aligned}(\mathbf{1}^{64 \times C})\right)^{T}, \tag{A6}
$$

<span id="page-16-0"></span>in Figure [A5.](#page-17-0) Temporal alignment is attained when we use aligned RoPE.

<span id="page-17-2"></span><span id="page-17-1"></span>

Figure A4. Illustration of the "sum sync with visual" ablation.

<span id="page-17-0"></span>

Figure A5. Affinity visualizations between two sequences with different frame rates when default/aligned RoPE embeddings are used. Left: with default RoPE, the sequences are not aligned. Right: with our proposed aligned RoPE, we attain temporal alignment.

## F. Training Details

We use a base learning rate of 1e-4, with a linear warmup schedule of 1K steps to train our model for 300K iterations. We use the AdamW optimizer [\[24,](#page-8-32) [39\]](#page-9-31) with  $\beta_1 = 0.9$  and  $\beta_2 = 0.95$ . We notice occasional training collapse (to NaN) if the default

<span id="page-18-2"></span><span id="page-18-0"></span> $\beta_2 = 0.999$  was used instead. We reduce the learning rate to 1e-5 after 80% of the training steps, and once again to 1e-6 after 90% of the training steps. We use post-hoc EMA [\[20\]](#page-8-30) with a relative width  $\sigma_{rel} = 0.05$  for all models. For efficiency, we use bf16 mixed precision training in all training runs. All the audio latents and visual embeddings are precomputed offline and loaded during training. Table [A6](#page-18-2) summarizes the training resources we used for each model size.

Model	Number of GPUs used Number of hours to train Total GPU-hours	
MMAudio-S-16kHz	22	44
MMAudio-S-44.1kHz	26	52
MMAudio-M-44 1kHz	21	168
MMAudio-L-44.1kHz	38	304

Table A6. The amount of training resources used for each model size. H100 GPUs are used in all settings.

# <span id="page-18-1"></span>G. Additional Visualizations

We provide generated samples and comparisons with state-of-the-art methods on our project page [https://hkchengrex.](https://hkchengrex.com/MMAudio/video_main.html) [com/MMAudio/video\\_main.html](https://hkchengrex.com/MMAudio/video_main.html). Below, we provide additional spectrogram visualizations comparing our method with prior works in Figures [A6](#page-19-0) and [A7.](#page-20-0)

<span id="page-19-0"></span>

Figure A6. Left: our method can precisely capture the distinct audio event of striking a golf ball. Right: a dog barks in successive bursts. Our generation does not line up with the ground-truth as precisely due to the ambiguous nature of video-to-audio generation, but does capture the rapid bursts.

<span id="page-20-0"></span>

Figure A7. Left: when visible audio events (*e.g*., when a string is played) can be clearly seen, MMAudio captures them much more precisely than existing methods. Right: in a complex scenario, MMAudio does not always generate audio aligned to the ground-truth (as common in the generative setting) but the generation is often still plausible.
